Chip J: Chip on top of the anode (spiral platinum pancake) for 90 hours after the electrolysis. 5.4 tr/cm^2 per hour. That was a surprize. My wire was not new; I will ask the electrochemist who gave it to me what was this wire used for before. In any case, I washed this wire and then kept it in the 1 M solution of HCl for 24 hours. Do I have to start wearing gloves while handling the cell components? I will ask Oriani if he looked for particles emitted from the anode.
Chip A:
Chip K: Chip exposed to the inner ("wet") surface of glass for 90 hours after the electrolysis. 18.3 tr/cm^2 per hour. Hmm, nearly the same as from the cathode. Is it a pure coincidence? The back side of that chip (exposed to air) had 0.9 tr/cm^2 per hr.
Chip L: Chip exposed to the outer ("dry") surface of glass for 90 hours after the electrolysis. 15.9 tr/cm^2 per hour. Hmm, nearly the same as from the cathode. Is it also a pure coincidence?
Chip M: Some tracks but not many.
Chip N: Some tracks but not many.

Experiment #2 (tracks collected during the electrolysis) cannot be trusted, as far as emission from the glass walls was concerned. That is because I was not sure which large chips were suspended from the insulated wire during etching. But this should not prevent me from saying that the average recording rates from glass (about 16 tracks/cm^2 per hour) were observed after the electrolysis. In other words, the glass situation is as puzzling as the nickel situation; the average rate of the recording after the electrolysis was higher than during the electrolysis (2.5 tracks/cm^2 per hour). How can it be? I also do not know why my average recording rate, below the cathode and during the electrolysis, was negligibly small in both experiments. This conflicts with what I observed in Minneapolis. It also conflicts with nearly 30 tracks/cm^2 per hour that Oriani recorded in the most recent experiment. The first time I failed to observe tracks below the cathode during the electrolysis was when the distance between the detector and the cathode was 1 mm. The second time I failed to see a lot of tracks was when the distance was 6 mm, the same as in Oriani's experiments.

199) Nonsense, fraud or very advanced science?

Ludwik Kowalski (December 28, 2004)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Extracted from <http://www.intalek.com/Products/Products.htm>

Products for sale:

DESCRIPTION: This high quality video details ALL of the amazing phenomena occurring in an area that's 300' in diameter in the beautiful wooded foothills of Santa Cruz California. ..... William Alek, a researcher and explorer, conducted experiments at the spot using the Explorers Kit shown below. He determined that time flows "slower" inside the spot by at least 3 minutes and 40 seconds per 24 day.....Because time flows slower, all of the metrics related to space and time change while walking through the spot. These metrics include volume, mass, frequency, gravity, time, and energy.

Mail Order:

Install the supplied software and attach the cable to your notebook computer, and your ready to explore!

PRICE: Call, prices range from $1000 to $1300

With this kit, you'll observe **RED SHIFTING** or **BLUE SHIFTING** of frequency generated by an Accutron Tuning Fork Watch. This tuning fork oscillates at a fundamental frequency of 360 Hz. . . .

2) Here is something that looks like nonsense, to me.

This is part of a much longer e-mail message received last night. The sender, who is a distant cousin and an architect, takes this text seriously. Is the author of the text a theoretical scientist (knowing much more than I do about modern physics) or is he a bluffer using scientific terminology to impress ignorant readers?

How fractal evolution works...

http://users.aol.com/leonmaurer/fixedtree.gif

... Is an interesting animation, related to ABC theory that describes how emanation of a dual entwined (positive-negative) ray (Superstring?) of Primal Force fractally involves radially (cyclically and vortically) out of the initial "spinergy" (or abstract motion) surrounding the absolute zero (laya) point -- to initially form the "coadunate but not consubstantial" fields of universal consciousness... That continues ("as above so below") in descending phase orders of frequency-energy, to eventually replicate into the seven fold fields of human consciousness. This also indicates why analogy and correspondence is a basic rule for understanding theosophical metaphysics or occult science. For diagrams

showing how this works, see:

http://users.aol.com/uniwldarts/uniworld.artisans.guild/chakrafield.html
http://users.aol.com/leonmaurer/invlutionflddiagnotate.gif

Science today -- while it is gradually approaching an understanding of multidimensional hyperspace fields (Superstring/M-brane theory, quantum field theory, etc.) that are analogous to the ABC fields, and is beginning to comprehend the relationship of the Aether (lower Astral field that, besides being the magnetic model of all forms of life, is also the medium of light) to the physical or metric fields of matter -- has still a long way to go before their wished for "Unified field Theory" (that baffled Einstein for more than 30 years) can become a scientifically proven reality. But, first, they have to solve the "hard problems" of explaining the "experience of consciousness" and "brain-mind binding" that is still baffling all of science -- even after the past 10 years of serious study as a recognized scientific discipline.

This won't occur until scientists realize that consciousness (as awareness and will or intent) is a universal aspect of fundamental reality related to the zero-point itself... That is everywhere (contiguous on the highest level of zero-point energy) and is the central origin of all fields of force... While being the basis of the so called "entanglement" or "action at a distance" between
fundamental quantum particles on any level. With this ultimate understanding they will also be able to synthesize information theory with relativity and quantum theories, along with recent theories of Aether physics, plasma electrodynamics, holographic paradigm, etc., and come up with an entirely new and synthetic scientific (physics, biology, cosmology, physiology, etc.) paradigm.
http://tellworld.com/Astro.Biological.Coenergetics

~~~~~~

My ABC (Astro Biological Coenergetics) theory postulates (predicts) that everything in the universe is fundamentally empowered by electricity and its laws of electrodynamics -- including all the hidden coadunate but not consubstantial hyperspace fields at progressively higher order spectrums (phases) of frequency/energy -- which is the basis of their coenergetic interrelationships and transfer of modulated magnetic wave carried holographic information between zero-point consciousness (awareness/will) and matter.

As a fundamental paradigm, it postulates that all substantial forms of this electromagnetic energy -- from the highest order hyperspace-time (spiritual field) through the six intermediate hyperspace fields, to the lowest order metric space-time continuum (our metric material cosmos of sidereal light) -- are directly involved and evolved out of the infinite "Spinergy" force or angular momentum of a zero-point-instant singularity simultaneously rotating at infinite velocity (Superspin) both clockwise and counterclockwise on at least three perpendicular axes... Thus, accounting for the spherical nature of the space-time continuum, its star forms and rotating galaxies. Also, from a quantum physics point of view, it accounts for both the positive and negative electro-gravity, electro-strong, electro-weak and electromagnetic forces... And, from a cosmological point of view, all particles and anti particles, along with both light and dark matter.

Thus, it predicts that the sun and all the stars are also electrical in nature... As is all the mass-energy composing all physical forms and organic bodies due to the vibrational patterns of the fundamental "superstrings" of primal electrodynamic force (emanating from the spinergy), and their derivative "strings," that determine the properties of the fundamental particles (wavicles). And, is the fundamental force underlying all their physical, chemical, biological, and physiological properties, interrelationships, and configurations. Also, it conforms with all principles of relativity in our sidereal space-time continuum, and considers their correspondence in each ascending phase order of hyperspace-time, modified by their varied time constants that determine their higher order light velocities (which would appear as instantaneous from our point of view).

200) Scientific methods

Ludwik Kowalski (February 6, 2004)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

What follows are comments on the so-called “scientific method” in the context of teaching science. They appeared (in recent days) on Phys-L, a discussion list of physics teachers. The names of particpants were replaced by Professor 1, Professor 2, etc.

Professor 1:
. . . Please, let's stop taking things on faith. That phrase refers to believing things in the absence of evidence. That's the opposite of what science is. For a discussion of scientific methods in general, see

http://www.av8n.com/physics/scientific-methods.htm [See appendix below.]

Professor 2 (myself):
It is not possible to "stop taking things on faith" and to help students to master material in any science course. The laboratory discovery approach is extremely important but it is used to learn only a small percentage of what is in a typical textbook. Even scientists do not perform all experiments in their specialties; they often accept discoveries made (and published in refereed journals) by other scientists. How many high school teachers had an opportunity to experiment with scattering of alpha particles, as Rutherford and Geiger did in 1911? How many university teachers had opportunities to perform experiments through which existence of quarks was discovered in 1960s and 1970s? Not too many. We read about such experiments in reputable journals, and in textbooks. Then we accept what was discovered by others. And we teach it. Should we feel guilty? We trust that contents of science textbooks are verified by recognized authorities in relevant fields. Yes, I know, it is a complicated issue.

Professor 3:
P2, you have defined "faith" vary narrowly--as anything that we accept other than that which we have personally experienced. I see that definition as flawed for two reasons,

First, as you have cogently pointed out, we can't directly experience everything, but we can examine the evidence presented, as well as other corroborating evidence, and the consequences of the findings, and come to a pretty reliable conclusion about what is being asserted. Factored into our acceptance or non-acceptance of the claim has to be such things as the methodology of the experiment reported, the nature of the data presented (size of error bars, number of data points, etc.), the reputation of the investigator (for honesty, objectivity, integrity, and skill as an investigator), how it fits in with, or explains other related results, and what it predicts that can be tested and verified, and others that depend on the nature of the experiment and the methodology of the particular discipline.

And second, personal experience is a notoriously poor indicator of reality. We all know about experiments that showed the results the investigator wanted to see. N-rays are the classic example of that, but the Vienese laboratory that was looking at the energy distribution of beta-rays during the 20s and found evidence of definite energies of the electrons emitted in beta-decay, because that was what they were looking for, is another and somewhat more subtle example (see Andrew Brown's biography of Chadwick, "The Neutron and the Bomb," for more on this). And of course, there are all forms of hallucinations, flawed memories, and other non-events that take on a compelling reality to the observer. So to be able to say, "I saw it with my own eyes," is not necessarily as reliable as looking at the record of data taken and examining the experimental set-up, so see if there were any missed systematic errors built into it.

One of the things that makes science more reliable now than in past centuries is the existence of permanent, more or less objective recordings of what happened--chart recorder tapes, photographs, automated data files, etc., instead of just hand-written collections of manually taken observations. this allows others to see exactly the same thing that the original investigator saw, and so provide it with a more or less objective analysis.

One can argue that all of that is fine, but the farther one is from the original, the weaker is the connection. So the textbook or monograph reader pretty much has to accept what book's author says is the truth. And where does that leave the student?

To an extent, that is true, but that chain also provides much reinforcement of the result, since each person who passes the result along, has at least given it enough examination to decide that it is of enough importance and reliability to include, and that it fits into the overall picture the author wants to paint. Of course that doesn't rule out all of the human fallibilities that befall textbook writers, and which can make almost anything is a textbook wrong. Keeping textbooks "honest" is a continuing process, and students need to know this.

Of course the original result can still be wrong, or incomplete, or not sufficiently accurate to account for subsequent results, or any of a number of things that can happen to experimental results over the years. But the big difference between scientific, or evidence-based conclusions and faith-based conclusion is that they are much more subject to change in the face of new evidence.

The faithful say, "I hear what you have said, and it's good enough for me. I believe." The scientist says, "OK, that sounds reasonable, and it fits with the accepted theories (or it explains something that current theories don't), so I'll take it and use it until I see evidence that it wasn't correct, in which case I will change my mind." I think there is a huge difference between these two stances.

Appendix - Scientific Methods (Professor 1 above):

Many textbooks and web-sites describe “the scientific method” in terms most scientists find objectionable. Here is an attempt to do better.

1. There is no such thing as "the" scientific method. Science uses many methods. There will never be a pat answer to the question "what is science". The very notion that there could be a pat answer bespeaks an attachment to rote learning that is incompatible with scientific thinking.

2. One of the goals of science is to make useful predictions.

3. A scientific prediction does not need to be exact to be useful.

4. Sometimes it is possible to make useful predictions, and sometimes not. If you are asked to predict the exact total shown on a particular roll of a pair of fair dice, you will be wrong at least 5/6ths of the time. But if you can get into a situation where the payoff is greater than 6:1, you can make some useful predictions, and you can make money on average.

5. Scientists use words like rule, law, equation, identity, principle, formula, algorithm, etc. almost interchangeably, to describe the process for making predictions (although there are slight variations in connotations).

6. The word “theory” can be used in two radically different ways. The first usage means something like law or rule, only much grander, namely a *system* of rules giving a coherent description and explanation of a topic. The other usage refers to a a mere speculation. Remarkably, both versions are correct, and both have been in use for over 2000 years. It is best to avoid the word entirely when talking to non-scientists, and especially when debating with persons who can’t be trusted, since if you intend one meaning they’ll use the other meaning against you. (It sure would be nice to find a word that expresses the idea of “coherent description and explanation” without risk of misunderstanding.)

7. Mathematical results are validated by formality and rigor. This gives us logical statements of the form “If *A* then *B*”

and suchlike. Physical-science results are sometimes validated by logic, but may also be validated by appeal to experiment. This gives us statements of the form "We observe *A*" and suchlike. Generally science is a complex lattice of facts and rules, combining observations and logic.

8. Predictive rules generally have a limited domain of applicability. To state the rule without stating its limits of validity is improper.

9. From time to time, an established rule may be refined. It may be supplemented by other rules so as to extend the domain of validity. It may be supplemented by exceptions to improve the accuracy. However a rule with too many caveats and exceptions is likely to be not only inconvenient but unreliable. Occam's razor and all that.

10. From time to time, a rule may be supplanted entirely by a simpler and better rule.

11. It is considered very poor form to gripe about the imperfections in an established rule, unless you've got something better to offer.

12. Creating new rules from scratch is exceedingly difficult. There is an infinite number of possible rules, and you will never have enough data to decide which of the contenders is best -- unless there is some sort of additional guidance. Sometimes guidance is taken from intuition and from notions of "simplicity" or "elegance". This is bordering on metaphysics, but it is an important part of science.

13. Scientists, like business executives, government leaders, and everyone else, must often make decisions based on highly incomplete data. The important thing is to be able to change your mind as soon as you get new data that contradicts old hunches. This requires keeping score on each of the rules, keeping track of which are well-supported by existing data, and which are least-well-supported and therefore most subject to revision.

14. An important scientific activity (which applies not just to pure science but also to engineering and even farming, etc.) is designing a series of measurements that will tell you what you need to know, without undue waste. See section 2 for more on this.

15. An important part of scientific thinking is being able to recognize non-scientific thinking. Examples include:
* Elementary logic errors, such as circular reasoning, non sequitur, and many others.
* Selecting the data. (It is not right to select tendentious anecdotes from a mass of data.)
* Other misuses of probability.
* Proof by bold assertion. (It's OK to assert something, so long as you don't pretend to have proved anything thereby.)
* Appeal to authority (as discussed in reference 4).
* *Ad hominem* arguments.
* Improperly weighted voting. (A thousand pieces of weak evidence should not outweigh one piece of strong evidence, as discussed in reference 4.)
* Et cetera.

2 Design of Experiment

Consider the famous *Twelve Coins Puzzle* as discussed in reference 6. Suppose you find a casino that is willing to pay you $350 for identifying the odd coin, but makes you pay $100 for each weighing. If you weigh the right combinations of coins, you can do the job in three weighings, so you make money every time. In contrast, if you follow a sub-optimal strategy that requires four or more weighings, you will lose money on average.

This scenario is reasonably analogous to many real-world situations. Commonly there's a significant price for making a measurement, and you want to maximize the amount of information you get for this price.

I mention this because all too often, people claim that a principle of scientific experimentation is to "change only one variable at a time". It's easy to see that such a claim is hogwash. The Twelve Coins Puzzle suffices as a counterexample. If each weighing differs from the previous weighing by only one coin, you cannot come anywhere close to an optimal solution.

The suggestion to “change only one variable at a time” might nevertheless be good advice in some special situations. That’s because the cost of making a measurement is not always the dominant cost in the overall information-gathering process. For example, imagine a situation where gathering the raw data is very cheap, while just plain *thinking* about it is expensive. Then you might want to follow a strategy, such as changing only one variable at a time, that makes the data easy to interpret, even though you had to do large number of experiments (much larger than theoretically necessary). Consider the contrast:

For young children doing cheap, simple experiments, it might make sense to tell them to change only one thing at a time, because the rate-limiting step is interpreting and understanding the data, and we want to make that step as easy as possible. For skilled scientists (and engineers, farmers, etc.) doing complex, expensive experiments, changing only one variable at a time would be an unnecessary burden, and often a disastrous burden.

Changing only one variable at a time is a crutch, which may partially compensate for the investigator’s lack of skill in interpreting the data. In contrast, for performers with ordinary ability and training, crutches are harmful, not helpful.

3 Correctness and Modesty

As mentioned above, a major *purpose* of scientific methods is to make useful predictions and to avoid mistakes. The known scientific methods are a collection of guidelines that have been found to work reasonably well. One of the most important steps in avoiding mistakes is to always keep in mind that mistakes are possible. This is so important that this whole section is devoted to emphasizing it and re-expressing it in assorted ways. James Randi said you should take care not to fool yourself, keeping in mind that “the easiest person to fool is yourself”.

It is OK to a limited extent to be an advocate for your favorite idea, but you must not get carried away. When you collect data in support of an idea, you must also look just as diligently for data that conflicts with that idea. Then you must weigh all the data fairly, and disclose all the data when you discuss your idea. This is what sets science apart from debating and lawyering, where advocacy is carried to an extreme, and it is considered acceptable to skip or make light of data that tends to support the “opposing side”. Another word for this is modesty. Being aware of your own fallibility is modest. Pretending you are infallible is immodest.

A related form of modesty, which is also crucial for avoiding mistakes, is to not overstate your results. Scientists use certain figures of speech that are designed to avoid overstatement. Among other things, this includes recognizing the distinction between data and the interpretation that you wish to place upon the data. As an illustration, imagine some children go on a field trip to the dairy. Upon their return, they write a childish report that says “cows are brown” -- or, worse, “all cows are brown”. A more modest, scientific approach would be to say “the cows we observed were all predominantly brown”. A statement about the observed cows sticks closely to the data, while a generalization about all cows requires a leap beyond the data.

As mentioned above, practically all scientific results have some limits to their validity, and you must clearly understand and clearly communicate these limits.

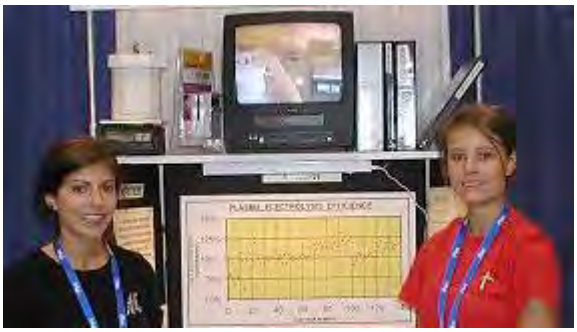
201) A “nuclear reactor“ in a garage?

Ludwik Kowalski (3/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

In the unit 170 I wrote: “. . . Another thing that impressed me was that one of the teams that confirmed Naudin’s findings consisted of highly trained electrochemist. On the other hand, I was slightly disappointed that the identity of the US laboratory, in which the confirming calorimetric experiments were conducted, was not specified. The document shows the photo of two researchers from Louisiana, [see below] and their first names (two nice looking young girls, probably students), but not the name of the laboratory, or the name of the project director. Was it a high school project or a projects at a well known university? Such information is important when controversial results are presented. Why was it not provided by Naudin?”



These students, X and Y, prefer to remain anonymous (see below).

Two weeks ago one of these girls, Y, sent me an email message. She wrote: “This project was not done at a laboratory. This was a Science Fair Project that Y and I did last year. The picture on Naudin’s website was actually taken at the 2004 International Science and Engineering Fair in Portland, OR. This was a team project. Y, being a senior, has now graduated, and I am continuing the project this year with the following changes:

1) A much more accurate scale, calibration checked at a local chemical plant lab.
2) Using Potassium carbonate rather than Sodium Hydrogen carbonate.
3) A completely sealed system to condense the steam and calculate the Hydrogen generated.
4) A new reactor (thermos design. mist eliminator, stainless internal used as the anode
5) Digital thermometer calibrated with distilled ice and boiling water
6) Input power readings taken with digital watt meter every 15 seconds.

. . . Last year our best was 147%, with an average of 117%, including our learning curve. This year the average is 143%, with the best being 271%. Being a senior, this is now my last year….but if I were to continue further, I would try the experiment under higher pressure – like 100 psi or so, to look for improvements.

This work was not done at a lab – it was done at my house, in the garage. Most of the items needed to build the power supply were purchased on eBay… Sounds dangerous….two high school girls build a nuclear reactor in their back yard… Finally, should anyone write to you for advice about a cold fusion project, prepare them for the amount of skepticism that they will be subject to with that kind of work. At Internationals, the worst thing we heard was from what we thought would have been the most educated judges…but they were not very accepting. More than once we heard “If it would have worked, you would be dead.

Y
Senior,Catholic High School
New Iberia, Louisiana

It is good to know that the spirit of scientific and technological adventure did not disappear; I am thinking about Marie Curie and Thomas Edison. But I am concerned about safety; the power supply they have (200 volts and up to 10 A) can easily kill a person. Such experiments should be conducted in school laboratories and be supervised by knowledgeable teachers. I sent Y a description of a recent accident with a similar setup in Japan (Mizuno's lab) but she did not comment.

Responding to the above I wrote (on 2/7/05):
1) I was very happy to receive your message; thanks for contacting me. I am also glad that you continue working on the project. But are you taking appropriate precautions in working with a very dangerous electrical power supply, and with hazardous chemicals? Is your work supervised by a trained person? I hope your teacher (or teachers) are there to prevent bad things from happening in the garage. Did you ask for permission to conduct the experiment at school?

2) I am not a chemist. Can you explain to me why are you changing an electrolyte that was delivering positive results?

3) I would not worry about the limited accuracy (0.2%) of the watt-meter when the average excess power is 43%.

4) The big challenge in this field is to convince others, including teachers and competition judges, that the anomaly is real. This is a very difficult task, considering the effects of negative publicity.

5) After retiring last year I decided to find an experiment that would be convincing to all honest skeptics. For that reason I contacted Dr. Richard Oriani (a retired chemist from the University of Minnesota) and we are working together now. The goal is to develop a simple setup that gives 100% reproducible results. Oriani's electrolytic cell is much smaller than yours; it is receiving electric energy at the rate of several watts. That is sufficient to observe nuclear particles; we are not focusing on excess heat, as you are.

6) After visiting Oriani, to work with him for one week. After that I performed ten experiments in my own home. Unfortunately, the goal of 100% reproducibility (ability to get an observable effect from each experiment in any laboratory) has not yet been achieved. But we are not giving up; this work is in progress.

7) I do believe that your excess heat, and excess heat in Naudin's experiments, are real. But that is not the main issue. The issue with all these experiments, as far as I can tell, is absence of evidence that the origin of excess heat is nuclear. One has to perform a complete analysis of all reactions to rule out chemical origin of excess heat. Neither Naudin nor you performed such analysis, as far as I know. Oriani also worked on excess heat experiments but decided (for the time being, I suppose) to focus on nuclear particles.

8) When will your next experiment be performed? I would be happy to send you several detectors of nuclear particles, if you want. They are small plastic chips (very clean polycarbonate) to be placed above the electrolyte, and in the electrolyte. After the experiment you would send the chips back to me and I would analyze them. If we see particles then we will try to repeat the experiment several times. Perhaps your large cell will become a simple setup needed to convince honest skeptics. If so we will try to publish these results in a mainstream journal.

9) Where is X now? Are you still collaborating on this project? What do you plan to do after the graduation?

That is how our correspondence started. Y will apply the chips to the electrolyte and to the electrodes this Sunday. The exposure will be three days. As usual, I want to be sure that nothing is radioactive before the main test. While waiting let me describe her setup. It is Naudin's "cold fusion reactor" with some modifications. Imagine a beaker with two electrodes, for example, both made of tungsten. The current flowing through the electrolyte, between 5 and 10 A, is sustained by a d.c. power supply of about 200 V. Intensive arcing and sparking is taking place in the liquid and the cathode is consumed rapidly, for example, after five to ten minutes. The claim is that the electric energy supplied to the

cell, Ee, is smaller that the energy released in the cell, Et. The difference, Ex=Et-Ee, is called excess energy; it is mostly thermal. The ratio of Et/Ee, is called efficiency.

The average efficiency reported by Y (see above) was 1.47. It means that for every 1,000 J of electric energy the cell releases 1,470 joules of heat. The origin of Ex (470 J) is assumed to be nuclear but no evidence for this is provided. The CR-39 chips will be used by us to explore a possibility that nuclear particles, similar to those discovered by Oriani, are emitted. That could become the needed evidence validating Naudin's claim. Ignoring that aspect let me focus on details of excess heat measurements. The value of Ee is determined by Y as the sum of many P*dT terms, where P are power readings of a watt-meter and dT is the time interval (15 seconds) between consecutive readings. One of Y's experiments lasted 3 minutes and the value of Ee, delivered during that time interval, turned out to be 87,780 J.

The efficiency of this experiment was reported as 1.92. This implies that Et was found to be 1.92*1,470 = 2,822 J. How was Et measured? It turns out that Et consists of several components; I will label them as E1, E2, E3, E4, E5, etc. The E1 is the energy needed to increase the temperature of the electrolyte to the boiling point, E2 is the energy used to evaporate m1 grams of water, and E3 is the energy used to decompose m2 grams of water (bubbles of oxygen and hydrogen escaping from the cell). It is well known that 2,260 J are needed to evaporate each gram of water and that 13,174 J are needed to decompose each gram of that liquid. Thus, in the first approximation:

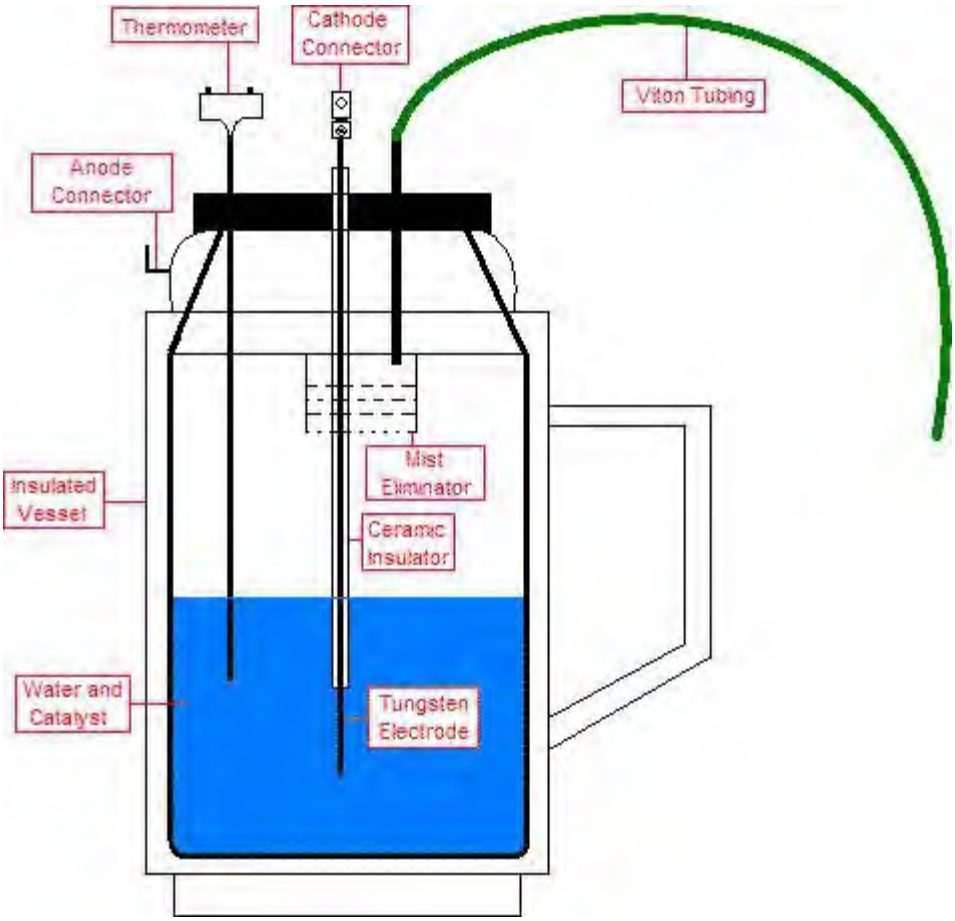
Et = E1+E2+E3 = s*(T2-T1) + 2,260*m1 + 13,174*m2

where T1 is the initial temperature, T2 is the boiling temperature and s is the heat capacity of the calorimetric vessel. The first term, E1, becomes negligible when the electrolyte is preheated before the current is turned on (to make T1=T2). In Y's experiment, however, (T2-T1) was 44 C and the value of s was found to be 116.4 J/C. That mean value of s was determined by Y from eleven preliminary experiments.

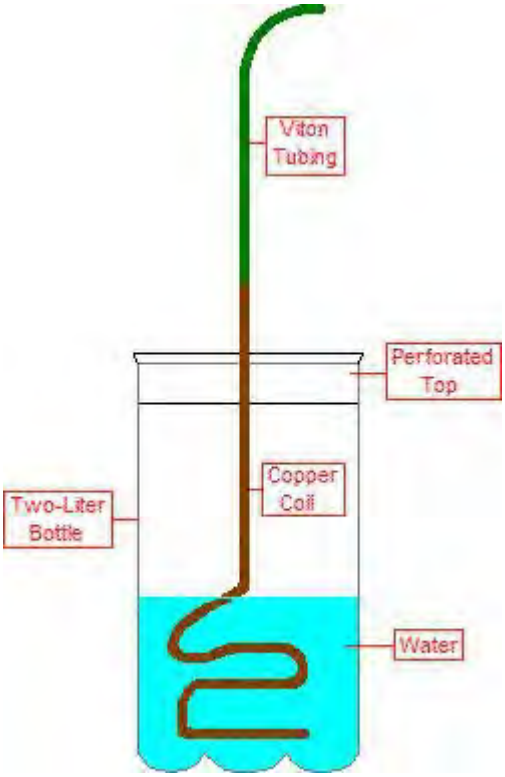
In many Naudin's experiments the vessel was an open beaker. Knowing that m2<<m1 (ignoring E3) Naudin measures the mass of the vessel before and after the electrolysis. The difference, identified as m1, was then used to calculate E2. An interesting innovation, introduced by Y, was to determine m1 and m2 separately. (In Naudin's experiments water vapor, oxygen and hydrogen escape into air and the measured mass difference is actually the sum of m1 and m2). I will return to this subject a little later. Using the above two equations one has:

Ex = (E1+E2+E3+E4) - Ee = [s*(T2-T1) + 2,260*m1 + 13,174*m2 + E4] - Ee

In this equation E4 represents the amount of thermal energy lost by conduction and convection during the electrolysis. It is interesting to note that by ignoring E4 one makes a systematic error of underestimation of Ex. In other words, the values of Ex reported by those who ignore E4 are smaller than the true values. Y's calorimetric vessel is a nearly sealed thermos, as illustrated in Figure 2. In that way the value of E4 is reduced significantly, in comparison with what it would be in an open beaker.



Sealed thermos. The green tube connects to the condenser below.



Condenser; the top is exposed to the atmosphere.

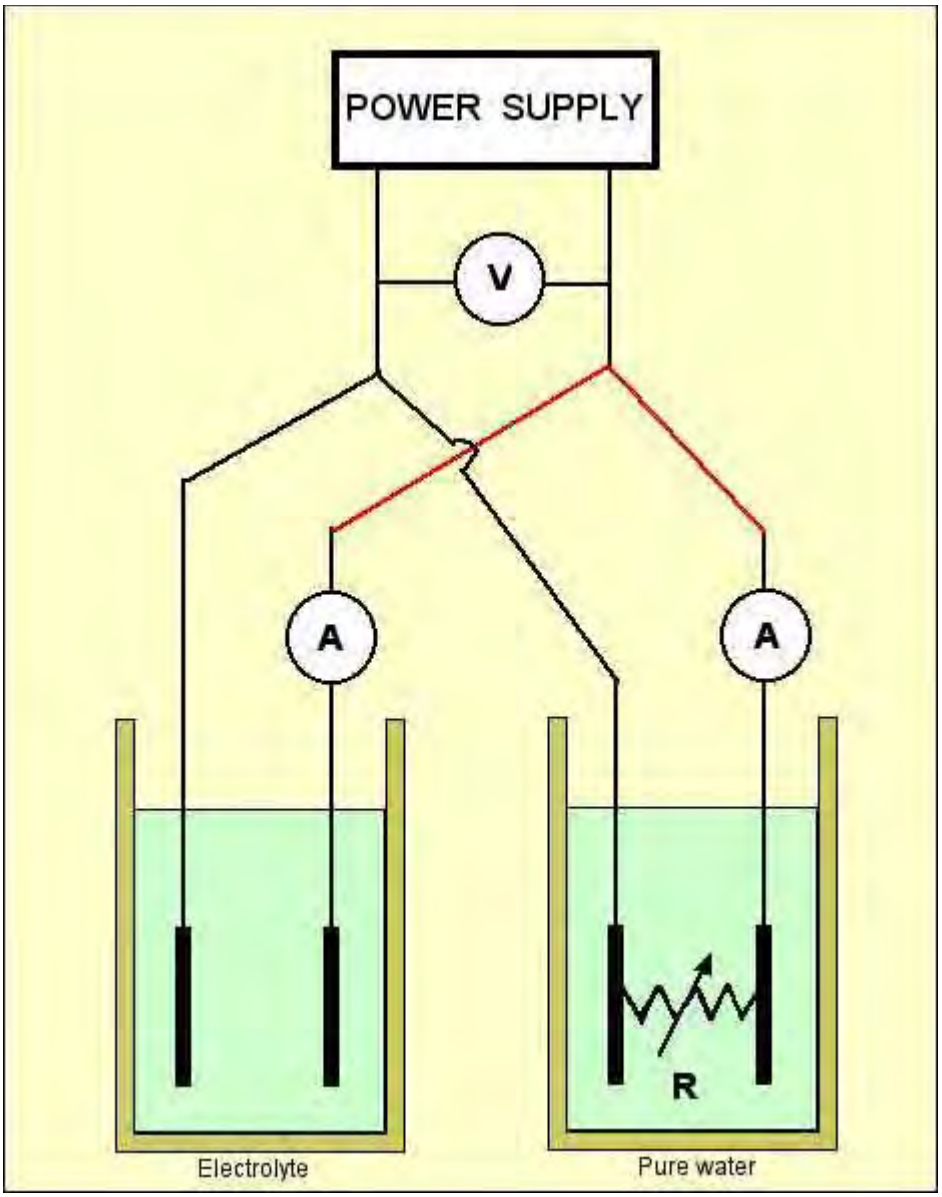
The vapor and gasses escape from the thermos through a flexible tube connected to a second container. That container,

called condenser, is filled with cold water. The exit from the flexible pipe is under cold water. Bubbles of hydrogen and oxygen escaping from the exit are released into the atmosphere. The water vapor, on the other hand, condenses and remains in the container. Both vessels, the thermos and the condenser, are standing of sensitive electronic scales. The change in the mass of the condenser is interpreted as m1 while the change in the mass of the thermos is interpreted as m1+m2. That is how the values of m1 and m2 are measured by Y. In the experiments in which the efficiency was 1.92 the values of m1 turned out to be 35.7 grams while the value of m2 turned out to be 0.6 grams. Showing that m2 is indeed much smaller than m1 has a great pedagogical value; most students are not aware of that fact.

Y also wrote to me about another complication. It has to do with vapors that condense in the thermos, for example, on its walls and near the exit to the flexible pipe. Suppose that 5% of vapor condenses inside the thermos. This has two important consequences: (a) the value of E2 is underestimated by 5% and (b) energy released through condensation remains in the thermos. Y tried to minimize condensation of vapors inside the cell but I am not convinced that she was successful. She wrote: "If you look at the attached picture you'll see a "sink strainer" where the insulator comes thru the thermos top. This is actually two sink strainers glued together with JB Weld epoxy. I got these at Wal-Mart. Between the two strainers I have three layers of 100 mesh stainless steel screen.

Once I put the preheated solution into the thermos and close it up, I let it set for a while for everything to come to an even temperature. This takes about a minute or so for the temp to level out. I ASSUME the mist eliminator is about up to temperature for very little condensation to occur at this point in the vessel ... although I'm sure there's some dripping back into the bottom of the reactor from here."

If I were asked to measure the Ex accurately I would not use a condenser. My setup would consist of two open cells, as illustrated below. The left beaker contains the electrolyte, the right beaker contains the same amount of distilled water and an ohmic rheostat immersed in it. The current in the left cell is ionic while the current in the right cell is electronic. The variable resistance of the rheostate would be chosen to make the two currents equal. To impose the right side current of 10 A at 200 V, for example, the resistance would have to be 20 ohms. To change the current to 5 A, also at 200 V, the resistance would have to be increased to 40 ohms. Note that the applied voltages are essentially identical because cells are connected to the same power supply. It would not be difficult to adjust the reostate manually during an experiment lasting several minutes. One would watch the current of the left ammeter and change the resistance, by as much as necessary, to match it with the current through the right ammeter. In that way the Ee would be identical in two cells.



A schematic diagram of a setup with two cells.

The sizes, of two cells, their masses, and their thermal capacities would be essentially identical. It is well known that a current flowing through an ohmic resistor (in the right cell) generates no excess heat. Therefore, the difference between E2 in the left cell and E2 in the right cell, if any, would be eqaul to Ex. Note that absence of information about E1, E3 and E4 would not prevent me from the determination of Ex. The same idea could be implemented with two cells connected in series. In that case I would use one ammeter and two voltmeters, one for each cell. The reostate would be adjusted to keep two voltages identical (to make sure that Ee are identical).

Let me end this essay by saying that I was highly impressed by what the two high school girls did in a Louisiana garage. It is a pity that "educated judges" were so skeptical when Y and X presented their outstanding work at an international competition. The judges probably thought that the project was pseudoscientific and not worth their attention. I would expect them to focus on what was positive in this explorative work. What is wrong with a student project trying to prove, or disprove, a controversial claim? What can be a better way to expose students to the excitement of scientific research than working on such projects? I am glad that Y decided to contact me and excited about our pending investigation of a "nuclear signature" in her setup. Information about that investigation is going to be appended below.

Appended on 2/18/05:
To concentrate on condensation inside the vessel let me consider a hypothetical example. An open jar, containing an electrolyte, stands on a scale; in that way the total mass can be measured at any time. The electrolyte is brought to the

boiling temperature (by warming it on a hot plate or by passing an electric current through it). The first measurement of P is made at an arbitrary moment after the boilimg started. Consecutive values of P are recorded avery 15 seconds, as in Y's experiment. Suppose that the current was turned off after 5 minutes. The amount of water, m, lost during that time was 50 grams. The value of Ee, calculated from consecutive recordings of P, was 80,000 J. Ignoring the mass the escaping hydrogen and oxygen the value of Et was calculated as 2260*50=113,000 J. The excess heat, and the efficiency, are then calculated as Ex = 113,000 - 80,000 = 33,000 J and ef=113,000/80,000=1.41, respectively.

The jar was not transparent and I assumed, in the above calculation, that no vapor condensed on the walls during the electrolysis. Suppose somebody tells me that 10 grams of vapor condensed and returned to the boiling electrolyte. My task is to recalculate the Ex by taking this into account. The first step is simple; I change the evaporated mass from 50 to 60 grams. The corrected value of Et becomes 2260*60 = 135,600 J. The difference between this value and Ee is 55,600 J (instead of 33,000 J above). This is 22,600 J larger than above. The reason for this is that thermal energy is released in condensation. The latent heat of condensation is the same as latent heat of evaporation. This means the 2260*10=22,600 j of thermal energy was released.

Does it mean that the corrected value of Ex should be 135,600 - 80,000 = 55,600 J? Not necessarily. That answer would be correct only if the thermal energy released through condensation went entirely to the surrounding air. That is one possible extreme. The other extreme is when all the released energy goes back to the electrolyte. In that case the Ex would be 135,600 - 80,000 +22,600 = 78,200 J. Why was the condensation energy added and not subtracted? Because that energy, like Ee, enters the system. In reality, however, only a fraction of 22,660 J enters the system; the remaining part goes into the air. Suppose that the unknown fractions are 50% each. In that case Ex would be 567,300 J. Unfortunately, it is very difficult to determine how the released energy is divided between the outside air and the inside electrolyte. This shows how much uncertainty is introduced into the calculation of Ex when condensations of vapors takes place inside the electrolytic cell. I think that Y recognized this fact and tried to reduce the uncertainties by using a condenser.

Appended on 2/19/05:
It is reassuring to know that by ignoring condensation of vapor inside the electrolytic cell, like ignoring heat losses due to conduction and convection, leads to an underestimation, not to an overestimation, of excess heat. The values reported by Naudin and others are most likely smaller than the true values of excess heat. But what is the origin of that heat? That is still an open question.

In most excess heat research Ex is generated at the rates of watts or fractions of watts. In Naudin-like experiments, on other hand, Ex is generated at the level of hundreds of watts. Tracing chemical reactions taking place in high power cells is likely to be more difficult than in low power cells. Nuclear signatures, by contrast, might be proportional to the cell power. If this is true then discovering nuclear particles in high power cells might be easier.

Appneded on 3/1/05:
Y sent me back the CR-39 chip that were exposed (for three days) to her electrodes and her electrolyte. These electrodes were to be used in our anticipated experiment. The chip exposed to the tungsten cathode had a lot of tracks. I suspect that tungsten rods are welding electrodes containing about 2% of thorium. Such electrodes were widely used in the past, probably to ionize air. The chip that was exposed to tungsten had thousands of tracks, even more than my control chip exposed to an alpha source. Informing Y about this finding I wrote: "Your tungsten has alpha-radioactive material in it; you can probably detect it with a Geiger counter in your school. I suspect it is thorium or uranium. We can not go ahead with the suggested experiment, unless you can use another cathode. Let me know." In the next message I added: "In reading Naudin's descriptions again I see that stainless steel could be used as a cathode. I would be surprised to find a radioactive material in a spoon or a knife made from this alloy. But the new material would have to be checked, if you decide to continue working on our project."

Appended on 3/7/05:
This web page contained true names of students. But I did not want to share this information over the Internet without asking for permission. I am glad I asked. The reply, received this morning, was: "We would prefer to keep our last names out of the reports. You never know these days". That explains why the real names were replaced with X and Y. Additional information about this project will be appended, if Y decides to continue.

202) Fraudulent claims of Professor Reiner Protsch von Zieten

Ludwik Kowalski (2/22/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

A colleague posted an article about fraudulent claims made, over the last 30 years, by a German anthropologist from the University of Hamburg. His claims were taken for granted until very recently. The story was reported on 2/19/05 in the Science News section of the "Guardian Unlimited," . Why am I posting extracts from this article on the website devoted to Cold Fusion? Because that field has often been described as pseudoscientific. The "Voodoo Science" book of Robert Park gives many examples of fraud. That book, and its Russian counterpart (by Krugliakov) give the impression that cold fusion claims are also fraudulent. That is not based on specific cases of "invented data"; the authors simply fail to make a distinction between cold fusion researchers and real con artists.

I think that fraudulent claims are more likely to appear in the area of accepted science than in the area of controversial science. What can a person gain by faking cold fusion data? All claims in that area are nearly automatically rejected. The only effect would be to impress a relatively small group of other CF researchers. On the other hand, absence of access to peer reviewed journals might encourage fraud. Do the editors of professional journals realize that their attitude toward cold fusion can encourage con artists and charlatans?

* * * * * *

It appeared to be one of archaeology's most sensational finds. The skull fragment discovered in a peat bog near Hamburg was more than 36,000 years old - and was the vital missing link between modern humans and Neanderthals.

This, at least, is what Professor Reiner Protsch von Zieten - a distinguished, cigar-smoking German anthropologist - told his scientific colleagues, to global acclaim, after being invited to date the extremely rare skull. However, the professor's 30-year-old academic career has now ended in disgrace after the revelation that he systematically falsified the dates on this and numerous other "stone age" relics..... According to experts, his deceptions may mean an entire tranche of the history of man's development will have to be rewritten. "Anthropology is going to have to completely revise its picture of modern man between 40,000 and 10,000 years ago," said Thomas Terberger, the archaeologist who discovered the hoax. . . .

During their investigation, the university discovered that Prof Protsch, 65, a flamboyant figure with a fondness for gold watches, Porsches and Cuban cigars, was unable to work his own carbon-dating machine. Instead, after returning from Germany to America, where he did his doctorate, and taking up a professorship, he had simply made things up. . . . "Prof Protsch's work appeared to prove that anatomically modern humans and Neanderthals had co-existed, and perhaps even had children together. This now appears to be rubbish." The scandal only came to light when Prof Protsch was caught trying to sell his department's entire chimpanzee skull collection to the United States. . . .

Other details of the professor's life also appeared to crumble under scrutiny. Before he disappeared from the university's campus last year, Prof Protsch told his students he had examined Hitler's and Eva Braun's bones..... Even the professor's aristocratic title, "von Zieten", appears to be bogus. Far from being the descendant of a dashing general in the hussars, the professor was the son of a Nazi MP, Wilhelm Protsch, Der Spiegel magazine revealed last October. The university is investigating how thousands of documents lodged in the anthropology department relating to the Nazis'

gruesome scientific experiments in the 1930s were mysteriously shredded, allegedly under the professor's instructions. . . . Yesterday the professor, who lives in Mainz with his wife Angelina, didn't respond to emails from the Guardian asking him to comment on the affair. But in earlier remarks to Der Spiegel he insisted that he was the victim of an "intrigue."

203) Proto-science is not pseudo-science

Ludwik Kowalski (2/24/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Irreproducibility, as we know, is typical in the field of cold fusion. I like to compare the situation with irreproducibility that was probably frustrating investigators of electrostatic phenomena before the role of humidity was recognized. Other comparisons are often mentioned, for example, the effect of impurities on performance of early transistors (before it was recognized that 99.99% purity of raw material might not be sufficient.) Failures probably resulted from hidden uncontrollable factors, such as sneezes, or from not washing hands.

Nuclear phenomena triggered but chemical activities remain irreproducible, as far as I know. Unfortunately, those who investigate such phenomena are often treated as pseudo-scientists or even can artists. This is regretable; existing controversies would have been solved more rapidly if "cold fusion" was treated as any other field of study. But let's face it, a field of research is not scientific unless at least something is 100% reproducible, or unless the irreproducibility is understood. Far from being pseudo-scientific the field is active and, as far as I know, its major player are well qualified and honest. Therefore it deserves to be labeled as "proto-science."

The basic idea in the field of CF, as mentioned above, is that "a chemical process can trigger a nuclear process." That controversial idea conflicts with everything we learn from existing textbooks. Yes, excess heat is an important technological issue. But the major controversy is not about the heat, it is about its nuclear origin. Numerous cold fusion claims have been made but the progress is slow because research is not coordinated. If it was up to me I would ask scientists to select one or two irreproducible phenomena and focus on them. But that is not what is happening. Instead of seeing many scientists studying a selected cold fusion phenomenon, such as emission of alpha particles, or large shifts of isotopic ratios, I see that each researcher does something different.

Excellent instruments to study nuclear particles, and isotopic ratios, already exist in numerous laboratories, all over the world. Therefore controversial claims in these areas would quickly be recognized as either valid or not valid if a research-supporting agency, for example, NSF, or CERN, promoted the idea of focusing on one or two claims. How much would it cost to perform ten or twenty reliable measurements of isotopic ratios (using cathodes supplied by CF scientists) in several independent laboratories? Probably not longer than one month, including preparations and testing of ion sources. Likewise, emission of charged particles, reported by many investigators (Jones, Lipson, Karabut, Oriani, etc.), could be quickly confirmed or not confirmed by scientists from several laboratories. To study Oriani effects (see item #192), for example, a single Si detector, or a dE-E setup of two such detectors (in a sealed container with a thin window), would be placed above the electrolyte, in the electrolyte and below the cathode. Showers of particles leaving tracks in CR-39 detectors should be easily observable by electronic means. Track detectors show cummulative effects, electronic detectors should allow observations of particles at the time of emission.

This approach, to solving a controversy, would be more natural than counting how many appointed panel members "voted" for or against various claims. The recent DOE panel report makes no reference to experiments. I still do not know why the names of panel experts were removed from their individual repotrs (see item #196).

204) An Israeli Connection

Ludwik Kowalski (3/8/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Israeli industrial researchers participated in both cold fusion conferences that I attended: ICCF10 and ICCF11. They did not represent well know research centers, like Weisman Institute or Technion, they came from a small private company called Energetics Technolpgies. Here is how the company activities were categorized in August 2003 by I. Dardik et. al. (ICCF10):

"Energetics Technologies (ET) was recently established to investigate possibilities for generating energy from Low Energy Nuclear Reactions (LENR) using a new approach of wave excitation. The new approach involves use of so-called "waves-waving-waves" or Superwaves for driving the processes that generate LENR. Four experimental approaches are being pursued: electrolysis (EC), glow-discharge (GD), gas loading in catalyst cells (CC) and high-pressure high-temperature cell (HPTC) with ultrasonic wave excitation."

And here is how their work was described in the January 10 issue of the New Energy Times <http://www.newenergytimes.com/news/8.htm>

Two groups who are relatively new to the ICCF conference series gained a significant amount of attention from the cold fusion veterans. The first was the American-Israeli team of Energetics Technologies. The Energetics Technologies Ltd. laboratory is located in Israel and is a wholly owned subsidiary of Energetics Technologies LLC in the United States. . . . [The company] presented data from its three best electrolytic cold fusion experiments at the conference:

- Run #56 gave 80% excess heat over a duration of 300 hours with a total excess energy of 3.1 Megajoules. [generating heat at the mean rate of 29 W]
- Run #64a gave 2500% excess heat over a duration of 17 hours with a total excess energy of 1.1 Megajoles. [generating heat at the mean rate of 17 W]
- Run #64b gave 1500% excess heat over a duration of 80 hours with a total excess energy of 4.6 Megajoules. [generating heat at the mean rate of 17 W]

[At the ICCF11] Ehud Greenspan of Energetics Technologies provided the following four points to summarize other key aspects of their claims:

'1. Excess energy generated was more than 25 times higher than the input energy. The next highest excess energy reported in ICCF-11 was obtained by Roger Stringham.

2. The remarkable excess-energy to input-energy ratio reported by Energetics Technologies has been obtained at relatively high power levels of several tens of watts and lasted for tens of hours.

3. It is instructive to compare the excess-energy obtained by Energetics Technologies to that of Mizuno quoted by Jed Rothwell as a remarkable achievement -- 84 MJ from 100 g of Pd. These numbers correspond to a "specific excess-energy" of 0.84 MJ per gram of Pd. The specific excess-energy obtained in the Energetics Technologies experiments reported at the ICCF-11 was ~20 MJ/g, i.e., more than 20 times higher.

4. The highest "specific-power" obtained in Energetics Technologies experiments -- ~70 watts per gram of Pd, is higher

than the average specific-power commercial fission reactors are operating at between 20 to 50 watts per gram of uranium.'

. . . Energetics Technologies and Mitsubishi may be the two most well-funded groups performing cold fusion research in the world. The angel investor behind the company is Sidney Kimmel, . . . The greatest challenge they face is reproducibility. Certainly, their claims of excess heat and energy appear to be among the highest ever seen in cold fusion experiments. The Holy Grail of clean nuclear power has not been obtained, however, because they have not seen high reproducibility with their work. If they can find a way to readily reproduce 2500% excess power, commercialization for electrical power generation is not far behind. But unlocking the secrets of nature to get to that point will not be an easy task..... "

Conference presentations of Israeli scientists -- they can be downloaded from the library at <http://www.lenr-canr.html> -- are very impressive. The most spectacular successes reported by them (see above) were obtained in electrolytic cells whose electrodes were prepared in close cooperation with a team of Italian scientists from the Frascatti Research Center. The current flowing through an electrolytic cells, or through a glow discharge chamber, was a "superwave," a mixture of several low frequency components. Browsing the Internet I found the following description of superwaves (by Arik El-Boher at a Frescati seminar on April 22, 2004):

"Energetic Technologies (ET) was recently established in Omer (Israel) to investigate intensification of Low Energy Nuclear Reactions (LENR) using excitation by SuperWaves©. SuperWaves is defined as a low frequency carrying wave with several successive stages of amplitude and frequency modulation – waves waving within waves. All stages of modulation are interrelated non-linearly. The inventor of the SuperWaves – Dr. Irving Dardik – has experimentally proven that these very special wave patterns are efficient in accelerating and intensifying different processes in metallurgy, biochemistry, health and other fields."

At the same Frescati seminar, entitled "Nuclear reactions through superwave excitation," El-Boher reported that "a significant amount of excess heat was measured in the first glow discharge experiment. The power generated during the experiment was up to 3.9 times the input power. When driven with SuperWaves the excess heat was higher than when driven with DC. A significant amount of excess heat was also measured after the shutdown of the cell, lasting for approximately 10 hours following the cell shutdown." Will the reported effectiveness of superwaves be confirmed in other laboratories? This remains to be seen.

The primary interest of the Israeli company, as far as know, is excess heat; I am not aware of their attempts to identify the origin of that heat. The essence of the cold fusion controversy, on the other hand, is not excess heat, it is its nuclear origin. I mentioned this recently to somebody who reported generation of excess heat at rates exceeding 100 watts. The answer was typical: "Since you can't have more than 100% efficiency - it must be nuclear." No, it does not have to be nuclear; it might be something else. Let me say, however, that emission of nuclear particles from a glow discharge chamber has been reported much earlier, as described in the unit #13.

Post Scriptum:
If the excess heat is nuclear then its generation can be described as an exothermic nuclear reaction:

$$A + B = C + Q$$

where A and B are masses of reacting nuclei and C, the product of the interaction, is usually the sum of masses of two or more nuclei. The Q stands for the amount of energy generated. In the very first nuclear reaction observed (Cockroft and Walton, 1931) A was the accelerated ion of hydrogen ^{1}H and B was a stationary lithium ^{7}Li.
Fusion of these two nuclei produced ^{8}Be which immediately decayed, producing two alpha particles, ^{4}He. In the so-called hot fusion A and B are rapidly moving hydrogen ions (in an ionized deuterium gas) while C stands for either ($^{3}He + {}^{1}n$) or ($^{3}H + {}^{1}p$). These two outcomes occur with about the same probability. The third possible outcome, production of ^{4}He, is extremely rare. Positively charged atomic nuclei, A and B, always repel each other. For that reason nuclear fusion of A and B is generally believed to be extremely rare at low temperatures. That is the essence of the controversy about cold fusion. The theory predicts that cold fusion of atomic nuclei is practically impossible while many

experimental scientists were able to detect it by observing nuclear particles: neutrons (^{1}n), tritium (^{3}He) and alpha particles (^{4}He).

If devices built by Israeli researchers generate nuclear energy then nuclear particles, or other reaction byproducts, should also be present. If it was up to me I would look for such "signatures" of nuclear reactions. The rate ot which nuclear byproducts are produced should be directly proportional to the rate of production of excess heat. Establishing this fact, in a highly reproducible setup, would finally resolve the cold fusion controversy. As far as I know the major issue on which Israelis are focusing is irreproducibility. But this should not prevent them from trying to demonstrate presence or absence of nuclear byproducts. How will cold fusion impasse be resolved? Will it be resolved by scientists or will it be resolved by engineers? Scientists are primarily interested in solving mysteries, engineers are primarily interested in building useful gadgets, such as airplanes and power plants. A 100% reliable gadget would stimulate scientific research, a 100% reproducible scientific setup would lead to technological innovations. Healthy competition between scientists and engineers is desirable.

Post-post Scriptum:
Basic laws of flying "heavier than air machines" were not known when first airplanes were built. But many laws of electricity were already known when first electrical power plants were built. The field of cold fusion, however, is still waiting for its Wylbur Wright, for its Michael Faraday and for its James Maxwell. Why does it take so long to resolve the controversy? I tried to answer this question in the unit #203.

Addeendum (3/16/05)
Interesting internet items about Energetics Technologies:

<http://www.zpenergy.com/modules.php?name=News&file=article&sid=1143>

Excess Heat in Electrolysis Experiments at Energetics Technologies
I. Dardik, T. Zilov, H. Branover, A. El-Boher, E. Greenspan, B. Khachatorov, V. Krakov, S. Lesin and M. Tsirlin;
Energetics Technologies P.O.Box 3026 Omer Industrial Park Omer, Israel

Using the electrolytic cells described in our ICCF-10 paper driven with Dardik's modified SuperWaves, significant amounts of excess heat were obtained in a number of experiments. The most successful of these experiments generated excess heat a couple of times: (1) Approximately 5 hours into the first loading of deuterium into the Pd cathode – giving an average power gain of ~2500% during 17 hours. The average current density was 7 mA/cm2. (2) The same foil was deloaded after the excess heat generation stopped for no apparent reason and than loaded again. After 16 hours of loading excess heat was generated again at an average level of ~1500% for 80 hours. The average current density was 8.4 mA/cm2. At the end of the two experiments the tritium concentration in the electrolyte was 270% of its pre-experiment level. The total amount of excess energy generated is approximately 1.1 MJ and 3.5 MJ in, respectively, the first and second experiments. This amount of excess energy corresponds to, respectively, ~4.8 KeV or ~15.3 KeV per Pd atom. The corresponding average specific power is 71 or 48 W per gram Pd. For comparison, the average specific power in commercial nuclear fission reactors is between 20 to 40 W per gram uranium.

The Pd cathode is a 50 μm thick foil that is 7 mm wide and 60 mm in effective length. It has been pre-treated by Dr. Vittorio Violante of ENEA in Frascati, Italy. The anodes are two 0.1 ? 20 ? 60 mm Pt foils. The electrolyte is 0.1M solution of LiOD in D2O. After the experiments the cathode was investigated using a number of probing techniques, including AES, SEM-EDS, TEM and SIMS. Significant amount of low Z contaminants were found on its surface, extending to a depth of dozens of Angstrom. Their origin appears to be the lubricant used for rolling the foil in the pre-treatment process. Their presence prohibited detecting nuclear reaction products with acceptable certainty on and near the surface. No transmutation products were found at deeper layers. However, no measurement of He inventory was attempted.

The Super Waves Principle
Irving Dardik
Energetics Technologies P.O.Box 3026 Omer Industrial Park Omer, Israel

The results presented at ICCF10 of Glow Discharge experiments performed by Energetic Technologies (ET) researchers in Israel were described as “dramatic”. I expect that no less will be said of the Electrochemical Cell results to be presented at this conference. It is the purpose of this communication to describe the technical features of the ET results that distinguish them from prior cold fusion results, and the governing principle and theory that guide these new experiments. This information is offered to assist others to make progress in developing new energy technology.

Unique to the ET experiments is the use of a new understanding of wave modulation. Rather than dc, dc + ac, dc pulsed or bi-level perturbation, the waveforms being subjected (successfully) to test by ET employ waves fractally nested in a specific non-linear manner designed to stimulate intrinsic oscillatory processes across a wide range of scales. I call these SuperWaves©. When properly implemented SuperWaves have been demonstrated to influence strongly processes in the realms of physics, physical chemistry, metallurgy and also in physiology.

Early validations of the SuperWaves principle were obtained in physiological studies and from theoretical and applied studies of the melting, stirring and strengthening of metals. The current presentation will focus on the organizing principle of SuperWaves in the D/Pd both as a means to improve the rate and extent of (D) loading, and to provide the stimulus needed to produce cold fusion heat (and nuclear?) effects.

205) Another negative encounter with DOE

Ludwik Kowalski (3/12/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The 9th issue of New Energy Times <http://www.newenergytimes.com> describes a deplorable episode; a scientific propsal submitted by a recognized scientist was rejected by the DOE without being sent to reviewers. Here is how this bureaucratic decision.was described by the affected scientist, Dr. Melvin Miles:

On January 24, 2005 I submitted a White Paper Proposal to Dr. James Decker of DoE. Basically, I proposed experiments to optimize the cold fusion excess power effects by going to higher temperatures. For materials, I proposed using Pd-B alloys prepared by NRL and codeposition materials prepared by the methods of Drs. Stan Szpak and Pam Mosier-Boss.

My proposal was forwarded to Jim Horwitz of DoE (Basic Energy Sciences) who telephoned me on February 17 with his feedback that was mostly negative. Some of his comments are as follows to the best of my memory.

1. Proposals for the optimization of cold fusion nuclear effects cannot be considered because the 18 DoE panel members concluded that such nuclear effects do not exist.

2. Electrochemical cells have been studied to death, for example, by McKubre at SRI. Proposals of further electrochemical studies will likely not be funded by DoE.

3. Any proposed new experiments need an acceptable theory to justify such further studies.

4. More peer-reviewed journal publications are needed before this field can be considered for funding.

Because of these points, Jim Horwitz concluded that he could not justify sending my proposal out for review.

Based on this experience, I think it is unlikely that DoE will fund any research on cold fusion. If anyone has a more positive encounter with DoE please let me know. - Melvin Miles

According to Steven Krivit, the editor of New Energy Times, “Miles is a published author of 200 papers, 70 of them in the cold fusion field. A physical chemist, he has been recognized for his excellence in science by a 1966 NATO Postdoctoral Research Fellowship Award, and the following awards from his 24-year tenure with the China Lake Naval Weapons Center: Sigma Xi Award for the Best Scientific Paper in 1985 and 1988, William B. McLean Award in 1987, Fellow Award in 1989.”

According to : his areas of research expertise are: “Thermal batteries, lithium batteries, fuel cells, cold fusion, corrosion, electrochronic materials, thermodynamics, chemical kinetics, and electrochemical super-capacitors.” I am not surprised that a scientist with this background, working in a US military laboratory (see my item #51) was among the first who tried to validate to the claim made in 1989 by Pons and Fleischmann. And his negative results used against the claim. But Miles recognized experimental difficulties and continued his research. About one year later he reported positive results. That was the beginning of a long period of systematic investigations; many of them are described in papers downloadable from . I recall his report on finding 4He (byproducts?) in the cathode used to generate excess heat. He also tried to find 3He but the result was negative. It is not fare that an honest scientist, motivated by a desire to resolve the cold fusion controversy, one way or another, is not taken seriously by our DOE.

Jed Rothwell, whose full paper can be downloaded from

http://www.lenr-canr.org/News.htm (click on the “DoE lies again”)

made several interesting comments about this strange episode. I think they are worth thinking about. Jed wrote:

[Miles] letter imposes impossible Catch-22 conditions. Let us consider each statement:

1. “Proposals for the optimization of cold fusion nuclear effects cannot be considered because the 18 DoE panel members concluded that such nuclear effects do not exist.”

First, Horwitz is incorrect. The Review says that about a third of the panel members agreed that nuclear effects were detected. In addition, most panel members concluded that the claims for nuclear energy being the source of measured energy were not convincing. This is a far cry from concluding that “nuclear reactions did not exist”.**Second,** the Review recommends that proposals for experiments be considered. How could such proposals be considered if the effect does not even exist? Such an attitude condemns all proposals to rejection.

2. “Electrochemical cells have been studied to death, for example, by McKubre at SRI. Proposals of further electrochemical studies will likely not be funded by DoE.” Studies of heat production have been made by dozens of laboratories with good success and such studies are presently underway in many countries. The reality of anomalous heat production is no longer an issue. The challenge now is to improve reproducibility and to increase the amount of energy produced. In addition, the source of this unexpected energy needs to be discovered, whether it be nuclear or from some other unexpected process.

Miles is one of the few scientists who have had good success and who understands the nature of the novel process so that worthwhile results can be expected. If his work cannot be supported by the DoE, no proposed work can be expected to meet the required standards.

3. “Any proposed new experiments need an acceptable theory to justify such further studies.”

This statement turns the scientific method on its head. Cold fusion is based on experiment, not theory.

Theory is never needed to justify or prove experimental results. There is no theory to explain other recently discovered phenomena such as high temperature superconductivity (HTSC), but no one rejects the reality of HTSC on that basis. Furthermore, this imposes another Catch-22: until additional experiments reveal the nature of the reaction, theorists will not have enough data upon which to base their theories.

4. “More peer-reviewed journal publications are needed before this field can be considered for funding.”

This is the most obvious and absurd Catch-22 of all. How will researchers publish peer-reviewed papers unless they first receive funding to perform experiments? Researchers must be funded first, then perform experiments, write papers, and submit the papers to reviewed journals. Without funding none of this can happen. Inadequate funding in the past has been one of the handicaps that has prevented enough measurements from being made to answer the normal questions posed by peer reviewers. Nevertheless, as can be seen in the list of references, much of Prof. Miles’ work has been peer reviewed, yet even this does not appear to be sufficient for the DoE.

I agree with Rothwell; the arguments presented by Horwitz make no sense. A propsal submitted by a recognized authority in the field of physical chemistry should have been given the courtesy of being reviewed by other scientists. Something is basically wrong when a bureaucrat, even a highly knowledgeable one, can reject a proposal made by a qualified scientist. This, as observed by Krivit, is not consistent with a recent statement of Jim Decker, principal deputy director of the Department of Energy 's Office of Science: "We make decisions on funding research proposals on the basis of peer review and relevance." Which policy is in effect, that described by Decker or that described by Horwitz?

Something is basically wrong when judgements about validity of experimental claims are not based on empirical evidence. I already wrote about this in ”The Open Letter to DOE scientists” (see unit #196). But nobody replied; probably because members of the DOE panel do not know about my letter. Several weeks ago a slighly modified version of unit #196 was submitted as a letter to the editor of Physics Today. Will that letter trigger a discussion of moral responsibilities of those who coordinate scientific development? I hope so. But I still do not know if my letter will be published in Physics Today.

206) A new Russian report on nuclear alchemy

Ludwik Kowalski (3/15/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Two years ago I mentioned that work performed in a Russian laboratory, Lutch, had a strong influence on my attitude toward cold fusion. The publication that impressed me, by Karabut, was translated from Russian in unit #13. Irina Savvatimova, also from Lutch, worked with Karabut, as reflected in their 1992 publication. I had a chance of meeting her at two cold fusion conferences. Two days ago she informed me that her ICCF11 report can be downloaded over the Internet. The URL is:

http://rapidshare.de/files/853392/Savvatimova_article_ICCF11.doc.html

Note that the "download" button, on the screen that opens, is at the bottom. Be aware that the file is in the MS Word format and that its length is 14 Mb.

2) The ion bombardment apparatus used by Irina is similar to that described in unit #13; it is the deuterium glow discharge chamber. The applied voltages were between 300 V and 850 V; the currents were between 10 mA and 20 mA. But the main tool was a scanning electron microscope. It was used to examine a titanium cathode before and after the ionic bombardment (in experiments in which excess heat was also measured). The microscope was equipped with a setup, called EDS, (elemental dispersion spectroscopy?) that analyses X-rays emitted from spots selected by the electron microscope beam. Another instrument, called TIMS (thermo-ionization mass spectrometer), was also used in the reported study.

3) The purpose was to demonstrate nuclear alchemy -- formation of new elements. That area of research, known as nuclear transmutations, has been investigated by several cold fusion researchers. (see my units #85, #104 and #105). Traditional alchemy is known to be impossible and transmutations, if confirmed in reproducible experiments, will convince us about reality of unexpected nuclear processes. The instruments used in Moscow are probably available in many US laboratories; I have no idea why others are not trying to either validate or contradict experimental data reported by Savvatimova and Gavritenkov. Counting how many DOE panel members believed (and not believed) in validity of experimental results is not a correct way to deal with claims made by experimental scientists. Don't we have experts able to perform experiments described by Russian researchers?

4) I suppose that it is a matter of poor translation to refer to "byproducts of transmutation" as "impurity elements." The terms "new elements" and "trace elements" would also be better for a situation in which authors are convinced that new elements were not introduced through a contamination. The English word impurity implies contamination, at least to me. With this in mind let me quote from the paper: "The exceeding content of the impurity elements on the irradiated titanium surface were found in 20 cases from 47 analyzed places. The amount of the impurity elements in the comparison with an initial material was more from 10 up to 1000 times and from the tenth parts of percent up to percents. The integral content of the impurity elements in an initial sample did not exceed $7*10^{-3}$ %. "

The initial overall concentration of iron in titanium, for example, was 0.002% but the local concentration in the selected 6 sites, after the exposure to deuterium ions, was twenty times higher (0.04%, according to Table 3). The situation for Al is even more dramatic: -- 0.003% before the exposure to ions versus 0.33% after the exposure, in 9 selected sites. Possibilities of non-nuclear origin of such findings are discussed and rejected on the basis careful examination. I recall an earlier publication in which a highly unusual isotopic composition of iron, found in the palladium cathode, was

reported. Irina was a coauthor of that paper (see item #13). Unfortunately, the isotopic composition of iron produced in titanium was not reported; that would be a very convincing argument in favor of its nuclear origin. Some speculations about nuclear reactions, that might be responsible for generation of new elements, are offered. The last paragraph consist of five conclusions:

"1. The following elements O, F, S, Al, Na, Mg, Fe, and Ni in amount of 0.3-0.5 % up to ten percents were found in Ti foil after deuterium glow discharge experiments with excess heat effect.

2. The appearance of new elements within structural defects on the surface (in the micro explosions places, micro craters, local melting zones, phases inclusions on the tracks and others formations) could be the result of unequilibrium processes such as a micro arc with overvoltage with some accelerated effect leading to fusion and fission reactions in the excited crystal lattice of cathode surface.

3. The appearance of most elements obeys the law of energy conservation.

4. Excess heat effect in Ti foil could be explained as a result of elements transmutation in the cathode under excitation of crystal lattice in the deuterium low energy glow discharge.

5. It is necessary to have more statistical results with sequential analysis for explanation and understanding of mechanism."

I do not know why the potential difference under which the reported results were obtained was not specified more accurately; a person desiring to replicate the experiment would not be happy with the 300 to 850 volts range. And I was not happy that isotopic ratios were not reported. I expected to see them because of the following introductory statement: "Investigation of the isotopic composition was carried out by the thermo-ionization mass spectrometry method (TIMS)." The only place in which isotopic masses are shown is Table 4. But that table does not list iron. Three isotopes of Sr are listed but isotopic ratios are not specified. What is interesting, however is absence of the isotope ^{87}Sr. In natural Sr that isotope is 12.5 times more abundant than ^{84}Sr, actually observed by authors. I suspect a typing error in Table 4; otherwise the observation would be discussed as highly significant. What can be a better indication of nuclear origin than a highly abnormal isotopic ratio? Another possibility is that the ^{87}Sr peak was covered by the tail of the eleven-times-higher ^{88}Sr peak. I am not familiar TIMS; I do not know what its resolution should be in different mass regions.

Normally the most abundant isotope of calcium is ^{40}Ca (97%). But that isotope is not listed in Table 4. Another typing error? The same question can be asked about the absence of ^{160}Gd. I will assume that trivial clerical errors were made in composing Table 4. What else can it be? Absence of information on isotopic composition of iron is likely to be disturbing to anybody who read unit #13, and papers listed in it as references. According to Lutch scientists one half of iron produced in a palladium cathode consisted of ^{57}Fe. That is over 20 times more than in common iron. Is the situation in titanium the same as in palladium or is it very different? I would expect Savvatimova to focus on that question. But she did not address it. I am puzzled by this.

Unusually high contamination at selected spots on the surface of a titanium cathode, in comparison with its nominal bulk composition, can possibly be due to factors that have nothing to do with nuclear reactions. All kind of impurities are likely to appear on surfaces when foils are manufactured. Lutch researchers are certainly aware of this; that is why they compare observations of two surfaces of the same foil. The surface bombarded by ions, has more "new elements" than the surface that was not bombarded. But the factor of twenty (0.002% versus 0.04% for iron), if my understanding is correct, does not refer to two surfaces. Arguments of that kind would become totally irrelevant if the isotopic composition on "new iron" were shown to be very different from that of ordinary iron. Savvratimova knows this very well; she was a coauthor of several publications in which highly unusual compositions of new elements, including iron, were reported for a palladium cathode. That is why I am puzzled.

Appended on 3/24/05:
This unit was listed as "work in progress" for eight days because I was waiting to for Irina's clarifications. And I am

glad that I waited; what she wrote to me (see below) is extremely important. In my opinion, the paper should be revised before it is made available over the Internet.

Irina's clarifications:
Your questions are very deep. Not all questions have simple answers.
1. The change of the potential difference has no significant influence on the results. The glow discharge in our chamber is stable for any potential difference between 300 and 800 V.

2. The change in chemical composition with initial structure was compared in the Table 4 . CPS is count per second during the mass-spectrometry analysis. Such significant numbers are not error. Table 4 does not content trivial clerical errors:

a) Ca40 is an isotope, which we observed in large quantity during the analysis of the initial sample and after after experiment. It is a reason of the excluding this isotope from table 4. [To avoid confusion I would not exclude Ca-40 from the table]

b) Sr 87 has the mass as Rb 87 (85, 87). It is not right to include in table for the comparison. Much mass 87 in the tungsten cathode by mass-spectrometry method was noted also before. [I am not sure I understand this point.].

c) The decreasing Fe 56 up to 100 times was observed after experiment. Fe57 had not significant quantity before experiment, and Fe57 had not change in the comparing with initial sample after experiment.

However:
** The peak of the mass 55, after the bombardment, was 40 times larger than before the bombardment. [In my opinion focusing on a single peak is less convincing than focusing on isotopic ratios].

** Mass 55 is Mn55 or Fe55 (electron capture). Mn was not detected by EDS method. Fe was revealed by EDS method up to 4±0.2% (I think that this is highly significant. I will look at this fact again more carefully. It may be an indication of a mechanism for the Fe56 - Fe55 transformation.

3. You are right, showing isotopic ratios would be a more convincing evidence of nuclear transmutations. I did not include the ratios to save place (I tried to put all results in 12 pages). I do have isotopic ratios but they were not included in the paper; I will add them soon. Thank you very much for your interest and questions.

[Jed Rothwell told me that the paper of Savvatimova and Gavritenkov will soon be downloadable from the library at <www.lenr-canr.org> I hope it will reflect information on isotopic ratios.]

Adenedum (6/24/05):
The updated version of the report has been in that library since last may. Table 5 reports data on ratios of Ca isotopes. The claim is that Ca is one of the transmutation products generated during the experiment in the titanium target and that its isotopic composition is significantly different from that found in common calcium (96.9% of Ca-40, 0.65% of Ca-42, 0.135% of Ca-43 and 2.0% of Ca-44). It would be preferable if percentages of individual isotopes found in the Ti target were reparted in the same way as for common calcium. Unfortunately, what is reported are relative abundances.

The table shows that the relative abundance Ca-40 with respect to Ca-44 was 31 (insted of 48.4, as in common calcium), the relative abundance Ca-40 with respect to Ca-42 was 125 (insted of 161), the relative abundance Ca-44 with respect to Ca-43 was 49 (insted of 14.8), and the relative abundance Ca-44 with respect to Ca-42 was 4 (insted of 3.3). I do not know why absolute percentages were not given; that would be more useful. Estimated experimental errors, associated with these abnormal relative abundances, would also be useful. I assume that more information will be available in a future publication. Changes in isotopic composition of all trace elements are worth studying. As I wrote before, the term "trace element" is better than the term "impurity" (used in this paper). Impurity implies contamination.

207) Cases of Scientific Controversies

Ludwik Kowalski (3/18/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I belong to Phys-L, the Internet discussion list for physics teachers. Last night a teacher from California posted a message with the following URL in it:

<http://www.newscientist.com/channel/space/mg18524911.600>

It is a link to an article that appeared in the current issue of **New Scientist Magazine** (dated as 3/19/05). The title is: "13 things that do not make sense." Describing
the article the teacher wrote: "The review has been one of a handful of American publications that has defended continued investigation into cold fusion - in contrast to other media which has ridiculed or ignored the issue. Now the New Scientist lists
cold fusion as one of a dozen 'observations that simply defy explanation . . . exceptions that could rewrite all the rules'. " The "13 things" are examples of protoscience; they are not examples of pseudoscience. Let me summarize these examples, and insert some comments. The last case is cold fusion.

Case #1 (Placebo effects):
This is about Benedetti's data on how " 'mind can affect body's biochemistry. ..... The relationship between expectation and therapeutic outcome is a wonderful model to understand mind-body interaction.' Researchers now need to identify when and where placebo works. There may be diseases in which it has no effect. There may be a common mechanism in different illnesses. As yet, we just don't know." The placebo effect, according to the article, is a well known experimental fact. That fact, however, has not yet been explained. So what? Absence of an explanation does not take away from its use in medicine.

Case #2 (The horizon problem):
This is a cosmological paradox. How can the microwave radiation fill the visible universe, whose size, from one visible horizon to another is 28 billion light years? This well recognized (?) fact is in conflict with a confirmed theory according to which nothing can travel faster than light. Attempts to solve the paradox lead to other paradoxes, according to a Cambridge astronomer Martin Rees. The conclusion is that "In scientific terms, the uniform temperature of the background radiation remains an anomaly."

Case #3 (Ultra-energetic cosmic rays):
"For more than a decade, physicists in Japan have been seeing cosmic rays that should not exist." Their energies exceed the theoretically established limit (known as the Greisen-Zatsepin-Kuzmin limit). How will this apparent contradiction will be solved in the future? Will experimental facts will be invalidated or will something wrong be found in the theory? The essence of science is to recognize contradictions and to find ways of solving them. An ongoing experiment designed to shed light on the well known problem is described in the article.

Case #4 (Homeopathy):
"Homeopaths prepare their remedies by dissolving things like charcoal, deadly nightshade or spider venom in ethanol, and then diluting this "mother tincture" in water again and again. No matter what the level of dilution, homeopaths claim, the original remedy leaves some kind of imprint on the water molecules. Thus, however dilute the solution becomes, it is still imbued with the properties of the remedy.

You can understand why Ennis remains skeptical.“ Me too. But I would not refuse an invitation to witness a properly conducted demonstration. According to the article, “No homeopathic remedy has ever been shown to work in a large randomized placebo-controlled clinical trial.”

Case #5 (Dark Matter):
Astronomers know that many galaxies spin faster than can possibly be explained in terms of our best gravitational theory. This paradox was recognized by Vera Rubin in 1970. “The best response from physicists was to suggest there is more stuff out there than we can see. The trouble was, nobody could explain what this ‘dark matter’ was.
And they still can't. ..... Astronomical observations suggest that dark matter must make up about 90 per cent of the mass in the universe, yet we are astonishingly ignorant what that 90 per cent is.” That is one possibility. The other is that our gravitational theory should be modified to deal with extremely large distances.

Case #6 (Life on Mars):
This is a case where an experiment performed on Mars (Viking Lander, 1976) indicated presence of organic molecules. The discovery made by Gilbert Levin was not recognized as a proof. “Almost all the mission scientists erred on the side of caution and declared Viking's discovery a false positive. But was it? The arguments continue to rage, but results from NASA's latest rovers show that the surface of Mars was almost certainly wet in the past and therefore hospitable to life. And there is plenty more evidence where that came from, Levin says. ‘Every mission to Mars has produced evidence supporting my conclusion. None has contradicted it’. " But not contradicting is not the same thing as confirming. The original experiment was not replicated during later missions.

Case #7 (polyneutrons):
At the last cold fusion conference (ICCF11) I learned about a suggested theory of cold fusion. That theory of John Fisher was described in item #191. The description, however, does not reflect recent modifications. Several days ago John wrote to me about the new version of the theory; it will be described in an upcoming conference in Italy. A new attempt to identify a polyneutron is apparently in progress in France.

Case #8 (Trajectories of two space probes):
Observed trajectories of two space probes (Pioneer 10 and Pioneer 11, launched in 1972 and 1973, respectively) did not coincide with what was anticipated. How can this be explained? “Nobody knows. Some possible explanations have already been ruled out, including software errors, the solar wind or a fuel leak. If the cause is some gravitational effect, it is not one we know anything about. In fact, physicists are so completely at a loss that some have resorted to linking this mystery with other inexplicable phenomena.” Another indication that our knowledge of laws of gravity is limited?

Case #9 (Dark energy):
The article claims that dark energy (a property of empty space) the most contradictory problem in physics. “In 1998, astronomers discovered that the universe is expanding at ever faster speeds. It's an effect still searching for a cause - until then, everyone thought the universe's expansion was slowing down after the big bang. Theorists are still floundering around, looking for a sensible explanation, ..."

Case #10 (Planet X):
Distribution of icy rocks, in our own planetary system changes suddenly beyond the planet Pluto. This has been interpreted as an indication that a planet, as massive as Earth, was attracted all the rocks around. But no such planet has ever been observed. This controversy is likely to be resolved in 2015 when the New Horizons probe (to be launched by NASA in 2006 will reach Pluto.

Case #11 (Extraterrestrials trying to contact us?):
An astronomer, Jerry Ehman, once detected a very unusual signal with a radio telescope. “And 28 years later no one knows what created the signal. ‘I am still waiting for a definitive explanation that makes sense,’ Ehman says.” Why is he waiting for it? Who is he expecting to provide it? Rare effect are very difficult to study because they are rare.

Case #12 (light from distant quasars):
Light emitted 12 billion years ago, and analyzed by spectroscopists on earth was found to contain peaks due to

absorption in atoms scattered in the universe. But locations of peaks seems to be shifted with respect to where they are on earth. That is what was discovered in 1997 by an Australian astronomer, John Web. But French astronomers, headed by Patrick Petitjean, failed to confirm this observation. The team is now conducting a new experiment to validate the data. What can be a better illustration of how controversies should always be resolved in science? But progress is not easy. “The more we look at these new data, the more difficulties we see’ wrote another team member, Michael Murphy.

Case #13 (cold fusion):
“After 16 years, it's back. In fact, cold fusion never really went away. Over a 10-year period from 1989, US navy labs ran more than 200 experiments to investigate whether nuclear reactions generating more energy than they consume . . . With controllable cold fusion, many of the world's energy problems would melt away: no wonder the US Department of Energy is interested. In December, after a lengthy review of the evidence, it said it was open to receiving proposals for new cold fusion experiments.
That's quite a turnaround. The DoE's first report on the subject, published 15 years ago, concluded that the original cold fusion results . . . were impossible to reproduce, and thus probably false. .....The snag is that fusion at room temperature is deemed impossible by every accepted scientific theory.”

Validation of experimental facts should be based on better experiments. Science has been highly successful because it is characterized by unity between theoretical models and experimental data. The principle, as somebody wrote, is that theories guide but experiments decide. In science, unlike in mathematics, validity of theoretical models is based on experiments. Unfortunately, as illustrated in unit # 206, the DoE does not seem to be open to support research in the area of cold fusion.

208) An interview with Martin Fleischmann

Ludwik Kowalski (3/20/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

For some reason I was not aware (or forgot) that Haiko Lietz, a science reporter from Germany, interviewd Fleischmann at the last cold fusion conference (September 2004). The original version of this interview, in German, has been posted at:

< http://www.heise.de/tp/r4/artikel/19/19257/1.html>

while the English translation has been posted at Steve Krivit's New Energy Times website:

http://newenergytimes.com/Conversations/FleischmannByLietz.htm

This interview is interesting and worth posting on my website as well. Haiko has no objection. I think that what Fleischmann did not say is even more interesting than what he did say when the question was "*What mistake have you made in your life?"*

I would expect him to say that the agreement to have the 1989 press release was a big mistake. Either he or Pons depending whose decision counted (in the eyes of university administration), should have resisted the premature release of information about cold fusion research. But that event was not even mentioned in the interview. I would also expect him to say something about the broken agreement to work together with Steven Jones and his team. Jones' lab, in Provo, was only 20 miles away from Salt Lake City. As far as I know, the agreement was to investigate the unexplained phenomena a little longer, and then publish the results in a peer-reviewed journal.

Did Fleischmann already talked about these things in another interview? Did he write an article about political manipulations at the University of Utah? If he did then I would very much like to refer to material with which I am not familiar. Please write to me at <kowalskil@mail.montclair.edu>; I would be happy to poste additional information. Please refer to my unit #131 (Jones' history paper) and #132 (extracts from Fleischmann sociology paper). Cold fusion would not be excluded from mainstram science if it were introduced to the world in the usual way. Allowing the press release to go on prematurely was a mistake of Fleischmann and Pons.

* * * * *

"Why is everybody waiting for America when it comes to research?"

A conversation with Martin Fleischmann, the discoverer of cold fusion

by Haiko Lietz

Professor Martin Fleischmann became world-famous when on March 23, 1989 he reported, along with his colleague

Prof. Dr. Stanley Pons, the discovery of cold nuclear fusion in a simple tabletop electrolysis experiment at room temperature. The Nobel prize seemed in reach for them. But since some laboratories failed to reproduce the results, scientific and public opinion changed against their favour. Cold fusion has long been a synonym for an error in science. In this interview, made at the 11th International Conference on Cold Fusion before the 2004 Department of Energy Review result became public, Fleischmann speaks about how he deals with criticism, the role of quantum theory, and the demise of a purely consuming society.

Martin Fleischmann was born on March 29, 1927 in Carlsbad, Czechoslovakia. Because he was adopted by a Jewish family he and his family were forced to flee from the German soldiers to England. At London's Imperial College and Southampton University he ascended to become a world-renowned electrochemist. His last publication <http://lenr-canr.org/acrobat/SzpakSthermalbeh.pdf> with US Navy scientists was one of the basic papers considered by the Department of Energy reviewers. Fleischmann lives with his wife in Wiltshire, England.

You could long be "kicking it in the Caribbean" – to use a famous quote from the Pulp Fiction movie – but you're here presenting your thoughts on quantum mechanics. Can't you let loose?

If you work in this field and you have a negative result, you can walk away from it. It doesn't hold. But if you get a positive result, then of course it gets a hold of you. But I'm going to give up. My wife says, you keep on saying that you're going to give up. But I really haven't done anything new since 1995. I've made certain number of observations which are still valid, and I would have to reinterpret them. But in fact I have not reinterpreted them. I've just given the same old interpretation as I've always given to those observations.

But if you plan to give up maybe you should wait until the end of the year because the U.S. Department of Energy will be putting out another report.

I don't know. I think that they will be putting out another report. But it is very difficult to see how a subject like this can attract government funding. This is difficult, because you have to demonstrate some sort of requirement. You have to say is there a military requirement? Or is there a civilian requirement? I think there is… there are requirements. But our society does not respond in that way anymore.

The German Ministry of Research wants to wait for the Department of Energy report before it acts in any way.

(Laughs) That is so stupid! Why is everybody waiting for America when it comes to research?

You said "cold fusion" is a horrible term. Why?

This was a term pushed on us by other people. But what we do is not fusion in the conventional sense – the fusion process as recognised by hot fusion. And the fact that it was given that name polarized people's opinions. They said, "Well, it has to be like hot fusion. But it isn't like hot fusion. There are no nuclear signatures. So it can't be fusion. So you're all wrong." they said. That's the way it happened. If it had been called something else it might still have happened, but it is less likely to have happened.

Here is the "sixty-four-dollar" question: Why is heat and helium-4 produced in electrolysis experiments involving heavy water and Palladium cathodes?

I'm afraid it is because two deuterons fuse together to form helium-4 and heat. That is actually true. But that still isn't the conventional nuclear signature of hot fusion. In hot fusion it would have to produce tritium and a proton or helium-3 and a neutron or helium-4 and a gamma ray. This is if you had two particles hitting each other at enormous energy.

Did those people that assumed that the result should be as in hot fusion fail to consider the different environment of your experiment?

Yes, it's completely crazy! I think they will come to realize that.

Why did you initially start your experiments?

This whole subject was driven by the need to find demonstration of the quantum electro dynamic paradigm. We've had the classical paradigm of Newtonian mechanics. We've had Planck's quantum mechanical paradigm. I think most people who work in physical science realize the limitations of the quantum mechanical paradigm and that it has to be replaced by the quantum electro dynamic paradigm, nevertheless the introduction of that paradigm is strongly resisted. And if you introduce the quantum electro dynamic paradigm you see that what is called cold fusion might be possible.

How could nuclear fusion at room temperature be explained using quantum electrodynamics?

Well, if you think about quantum electro dynamics you realize that you get a large assembly, a large collection of atoms and molecules behaving as a single quantum system. So then you say, if I build a small amount of energy per atom into this large assembly of atoms and molecules then I will have a very large energy. And that large energy of course translates in the end to observable nuclear effects.

So physics actually drove your research?

I had worked since the 1960s on quantum electro dynamics in conventional chemistry. I had realized that all those systems had to be modelled in terms of quantum electro dynamics. And then I said, well, what is the most extreme question we can pose in quantum electro dynamics? And that is, can we get a nuclear effect by chemical means? I thought it would happen, but you might not be able to observe it. What happened is that it is possible and you can observe it.

That's what drove your cold fusion research?

That was the underlying question. I thought it had to be true, but I thought that we would not be able to observe it.

There is the next generation after yours, you could say, that is now continuing what you had started… one hope*... and what is for you the most interesting work being advanced by this generation in the field?*

Well, the most interesting work that has been done, in my opinion, is the work which was done in Frascati, which is not mentioned by the current people coming from Frascati. That is the work which was started by the late Prof. Preparata, his colleague Emilio Del Guidice, Antonella De Ninno, and Antonio Fratolillo on the effect of electric fields in creating more extreme conditions in the lattice, leading to the generation of excess heat and the generation of helium-4. To me that is the most significant result which has been reported in the last two years.

What does Stanley Pons actually do?

I don't know what has happened to him. He's sort of disappeared. I am not in contact with him although I would be prepared to be in contact with him. But he obviously doesn't want to be in contact with me. As far as I'm concerned he has disappeared, which is very sad.

Which cold fusion related events in your life do you like to remember?

None! (laughs) No, I don't really. This has been a terrible experience.

Come on, you must have at least met some nice people?

Of course there are people I appreciate meeting, but on the whole, when you get into this sort of situation, when you become a non-person, you become extruded from the society – but that's alright, that people ignore me. To hell with reputation! In science there's only one thing which matters. And that is the experiments. People periodically forget that you can say, "well, something might be possible, it might not be possible, now let's put it to the test."

But your critics also did experiments.

That was terrible! There were three studies which did us a great deal of harm. One was the study in the California Institute of Technology. Another one was the one in MIT. And the third one was in Harwell. MIT simply changed a graph. They changed the baseline. And actually if you look at Nathan Lewis' results (CalTech) rather carefully you will come to the conclusion that he observed excess heat! The only study which was honestly reported was the study in Harwell. That was actually honestly reported. They actually observed the generation of excess heat. They did not look at their data with sufficient care, but if you look at their data with sufficient care, you will see they observed the generation of excess heat – as I pointed out to them. I wrote to the head of the laboratory and said you observed excess heat – look at your results!

What mistake have you made in your life?

Oh, I've made plenty of mistakes.

Can you name one?

It's difficult for me because when I make a mistake I acknowledge it. I say I made a mistake. It's no big deal. I made a mistake. You put it right. So, I don't really remember. In truth, I don't make many mistakes.

You said you are pessimistic about the future.

I'm pessimistic about science.

The future of science or the future in general?

No, not necessarily… In the short term I'm not pessimistic about the future, but I think that we have to acknowledge that our society has become orientated towards consumption rather than production. And a society that becomes orientated towards consumption abandons scientific investigation. There are plenty of historical precedents of this phenomenon. And in the end, what has happened in the past is that societies which abandon the pursuit of science die. Our society will not necessarily die, but it will become unimportant.

If cold fusion should be developed to an energy source I'd like to thank you and leave the last words to you.

Well, I hope and pray that Germany will contribute to this science. It has a long scientific tradition, which could contribute a great deal to advance this subject. And I hope that the topic will be reconsidered and that especially the young people will enter the field and produce useful results. That's my hope.

Addendum (3/27/05):
Steve Krivit read my comment in the preface (about regretting the 1989 press conference) and sent me his own interpretation. He wrote:

1. From all my conversations with Martin, he seems to not want to publicly criticize the University of

Utah. It appears to me that the University of Utah administrators twisted his and Stan's arms. In my conversation with him during this interview, the clear impression I was left with was that at the time, he and Stan had the opportunity to co-operate with the University's wishes or they could find employment elsewhere.

2. He would not say anything about Jones publicly. Privately, he will express great bitterness and rage towards Jones. He's British, remember.

3. You may post this excerpt from my book if you think it is helpful.

Reprinted from **"The Rebirth of Cold Fusion"** by Steven B. Krivit and Nadine Winocur, with permission

The Infamous Press Conference

Fleischmann and Pons had little choice in matters pertaining to the initial publicity and the infamous press conference. The University of Utah's patent- and grant-seeking interests took precedence over scientific protocol. Fleischmann and Pons told the university that they would need many more months to complete a formal paper on the subject before making any announcement to the scientific community, but administrators wanted to announce the discovery before any paper had been published.

Fleischmann reflected on this stressful period of his life in an April 2004 letter: "I was not at all in favour of the high publicity route adopted by the University of Utah and wanted to delay consideration of publication until September 1990." But the university made it clear to him that he "had to appear supportive of their position." Fleischmann ran up against a wall with the university administration and attempted to use his prestigious connections to halt the press conference:

I cast around for other means to put a spoke into the university's objectives. I tried to get hold of Lord Porter, the president of the Royal Society, to ask him to contact Mrs. Thatcher, to ask her to get hold of George Bush (senior) to block the proceedings. I failed in my manoeuverings!

Eventually, the two electrochemists agreed with the university administrators to submit an abbreviated paper called a "Preliminary Note."

The University of Utah administration received word that the Fleischmann and Pons paper, "Electrochemically Induced Nuclear Fusion of Deuterium," had been formally accepted for publication on March 22, 1989, in the Journal of Electroanalytical Chemistry. Arrangements for a press conference to announce this news to the world were made sometime between March 20 and March 22. The press conference, not surprisingly, was a hastily and poorly planned affair.

The rushed announcement has been attributed to several factors. First and foremost was the universitys objective to secure first place in the cold fusion race and to corner the market on the cold fusion intellectual property. A few miles away, at nearby Brigham Young University, physicist Steve Jones was working on another type of cold fusion experiment. It is now known that Jones'cold fusion was markedly different from Fleischmann and Pons': Jones' work showed no signs of being an energy-producing device.

But this distinction was poorly understood by university administrators. On hearing rumors that Jones may be poised to announce "cold fusion," the University of Utah moved to secure its place at the patent office by publicly announcing its "prior claim."

The press conference was a disappointment to many scientists who were eager to learn the details of the experiment. The press release announcing the March 23 conference, edited by university administrators, carefully limited the scientific details. Furthermore, and unfortunately, as author Charles Beaudette wrote, there were other communication problems:

"The Preliminary Note that was accepted for publication the previous day was not made available for distribution [at the press conference]. The omission constituted a breach of protocol, as did their failure to brief their colleagues in the chemistry and physics departments beforehand."

It wasn't until 2? weeks later, on April 10, that the paper was published in the Journal of Electroanalytical Chemistry. Still, the preliminary note was devoid of many important details and highly inadequate as a guide for other scientists to replicate the experiment. It was clearly a hasty attempt on the university's part to establish a foothold for its patent objectives and, perhaps, its fame.

The university believed it had its hands on the most valuable patent in modern history, and for this reason it also prohibited Fleischmann and Pons from personally disclosing key details to their fellow scientists. Dr. Chase Peterson, the university president at the time, was forthright about the university's interest, as shown in written testimony to the U.S. Congress:

"Upon the advice of our patent counsel, it is not possible for the University of Utah to share research results with other laboratories, particularly national laboratories, until the information has been incorporated into a patent application and the application is on file in the patent office."

This secrecy generated ill will not only among skeptics from around the world but also among academic peers at the University of Utah. Distrust, anger, and even rage mounted almost immediately when other scientists attempted to learn the essential details of the experiment so that they could, in earnest, prove or disprove the experiment, a normal part of the scientific process. But this was nearly an impossible task, considering the legal restrictions.

"Fleischmann looks back with sadness on these times. 'I really didn't want to do it this way. I did not want to do this project this way,' he said in an interview in 2003."

209) Australian connection

Ludwik Kowalski (3/27/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This is to another ICCF11 paper. I consider it to be an "Australian connection" because three out of five authors, including the first author, are from Australia. The title of the paper is "**Low Energy Nuclear Reactions resulting as picometer interactions with similarity to K-shell electron capture;"** the authors are H. Hora, G.H. Miley, X.Z. Li, J.C. Kelly, and F. Osman. George Miley is from Fusion Studies Laboratory at the University of Illinois, USA, and X. Li is from Tsinghua University, China. Miley is a recognized authority in both hot fusion and cold fusion; I read many of his papers. Let me begin by quoting an observation made in the Introduction; it resonates with what I wrote in unit #203"

"Since every cold-fusionist likes to get his own credit, nearly nobody is taking the work of colleagues serious or carefully reproduces the other's work. It is really the responsibility and duty of funding agencies like DOE or others to financially attract most carefully selected teams to reproduce the one or the other serious result as the very first step. Only after this clarifying progress on experiments, one may talk about any theory or model."

In writing about excess heat experiments I often wrote that nuclear origin of that heat must be demonstrated. Many researchers reported excess heat (generated at the rates of below and above one watt) but failed to demonstrate its nuclear origin. here is how this issue is addressed by Hora et. al:

". . . The generation of heat was indeed in the focus of interest. Experiments were performed in gaseous atmosphere at different pressures and temperatures placing Pd wires in deuterium gas but observing also effects if not deuterium but light hydrogen is loaded into the palladium. Long time repeated experiments with Pd wires in hydrogen atmosphere showed . . .heat was . . . produced [at the rate of] 3.6 kW/cm3 heat or 13 keV per palladium atom. Such energy cannot be produced by chemical processes."

In other words, the issue of the "non-chemical origin" can be ruled out when heat is generated at a sufficiently high rate, and during a sufficiently long time. In the described experiment heat was generated for 43 hours after the glowing discharge was terminated. But the 13 keV per reaction is still lower than a typical energy of several MeV known to be generated in many nuclear reactions. Addressing this issue the authors wrote:

"Since any heat generating process will not be due to every average Pd atom but to specific ones only, reactions with the well known MeV can be concluded as expected from nuclear reactions If such nuclear reactions occur - even without emission of alphas, betas, neutrons or not resulting in radioactive reaction products - the MeV recoil of daughter nuclei should produce x-rays in the few keV range and the MeV daughter nuclei should appear as traces in CR39 foils. Both has been detected."

I am not going to focus on essential ideas developed in this theoretical paper. The main point is that "hot fusion" was also very controversial when it was discovered in early 1930s. A conflict with an existing theory (this was before the tunneling effect was recognized) should not be a basis for rejection of highly reproducible experimental facts. Let me quote an interesting quotes from the Introduction.

The problem may be that the phenomena [of cold fusion] were brought forward to physics by non-physicists. In this situation it may be permitted to recapitulate what happened in similar cases before. When Becquerel discovered 1896 that the pitchblende from St. Joachimstal in Bohemia and other minerals containing uranium are emitting certain

radiation blackening photographic plates, a wide range of people were speculating about this phenomenon. There were even papers explaining that some ghosts are involved. Ernest Rutherford after his undergraduate studies in New Zealand produced splendid results with his Ph.D. in Cambridge where he before 1900 contributed to Marconi's detection of electromagnetic radiation by discovering very ingeniously the "radiomagnetic detectors". After becoming a professor at the McGill University in Montreal, he discovered that pitchblende emitted helium as demonstrated spectroscopically and found that another emission were energetic electrons which were just recognized at this time. With this discovery of alpha- beta- and gamma-radiation he became the founder of nuclear physics but his faculty was going to dismiss him because he was working in a field related to ghosts. He was saved in last minute by the offer of a professorship in England.

The discovery of fission is a well known case of unexpected phenomenon. I do remember what O. Hahn and F. Strassmann wrote in their famous 1939 paper. It was something like this: "We know that our discovery makes no sense in terms of what is theoretically expected. But we are analytical chemists and we have no doubt that barium is produced when uranium is bombarded by neutrons." L. Meitner was no longer in Germany when this paper was published. But it was she who were the first to say, in a paper published in England, that uranium might be splitting into two large fragments and that the process generates more than 100 MeV of energy per event. The term fission, that she introduced to name this mechanism, was already used by biologists to describe division of cells.

"The more skeptical are physicists when chemists or others are claiming anomalies in physics. Such a problem was between the chemist Otto Hahn and the radiation physicist Lise Meitner, a most prominent team e.g. with the discovery of the new element protactinium in 1918 where they – against the rules – did not receive the Nobel prize. Physicists expected the production of heavier nuclei when bombarding uranium with neutrons into which direction Meitner was looking when she left Berlin mid 1938 under unfavorable circumstances to Stockholm. Meitner meeting Hahn November 1938 still "objected to the most recent findings" of Hahn who then again with his world best techniques of chemical micro-analysis confirmed that elements of middle weight were produced, proving that the neutrons were splitting the uranium nucleus. These results were reproduced very quickly in comparably easy experiments and the enormous consequences are known."

Possibilities of practical applications of fission, via a chain reaction, were recognized as soon as reality of the new process nuclear was confirmed. The authors of this ICCF11 paper claim that their experiments were 100% reproducible. Numerous references to their publications are shown.

210) Investigations of Oriani solid effect: Work in progress

Ludwik Kowalski (4/4/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction:
My attempts to get involved in cold fusion research were described in unit #189. The first attempt was to work with Harold Fox. We demonstrated that the anticipated transmutation of a radioactive thorium material into a non radioactive material did not take place. The second attempt was a short cooperation with Steven Jones. Only one experiment was conducted by me and it could be interpreted as a confirmation of findings reported by Jones and his team. The third attempt was a short cooperation with Dennis Letts and his team. A very strong anomalous effect was discovered but, unfortunately, the experiment was not repeated. Both attempts were described at the last cold fusion conference (ICCF11, 2004). Our paper presented at that conference can be downloaded from the library at <www.lenr-canr.com>.

The first three attempts had two things in common: (a) I was only marginally involved, and, (b) I had no opportunities to repeat experiments. The fourth attempt was, and still is, very different. It is a study of Oriani effects described in unit #188. I have a replica of Oriani's cell at home and often use it, since november 2004, to perform experiments. Preliminary results, described in units #192 and #197, reflected my learning. Descriptions are too long and boring; it was naive to think that people would be interested in so many irrelevant details. But I am not sorry for being actively involved in a study which may turn out to be very significant.

Oriani vapor and liquid effects have been described in 2003, at ICCF10 (International Conference of Cold Fusion). Papers of Oriani and Fisher, presented at that conference can be downloaded from the library at <www.lenr-canr.org>. The Oriani-solid effect, which we are now studying, has been published in 2004, at ICCF11. That effect consists of particles detected in air below the 0.12-mm-thick nickel cathode (at the bottom of the cell). The cathode is thick enough to stop natural alpha particles coming from the electrolyte. Oriani thinks that alpha-like particles must somehow be produced in nickel, or in air below it. Studying particles in air, outside the electrolytic cell, can be conducted not only with track detectors (used by Oriani), but with surface barrier detectors as well, as in Jones' experiments.

The goal of our research was to turn Oriani's vertical cell (described in unit #188) into a simple setup for student-oriented experiments. Track detectors are ideal for that purpose because they are extremely sensitive, relatively inexpensive, and simple to understand. That is why our work, so far, was done exclusively with track detectors (CR-39 chips). Surface barrier detectors will probably be used after finding conditions under which observations are nearly 100% reproducible. Information about energies of particles, and about times of their emission, would help us to understand what is going on.

2) From Oriani's recent e-mail messages

a) According to what I wrote in unit #188, the CR-39 chip (area 0.6 cm^2) placed 1.5 cm below the cathode, recorded 1818 tracks of alpha-like particles in 72 hours during the electrolysis. This however, as Oriani discovered after my departure, was due to a contamination. Not surprisingly, I failed to replicate these results in two experiments at home. But Richard's recent results are remarkable; he continues observing anomalous alpha-like particles below the cathode. In a recent message (3/21/05) he sent me a table showing that such particles were observed in 9 out of 9 experiments. The recording rates, expressed in tracks/cm^2/hr, fluctuated from one experiment to another with the mean being 1.70 and standard deviation being 0.71. Nine control experiments, with detectors placed far away from the electrolytic cell,

showed fluctuating backgrounds. The mean background, also in tracks/cm^2/hr, and standard deviation, turned out to be 0,27 and 0.083, respectively. That is a very impressive result; the difference between the two means -- 1.7 and 0.27 -- seems to be real, as far as statistical fluctuations are concerned. But that, as always, has nothing to do with possible systematic errors.

In another message (3/26/05) Oriani described two additional control experiments. In these experiments detectors were placed below the cathode with no current flowing through the cell. A small amount of ThO_2 powder was added to the electrolyte (in a specially constructed cell and in another room) to test a theoretical prediction of John Fisher. I am mentioning this fact because recording rates, first with zero current (no electrolysis) and then with the current of 180 mA, are interesting. The zero current results, in two different cells, were not significantly higher than the mean background in the air, far away from the cell. Presence of an alpha radioactive substance in the electrolyte has no significant effect on the background below the cell. This is not surprising; the cathode thickness of 0.12 mm is larger than the range of alpha particles. The 180 mA results also turned out to be not significantly different from what was measured, with the same current, without thorium.

3) Description of my recent findings:
In trying to replicate Oriani's recent results I used the same concentration of the electrolyte (23 grams of Li_2SO_4 per liter of distilled water) and the same current (180 mA) as he. I conducted five new experiments, two controls and three tests. The first control (chip area 1.2 cm^2) was a zero-current experiment lasting three days. The second control was a 0.60 cm^2 chip situated in air, one meter away from the cell. The tests were two-days-long treatments. The results are shown in the table below. The 3th column shows the chip areas, the 4th column shows the numbers of preexisting (old) tracks, the 5th column shows the numbers of new tracks and the last column shows the average track recording rates.

Table 1 (Ludwik's data)

	exposure hrs	chip area cm^2	# of old tracks	# of new tracks	tracks/cm^2/hr
Control 1	72	1.2	23	59	0.70
Control 2	72	0.6	6	19	0.44
Test 1	48	1.2	20	65	1.13
Test 2	46	1.2	23	39	0.41
Test 3	47	1.2	24	50	0.87

The mean from my three tests, 0.80 tr/cm^2/hr, is not significantly different from the zero-current Control 1. It is clear that my attempt to observe alpha-like particles below the cathode, and due to the electric current, was not successful. The table below can be used to compare my raw data with his. It consists of five typical results; they were extracted from tables describing nine tests and nine controls.

Table 2 (Typical samples from Richard's data)

	exposure hrs	chip area cm^2	# of old tracks	# of new tracks	tracks/cm^2/hr
Control 1	47.5	1.0	3	19	0.33
Control 2	92.6	0.87	10	41	0.37
Test 1	23.5	0.6	2	20	1.4
Test 2	46.5	0.8	5	82	2.2

Test 3	47.8	0.72	4	62	1.8

One thing is immediately obvious. My old track densities, about 20 tr/cm^2, are much higher than old track densities reported by Richard. But my counting geometry (chips were ~1 mm from the cathode) was different from his (chips were ~6 mm from the cathode). Furthermore, my etching conditions (6.25 N, 75 degrees C and 6 hrs) were different from his (6.5 N, 80 C and 2 hrs). And on top of this I counted all tracks while Richard counted very dark tracks only. Taking all this under consideration, I think that my results neither contradict nor confirm Oriani's new results. They are not as good as his. I should conduct experiments with chips that also have smaller numbers of preexisting tracks.

4) Discussion:
If I were to take the results of Table 1 seriously (I am not) I would say that the effect has nothing to do with electric current. In that context the first 72-hours-long experiment would be a test, not a control. The only control would be a chip in the air, away from the cell. By taking this attitude I would say that the four chips below the cathode (mean 0.78 tr/cm^2/hr and standard deviation 0.30) record something that can not be attributed to background (0.44 tr/cm^2/hr). But how can one draw such conclusion from a single set of data? Like Oriani, I should have many controls and many tests. The effect that is only one standard deviation stronger than the background cannot be taken seriously.

The issue of irreproducibility has been discussed by Edmund Storms; his papers can be downloaded from the library at <www.lenr-canr.org>. Storms keeps emphasizing that cold fusion phenomena depend on NAE (Nuclear Active Environment), a mysterious ingredient that has not yet been identified. And he is convinced that the situation will improve rapidly after the NAE is discovered. If he is correct then cold fusion has no precedence in nuclear science. Other phenomena, such as artificial radioactivity, heat generated by radium, neutrons and fission, did become reproducible shortly after they were discovered. On the other hand, one might speculate that the cathode we used in November had more NAE than cathodes we used in March. As an experimentalist I will accept the NAE after it becomes something specific; for the time being it seems to be nothing else but a philosophical idea. For the time being I will expect our cathodes, (made from 99.99% pure nickel) to be interchangeable.

As I indicated above, the discrepancy between our new results might be due to differences in etching and differences in deciding what to count and what not to count. I counted all tracks, large and small, while Oriani counted very dark tracks only. Suppose that tracks that are small, after the first etching, become large after the second etching. In that case old tracks can easily be counted as new tracks. We are currently discussing ways to make our future experiments more compatible and less subjective. Hopefully both of us will arrive to more or less identical conclusion. After studying three different effects (nuclear particles in the liquid, in the vapor and in the air below the cathode), Richard now thinks that we should focus on the third effect because it seems to be the most reproducible.

211) Fatal confusion about cold fusion

Ludwik Kowalski (4/11/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Charles Beaudette, the author of a well known book about Cold Fusion, made interesting comments on the second DOE report. His paper can be downloaded from the Library at <html://www.lenr-canr.org>. Let me focus on some ideas discussed in that paper. His observation that the "Office of Science did not have a choice in this matter [selecting the cold fusion panel] given the pariah status of the field" is questionable. The DOE had many choices, selecting a panel whose task was to express opinions was only one of them. A better choice, as I wrote in unit # 196, would be to select two teams to perform critical cold fusion experiments. I will have more to say about this later. Claims based only on opinions are not as convincing as claims based on reliable experimental data.

I agree with Baoudette that "there is a considerable level of confusion as to how the field of cold-fusion research began, and how its several parts now relate to one another." He is making this observation on the basis of what the DOE referee wrote in their individual reports. Some anonymous referees seem to be unaware that two different claims were made, sixteen years age, under the same label. The first was the discovery of the unexplained excess heat (by Fleischmann and Pons) and the second was the discovery of unexplained neutrons (by Jones and his team). The label cold fusion, introduced by Jones, was a natural consequence of his earlier investigations of muonic molecules, and of highly compressed matter.

But imposing the same label on research devoted to excess heat was totally inappropriate. In a recent interview (see item # 208) Fleischmann said that the term cold fusion "was pushed on us by other people." This, however, was not at all obvious sixteen years ago. Fleischmann and Pons themselves were promoting the idea that excess heat is accompanied by emission of neutrons. Here is how this tragic confusion, now a piece of history, is described by Beaudette: " By pretending that they were experimental physicists during a few weeks prior to the announcement, the two chemists made mistakes in their attempt to measure neutron radiation. They erred badly collecting data, and their errors were quickly discovered and emphasized." The resulting consequences are well known. Even today, as illustrated by Beaudette, the claim of excess heat is often confused with the never-made claim that excess heat is due to thermonuclear reactions. The main issues are:

a) Is it true that the amount of thermal energy, released in some electrolytic experiments, exceeds the amount of electric energy received during the electrolysis?

b) Can the excess heat, if confirmed, be explained by chemical reactions taking place in materials from which electrolytic cells are constructed?

And additional non-chemical issue has to do with reality of nuclear particles, such as neutrons, protons, tritons and alphas, claimed to be emitted from solid metals loaded with hydrogen ions. The first issue has to do with calorimetry, the second has to do with quantitative chemical analysis, and with chemical thermodynamics. I see no reason why the DOE could not find a group of experts able to answer the above two questions in its existing laboratories. That would be much more useful than creating a panel whose task was to express opinion. Another panel, composed of physicists would be assigned a task of either confirming or refuting emission of nuclear particles from hydrogenated metals.

Expertise and equipment for addressing the above three issues were, and still are, available to the DOE. I agree with Baudette that it was a mistake to initiate a peer-review work of the cold fusion field by panelists who "were unfamiliar with its technical development, leading scientists, significant experiments, and principal papers." I also agree with his

criticism of approaches used by some panelists. Criticizing experimental findings on the basis of conflicts with the accepted "canon of nuclear science" is certainly not consistent with our scientific methodology.

To end this unit let me address two other topics raised in Baudette's paper: the issue of the "burden of proof' and the issue of "reproducibility." I disagree with him that those who criticise nuclear interpretation of excess heat, and who suspect that the heat might be due to something else, should "have a duty to elucidate possible [chemical or] storage mechanisms as disturbing artifacts." Their duty is to mention such artifacts, the burden of showing that the artifacts are not responsible for what is observed is on those who claim that the effect is highly unusual, in terms of our current paradigm.

Addressing the second issue Baudette writes: "Concern for experimental reproducibility (repeatability) sometimes overshadows experimental results in cold-fusion research, both among its practitioners and its critics." That is certainly true. Franco Scaramuzzi, an esteemed hot-fusion physicist who practiced cold-fusion research for fourteen years, wrote: "a) I agree that reproducibility is a 'must' in experimental research; b) however, a new field, at it beginning, is often characterized by a lack of reproducibility , and it is the task of the scientists operating in the field to understand what is going on, in order to pursue reproducibility." I agree with this. In my opinion, however, a field in which reproducibility (of experiments conducted by qualified researchers) is poor is not yet scientific. Protoscience should not be confused with science.

Unlike pseudoscience, the term protoscience is not pejorative. Many alchemists and astrologists were protoscientists before chemistry and astronomy became scientific fields. Cold fusion research will become scientific when at least one of its numerous discoveries is recognized as highly reproducible. I like how Beaudette refuted claims, made in 1989, that Fleischmann and Pons were offering only pseudoscience. He refers to Lagmuir's description of pseudoscience and contrasts it with what was actually stated, or not stated, in the published reports. Beaudette also reminds us that "Langmuir says nothing about reproducibility." His paper ends with an extensive list of references.

212) Answering four questions

Ludwik Kowalski (15/4/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This morning I received a set of survey questions, from a friend in Europe. Here are my answers:

- WHAT IS COLD FUSION (LENR, CANR, CMNS)?

It is certainly not pseudoscience, as many think. It is protoscience claiming that nuclear activities result from some chemical processes, such as those taking place in electrolysis, or when hydrogen ions diffuse through some solids. Kinetic energies of such ions, and dominant products of reactions, are believed to be very different from those observed in the so-called “hot fusion.” The term hot fusion usually refers to thermonuclear reactions, and to reactions in which ions are electrically accelerated before colliding.

- HOW DOES IT WORK?

I do not know.

- WHAT CHANCES DOES IT HAVE TO BE SCALED UP TO A TECHNOLOGY?

Impossible to predict at this time.

- WHAT HAVE WE TO DO IN ORDER TO ATTAIN THIS?

Experimental results, performed by qualified researchers, must become 100% reproducible anywhere and any time. Protoscience will then become part of mainstream science. Also see items #210 and # 211 at my cold fusion website:

213) More about Energetics Technologies

Ludwik Kowalski (20/4/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Yesterday I visited Energetics Technology (ET), a small private company in Israel (subsidiary of an American company) conducting cold fusion research (previously described in unit # 204). The company is also interested in magneto-hydrodynamics processing in metallurgy, a field with which I am not familiar.

Two things impressed me the most. The first was the high caliber of technical expertise and equipment assembled at ET in the last three years to deal with several aspects of cold fusion. The second was the difficulty under which industrial research is conducted. I am familiar with scientific research at universities and in national laboratories; the area of industrial research is new to me. Academic researchers usually have tenure; scientists conducting industrial research here work under a contract that is expected to be renewed each year. This, I suppose, has to do with the high risk of investing in a controversial technology.

The company which is focused on the use of a special wave form (SuperWave) proposed by one of the company's owner, Dr. Dardik, is headed by Shaul Lesin, an expert on magneto-hydrodynamics. The second in command is Arik El-Boher (see photos below), conducting research in cold fusion. He is focusing on glow discharge cells. Arik has six such cells working in parallel. The geometry of each cell is cylindrical -- the anode (molybdenum or tungsten wire) in the center and the cathode (pure or alloyed PVD coatings on stainless steel cylinder) approximately one centimeter away.

KEEP READING IF LOADING OF PICTURES IS SLOW

. . .

SHAUL AND ARIK

At one point I said that my choice would be to have a cathode in the center (to increase the electric field near it). Arik indicated that such geometry was tried but the results were not better than with the presently used cells. He believes that the

area of the cathode must be maximized to enhance excess heat. Arik hopes to obtain better results from the ongoing experiments in which thin layers, and sets of layers, are deposited on cathodes.

I also had a chance to talk with other four researchers: Tanya Zilov, Boris Khachturov, Vitali Krakov and Mark Tsirlin. All of them were educated in the former Soviet Union. Tanya is an electrochemist, Boris is a nuclear physicist, Vitali is a physical chemist while Mark is a material scientist. I can not imagine a better set of specialists hired to investigate practical aspects of cold fusion. Each of them spent about an hour with me, explaining their setups and talking about results. The pictures of these scientists are shown below.

. .

. .

. .

. .

TANIA, BORIS, VITALI AND MARK

Tanya has a set of nine electrolytic cells (heavy water and LiOD) working in parallel. Each cell is equipped with a commercial recombiner (turning oxygen and hydrogen into D_2O) and with a set of temperature sensors. Loading of deuterium ions into cathodes is controlled by measuring cathode resistances. Rare episodes of very high efficiencies (excess heat of up to 2500% of electric energy supplied) at low reproducibility rate, described in unit # 204, were obtained with electrolytic systems driven by superwaves. Like many other cold fusion researchers, Tanya does not know why large excess heat is not observed more frequently. A reproducible setup generating excess heat at the efficiency of more than 100% or 200% would probably lead to a commercial success. Recently in one of their ultrasound electrolytic cell experiments (after analyzing the experimental data), they achieved an efficiency as high as 1200%. These results will be presented in the coming workshop May 2005 on cold fusion in Siena, Italy.

At present she and Boris are trying to irradiate cathodes of electrolytic cells with ultrasounds. The idea is to expose palladium cathodes to cavitational bubbles. Preliminary results from this approach are very encouraging. Excess heat generated at the level of several watts, she said, is 100% reproducible, but only when the efficiency is low. More specifically, the 100% reproducibility was recorded for electrolytic cells in which the cathode is Pt and the anode is Pd. They call this arrangement reversed because Pd and Pt are most often used as a cathode and anode, respectively. The highest efficiency has been14.5%. In my opinion this is a monumental achievement. But Tanya is not satisfied; the common efficiencies of ~10% she said, are too low to be practically useful. In my opinion, focusing on what is 100% reproducible would be very useful at this stage. A Russian saying "tishe jedesh dalshe budiesh" (those who advance slowly will get there sooner) seems to be applicable in this case.

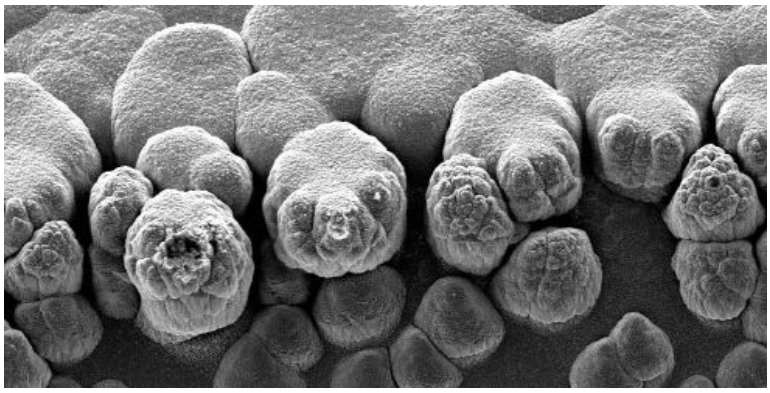
The error of measuring excess heat, in Tania's and Boris' experiments, is close to 1% -- this is good enough to conduct systematic investigations at the level of ten percent efficiency. That is what I would do in such a situation. Taking advantage of 100% reproducibility I would systematically investigate effects of various parameters, such as concentration, temperature, pressure, current density, etc. I would not worry about low efficiencies. Then I would publish the results. Yes, I know that people directing industrial research might be reluctant to share essential information; academic research, with which I am familiar, is different from research focused on commercial success. My goal would be to identify the mystery of the NAE (nuclear active environment) that, according to Storms, makes generation of excess heat possible. In other words I would take advantage of the achieved experimental reproducibility and try to turn protoscience into science. That seems to be the most urgent issue in the area of cold fusion.

Tanya said that highly reproducible Pd/D loading results were obtained by using superwaves, rather than commonly used dc. Furthermore, the highest excess heat has been generated using superwaves with very low current density. My first reaction to this was to think about the power factor (cosine phi due to phase shift between the current and the voltage) at different

frequency components. I asked Arik about this. He said that they do not worry about power factors because sampling rates in measuring voltages and currents are at the level of 50KHz. This is well above the highest frequency components (up to 1 kilohertzs) of their superwaves. Furthermore, calibration experiments with dc and with superwaves were in very good agreement (less than 0.5%), using 1 MHz Yokagawa power meter.

Vitali specializes in catalytic materials and in gas loading. If I understood him correctly, he was not able to reproduce the effects discovered by Case and by Paterson. These effects were described at the 10th cold fusion conference (ICCF10). He works with compressed palladium powders in dielectric and conducting materials. Mark specializes in the analysis of materials. Using sophisticated analytical instruments, available at Ben Gurion University and at other Israeli Universities centers, he performs both elemental and isotopic analysis. No evidence of alchemy (production of new elements) or abnormal isotopic ratios was confirmed by his investigations, even in cathodes that generated spectacular amounts of excess heat.

He explained to me why results of elemental analysis are so difficult to interpret. For example, relative squares of the X-ray spectroscopic peaks (EDS method) strongly depend on local topography of the surface bombarded by electron beam as well as on sizes and phase composition of analyzed area with rather small impurities content. Therefore the obtained results fluctuate widely as one examines different spots even on the same surface. This complicates comparisons of impurities concentrations for different samples. That factor is usually not mentioned by those who report on nuclear transmutations. But Mark is fascinated by structural changes on palladium surfaces resulting from such processing. Many of his SEM pictures have artistic values, as illustrated below.



_ . _ . _ . _ COLD FUSION IN HEBREW _ . _ . _ . _ A SCANNING ELECTRON MICROSCOPE PHOTO

Appended on 1/13/2008

Steve Krivit, a scientific reporter, and the editor of New Energy Times, published an interview with interesting information about Energetic Technology. It is item #7 in the just-published issue #26 of his online journal.

http://newenergytimes.com/news/2008/NET26.htm

The title of the item is “Interview with Irving Dardik and Alison Godfrey of Energetics Technologies LLC.” The journal website is:

214) That is not cold fusion!

Ludwik Kowalski (5/1/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) The following reprint was posted on Phys-L, a discussion list for physics teachers:

Observation of nuclear fusion driven by a pyroelectric crystal
B. Naranjo, J.K. Gimzewski & S. Putterman
NATURE _434_ page 1115 (28 APRIL 2005)

While progress in fusion research continues with magnetic and inertial confinement, alternative approaches such as Coulomb explosions of deuterium clusters and ultrafast laser plasma interactions also provide insight into basic processes and technological applications. However, attempts to produce fusion in a room temperature solid-state setting, including cold fusion and bubble fusion, have met with deep skepticism. Here we report that gently heating a pyroelectric crystal in a deuterated atmosphere can generate fusion under desktop conditions. The electrostatic field of the crystal is used to generate and accelerate a deuteron beam (>100 keV and 4 nA), which, upon striking a deuterated target, produces a neutron flux over 400 times the background level. The presence of neutrons from the reaction D + D ==> 3He (820 keV) + n (2.45 MeV) within the target is confirmed by pulse shape analysis and proton recoil spectroscopy. As further evidence for this fusion reaction, we use a novel time-of-flight technique to demonstrate the delayed coincidence between the outgoing a-particle and the neutron. Although the reported fusion is not useful in the power-producing sense, we anticipate that the system will find application as a simple palm-sized neutron generator.

http://www.nature.com/nature/journal/v434/n7037/edsumm/e050428-06.html

2) Yesterday, replying to the above, I wrote: “The most interesting is generation of high potential differences by small differences in temperatures. I was familiar with piezoelectric, but not with pyroelectric, crystals.” Then I discovered that Google points to many references on that subject. One paper (see the URL below) prompted me to write the following private Email message:

“I enjoyed reading your description of the new neutron source at:

http://www.nature.com/nature/journal/v434/n7037/full/4341077a.html

Can I have your permission to post it on my website? That website:

http://blake.montclair.edu/~kowalskil/cf/

is devoted to cold fusion but I am sure that people interested in that controversial subject will also be interested in what you wrote. As you probably know, several years ago CF researchers were discussing high electric fields (due to + and - charges across different highly localized surface defects) as a possible cause of cold fusion.”

Here is the reply from Dr. Mike Saltmarsh:

"The copyright to my article belongs to Nature, so I'd guess that it is their permission not mine that you need. Of course you need no permission to post a reference to the article on your website. However as you are presumably are aware, the pyroelectric generator idea has absolutely nothing in common with the cold fusion furore. There is no new physics involved, indeed fusion has been produced by beam-target interactions for decades. It's easy, but regrettably useless for energy production.

Parenthetically, I was involved in the original cold fusion fiasco, and had overall charge of the effort to investigate the phenomenon at ORNL. I was absolutely stunned to find that so many apparently competent researchers seemed to suspend their critical faculties when presented with an exciting result. **Do not underestimate the power of self delusion! Irreproducibility is still a key indicator of a lack of understanding.**"

Responding to the above, and hoping to enrich this item, I asked Mike to elaborate on the power of self-delusion. He wrote: "I don't think that I will amplify what I said before. To do justice to the topic I'd need to collect some references and do a decent job for you, and I'm not willing to put in the time right now. If you're interested, you might like to look at the history of "polywater", which caused a furore about 20(?) years ago. Or read Steven J Gould's article on the measurements of the speed of light as a function of time (I think it's in his book The Mismeasure of Man). Good luck with your website. You can quote whatever I've emailed to you." Too bad; input from a retired national laboratory scientist, who was in the center of a recent controversy about cold fusion via ultrasounds, would be interesting.

The controversy is not over; researchers from Energetics Technologies (see item #213) did say that ultrasonic cavitation was an important factor in their excess heat experiments. The first topic on the agenda of the upcoming cold fusion workshop at MIT (May 21, 2005) is "Acoustic-induced Cold Fusion Experiments." Russ George, who I met at ICCF11, has a website <http://www.d2fusion.com/> at which he writes that tiny-heavy-water bubbles, collapsing on metallic surfaces, cause cold fusion. Responding to the search phrase <nuclear "bubble-fusion"> Google delivered 771 references. Yes, I know that sonofusion might turn out to be hot fusion, and that it has nothing to do with the title of this unit. But the connection is obvious: from tiny bubbles to ultrasounds that produce them; from ultrasounds to piezoelectric generators, and from piezoelectricity to pyroelectricity.

215) Technology -- solar versus cold fusion

Ludwik Kowalski (5/3/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

After spending a day at Energetics Technologies (see item #213) I had a chance of visiting Jacob Blaustein Institute of Desert Research (Israel). It is located at the Sede Boker campus of Ben-Gurion University. This visit made me think about differences between applications-oriented research in the field of solar energy and in the field of cold fusion. In the former case research is based on science, in the later case it is based on protoscience. Not a single cold fusion application has been commercially successful, so far, while progress in the area of solar energy has been enormous. Will practical applications of cold fusion start to appear after the field becomes scientific? I hope so. But for the time being emphasis must be on science, not on technology. I am particularly impressed by recently published roadmaps for implementations of photovoltaic (PV) technology in different countries, as described in

<http://www.epia.org/05Publications/OtherRoadmaps.htm>

They indicate that solar batteries are likely to become dominant suppliers of all our electric needs, including industry, before the end of this century. The American roadmap, entitled “Our Solar Future,” is downloadable as:

<http://www.seia.org/media/pdfs/pvroadmap.pdf>

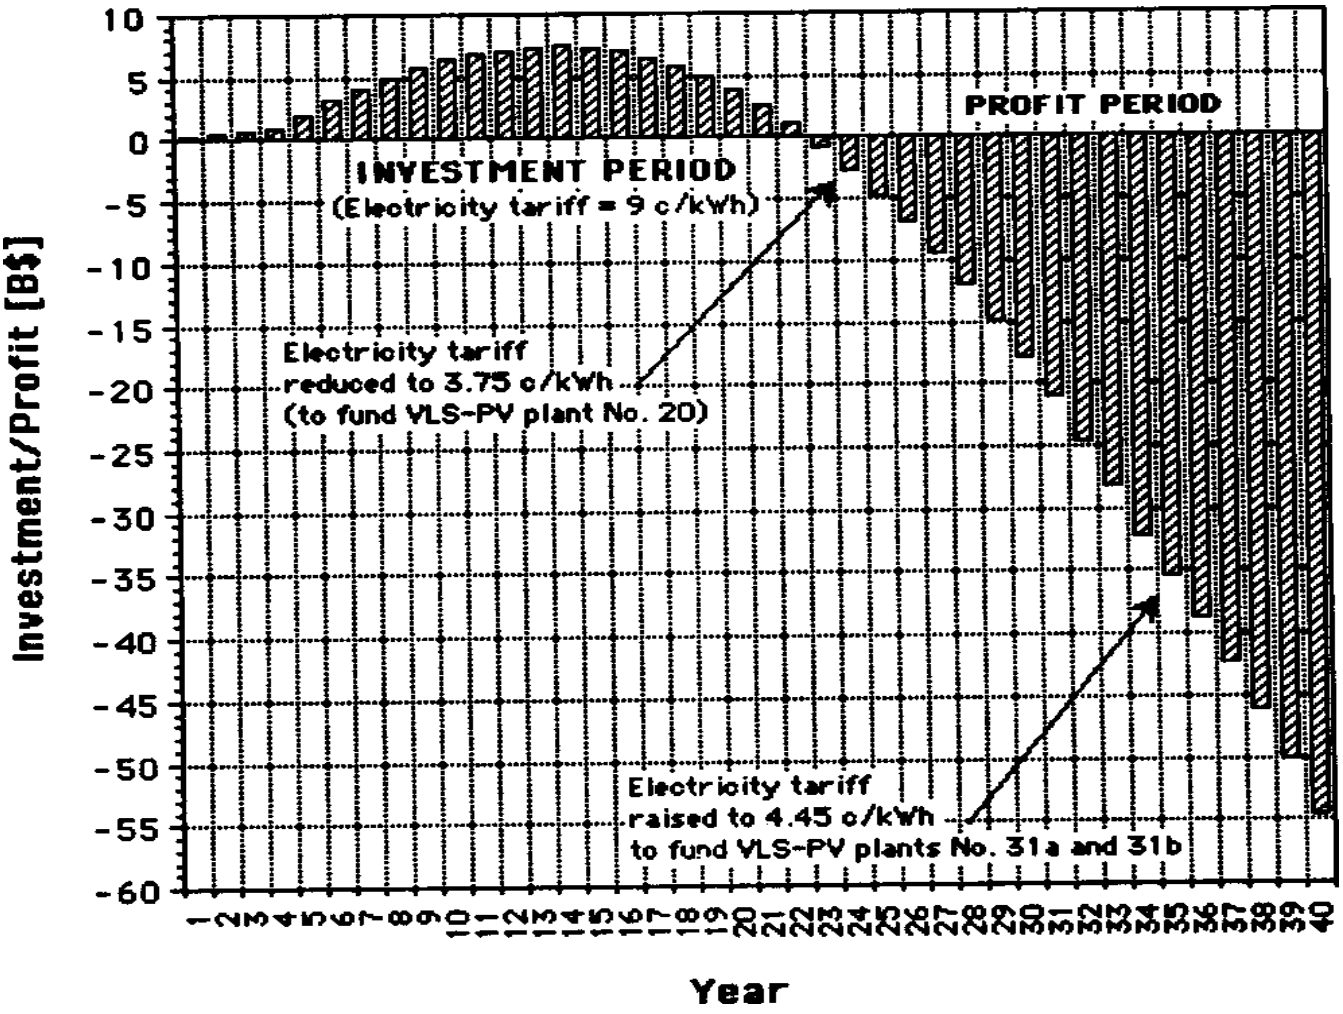
David (pointing to a mirror) and myself below the concentrator.

According to Dr. David Fainman, the director of the Israeli solar research center at Sede Boger Campus, the problems of implementation

are no longer technological; they are primarily financial. He gave me the preprint of a paper to be presented at the International Conference on Solar Concentrators for Generation of Electricity or Hydrogen. That invited paper describes a proposed financial model for a country like Israel. I am sure that this paper will be available over the Internet after the conference (May 1-5, Scotsdale, AZ, USA).

Solar concentrators, by the way, are computer-controlled reflectors that focus solar radiation. A photovoltaic panel, receiving concentrated radiation, is a set of solar batteries. I wish I had time to ask technical questions after the brief description of the financial model. One of my questions would be about the need of cooling. To keep the cells cool one must constantly remove a lot of heat. This would probably not be necessary if inexpensive mirrors were replaced by very expensive batteries of cells.

According to the model used by Fainman, the CPV (concentrated photovoltaic) technology will pay off the expenses, and will generate profits, after 23 years. This is illustrated in the figure below.



Credit line during the first 40 years. (Negative values show profits in billions of $ per year)

The figure, describing the forecast for a country like Israel, is based on a set of assumptions. Some of these assumptions are:

a) Subsidy-free financing, at an interest rate of 5%, “via an open credit line that is repaid with interest entirely from revenues that accrue from a steadily increasing number of [very large] power plants.”

b) It will take four years to build a facility to make large solar power plants.

c) “Starting from Year 5, one 1000 MW plant is erected per year.” The first erected plant will start to generate revenue in Year 6, the second will start to generate revenue in Year 7, etc.

d) To start off, electricity is sold at approximately the prevailing market tariff, until the credit line has been paid off.” All the revenue is used to pay for the the operation and maintenance, for general and administration expenses, and for the credit line with interest.

e) The cell efficiency will be 32% and “plants will have 30-years lifetimes without undergoing degradation.” In reality degradation is

expected but the initial efficiency of cells is expected to increase gradually in the next 35 years.

I was not aware that 32% efficiency is already possible today, and that 50% efficiency is expected in 35 years. But I will assume that Faiman, and his coauthors, are not science fiction writers. They probably have good reason to believe that modeling assumptions are realistic. The Internet is full of information about photovoltaic cells and I should learn about new things. Here are some links:

```
http://www.eia.doe.gov/cneaf/solar.renewables/renewable.energy.annual/backgrnd/chap11i.htm
http://www.fsec.ucf.edu/pvt/pvbasics/index.htm
http://www.sandia.gov/pv/
http://www.fsec.ucf.edu/pvt/
http://64.243.182.248/includes/pv%20tutorial.pdf
```

The main point is that solar electricity is already a practical reality on a small scale, and that it is likely to become a dominant source of electricity in many countries. That is good; fossil fuels will soon be too expensive to compete with solar energy. Dreams about abundant, and pollution-free (?), energy seem to be turning into reality. Yes, scientific and practically-oriented research, in the area of solar energy, were initially subsidized (and are still subsidized) by governments and private agencies. But subsidies would not materialize if experimental results were irreproducible, as they still are in the areas of cold fusion.

216) Too good to be true?

Ludwik Kowalski (5/5/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

One of the most important achievements of the 19th century physics was the discovery that a well defined amount of mechanical work is needed to generate one unit of heat -- not less and not more. Joule demonstrated this in a well known paddle wheel experiment. Water was forced to flow through small holes in the paddles of a rotating wheel and the amount of heat was measured calorimetrically. But, at a recent conference, a Russian scientist, A.I. Koldamasov (1), described an exception from this rule. He claims to have a device in which the heat to work ratio is twenty times larger than what would be allowed according to Joule's equivalence rule.

His device, named reactor, is similar to Joule's paddle wheel. But water, free of ions (resistivity 10^{11} ohm*m), is forced to flow through holes (diameters 1-2 mm) drilled in a plate made from the dielectric material (rather than from a metal). After reviewing basic concepts of thermonuclear physics Koldamasov writes: "On the basis of the above theoretical ideas, a nuclear reactor producing energy of nuclear fusion reactions was designed and tested (see Fig. 1). The reactor operation is stable and well controllable. It gives 20 units of useful power per unit of supplied power. Furthermore, it is possible to obtain power both in the form of heat and directly electric energy, omitting steam water cycle. According to the consumer's needs, the electric energy can be of both direct and alternating current. [Russian patent reference is given.] . . .

The working fluid is fed by a gear pump under the pressure of 5 to 7 MPa; the channel is 25-30 cm long, and the orifice diameter is 1-2 mm. By changing the electric motor rotation rate, we change the frequency of flow pulsation's and reach the resonance frequency of the orifice, which causes intensive cavitation. Under the action of this cavitation, the plate material emits electrons from the input edge, which are carried away by the flow, and at the output edge a high-density positive charge is formed (see Fig. 6). The charge is annular, its density is practically uniform, and it constitutes a medium temperature plasma ~10000 K with the density ~10^4 J/cm^3. If heavy water possessing the same dielectric properties as the working fluid is added to the outflowing medium, then nuclear fusion reactions arise in the zone of influence of the charge."

What kind instruments were used to demonstrate occurrence of nuclear reactions? I was not able to find the answer to this question in the Koldamasov's paper. Here is how this paper ends: "The number of deuterium atoms collisions, and hence the magnitude of the released energy, depends on heavy water concentration in the working fluid. In our experiments we used a mixture with the ratio 1:100 (1 part of heavy water per 100 parts of light water). The continuous operation time was up to 100 hours. The experiments are entirely reproducible." Who is Koldamasov? Where were his experiments performed? Who are his coworkers? How much of "excess energy" was generated in 100 hours? Not knowing how to answer such questions I turned to the Internet.

The first item that came up, after typing "Koldamasov" indicates that reproducible results were first reported by the author seven years ago. Here is the extract from what was delivered by Google: "Six authors who stated 100% reproducibility of the effects detected are Bazhutov, Kanarev, Karabut, Savvatimova, Notoya, and Koldamasov." And here is another earlier reference (2). On Hideo KozimaÕs website:

http://web.pdx.edu/~pdx00210/News/CFRLEngNews/CFRLEN35.htm

I see a list of papers read at the 9th Russian Conference on Cold Nuclear Transmutation of Chemical Elements (September/October, 2001). It contains references (3) and (4). The session at which these papers were presented was chaired by A. B. Karabut, the author of what I described in item 13. The device is said to generate twenty times more electric energy that is needed to run its motor. Why is it not manufactured and used all over? I suspect that the 100% reproducibility claim was found to be highly exaggerated. Somebody probably tried and failed to produce a commercially successful gadget.

ADDENDUM:

While searching on the Internet I found a useful compilation about "who is who" in Russian cold fusion research. The authors are I.V. Goryachev, and Y.N. Bazhutov; the title is " Organization, current status and main results of Russian research in cold fusion and transmutation of chemical elements." It shows that the author of the last reference, a Ph.D. physicist, is from the Research Institute of High Temperatures, Russian Academy of Sciences in Moscow. His specialty is listed as experimental " investigations of the methods of initiating nuclear reactions in deuterated dielectric liquid under the conditions of cavitation." The name Koldamasov does not appear in the downloaded document: <GoryachevIorganizati.pdf>

Appended on 5/22/05:

1) On 5/13/05, after finding the sentence quoted below (at the website of CNW -- Group Canada NewsWire), I sent an e-mail message to Dr. Yang, the Chairman & Founder of the Hy-En Group of companies:

Dear Dr. Hyunik Yang:
Browsing the Internet (before going to the MIT cold fusion colloquium next Friday) I found this description of your commercial activities:

". . . The three main applications derived from "Cold Fusion" are massive production of low cost hydrogen and heat energy for commercial and industrial applications steam or hot water and electric power..... "

Please provide a reference (or references) about the method used to obtain electric power via cold fusion. Thanks in advance,
Ludwik Kowalski

2) The above message was not answered. During the MIT colloquium I heard that Koldamasov died and that his invention is going to be used by a company whose name is iESiUSA (Innovative Energy Syatems Inc.). Materials on the company's website<WWW.iesiusa.com> do not refer to clod fusion. But they are worth quoting.

a) "Innovative Energy Solution Inc. is a leader in developing reliable next generation, clean energy technologies. iESi owns several patents related to its proprietary hydrogen generation, heat generating and waste heat recovery technologies."

b) "The new clean energy plant will enable Norwood Foundry to generate six times (12 MW) more electricity than it consumes (2 MW) at its foundry located in Nisku, Alberta, Canada." That is indeed extraordinary - consuming

electric energy at the rate of 2 MW and generating it at the rate of 12 MW, presumably at the same time. This would be a giant perpetual motion machine. Recall that Koldamasov's device had the output/input ratio of twenty, not six. But even a factor of two would be extraordinary.

c) "The revenue to be generated through the joint venture project is expected to exceed $6 million annually. Under the joint venture, iESi is responsible for the implementation of its revolutionary clean energy technologies, while Norwood [the old existing foundry] will finance the project.....The plant is slated to be fully operational by the third quarter of 2005..... iESi owns several patents related to its proprietary hydrogen generation, heat generating and waste heat recovery technologies. Headquartered in Las Vegas, Nevada, iESi also has offices in Canada, Europe and South Korea." I hope that my retirement savings are not invested in iESi.

d) Innovative Energy Solutions Inc. (iESi) today announced that it raised $3 million in its first round of financing. The investor group consists of more than 300 individuals from Canada, Europe and the United States. iESi will use the investment to accelerate product development, push market penetration and establish manufacturing facilities in Alabama. 'The success of our initial funding is encouraging to iESi as we focus on executing our business endeavors and growing the company. The first round closed with an oversubscription of 200,000 shares, which demonstrates a substantial interest in our energy generating technologies and what they can do for a fuel-based economy,; said Ron Foster, chairman, iESi. iESi will open its second round of financing on July 29, 2004, by offering 500,000 shares at $4 apiece. Established in 2003**,** iESi's mission is to offer clean, viable solutions to traditional energy sources, and reduce the world's dependence on oil from the Middle East. iESi is organized into three broad divisions to maximize return on its intellectual capital and intellectual property."

Too good to be true? Yes, I think so. But the company website provides many claims that are worth discussing with students. Physics teachers should take advantage of this. Something is not right in this business of promoting nonexistent technologies. In unit #224 I referred to a colloquium presentation of Robert Rines, the patent counselor at MIT. At one point he asked a question; "what harm can possibly result from granting a patent whose validity cannot be established at sufficiently high level of certainty?" He was referring to patents in the area of cold fusion. Nobody, he said, will be stupid enough to invest in things that are still uncertain. I now tend to disagree. A granted patent gives some kind of legitimacy to unjustified commercial claims. Patents can be viewed as instruments of protection of citizens. Yes, I know that such instruments are not very effective. But they are better than nothing. Citizens should also be economically protected by other legal means.

Addendum (5/25/05):
Here is the content of a document, dated as 5/23/05, that I found on the Internet. It provides background information about promoters of cold fusion technology.

EDMONTON, Alberta, May 23 /PRNewswire/ -- Innovative Energy Solutions, Inc. (iESi) today announced the arrival of the Company's co-founder and Chief Technical Officer, Hyunik Yang, Ph.D. and Dr. Nahm Cho in Sherwood Park, Alberta, just southeast of Edmonton. The recent relocation of Dr. Yang and Dr. Cho should expedite the efforts that are already well underway on the Direct Electrical Power, Heat and Hydrogen Generation units and allow the Company's team of scientists to advance the impressive work they accomplished for iESi while in South Korea.

"Much of iESi's proprietary intellectual property is based on the research in the field of quantum energy generation authored by Dr. Yang," said Patrick Cochrane, CEO, iESi. "Drs. Yang and Cho and our team of scientists are continually conducting research to enhance iESi's technological offerings and we look forward to their continued presence in Edmonton."

"Dr. Cho and I are pleased to finally be here in Canada. We're eager about working closely together with our scientific and management teams to implement such a worthy offering that will allow the world to go from dependence on energy providers to energy self-sufficiency," said Dr. Hyunik Yang, Chief Technical Officer, iESi.

As concern grows for the world's natural resources, energy efficiency is gaining worldwide attention. iESi is poised to be the leader in the development of innovative energy solutions through its safe and patented plasma processes which

included Direct Electrical Power Generation, low-cost Hydrogen Generation and low-cost Heat Generation, all three of which were developed by Dr. Yang.

In his career, Dr. Yang has also held positions as professor at Hanyang University and as senior research engineer at Hyundai Electronics. Dr. Yang has designed several new inventions in the field of quantum energy and cold fusion. Dr. Yang received his Engineering B.S. from Hanyang University in South Korea, and completed his Engineering M.S., Ph.D. and post-doctoral work at Columbia University in New York. He is a member of the American Society of Mechanical Engineers, Society of Automobile Engineers, Korean Society of Mechanical Engineers, Russian Academy of Natural Science, Korean CAD/CAM Society and the Korean Society of Machine Tool Engineers. Since 1997, Dr. Yang has been listed in the Who's Who in the World, and in the Who's Who in Science and Engineering since 1998.

Dr. Cho also held positions as professor at Hanyang University. Dr. Cho is the author of four patents in South Korea and is an expert in the field of Nuclear Transmutation and Fusion. Dr. Cho received his Precision Mechanical Engineering B.S. and M.S. from Hanyang University in South Korea, and completed his Ph.D at the Tokyo Institute of Technology. He is a member of the Japan Society of Mechanical Engineers, Japan Society of Precision Engineers, Korean Society of Mechanical Engineers, Korean Society of Precision Mechanical Engineers, Korean Society of Manufacturing Engineers and the Micro Biochip Center.

About iESi
Innovative Energy Solution Inc. (iESi) is a leader in developing next generation clean energy technologies. iESi owns several patents related to hydrogen generating technology, heat generating technology and waste heat recovery. The Company's Corporate Offices are in Las Vegas and iESi also has offices in Canada, the United Kingdom and Europe. For more information please visit: **http://www.iesiusa.com**

217) An Ukrainian Connection

Ludwik Kowalski (5/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Research of Adamenko and his associates was described in unit #168. At the Informal Workshop organized by the University of Bonn (IZKS Center, February 6-7, 2004) that work was described as follows:

THE KIEV EXPERIMENTS ON LOW ENERGY NUCLEOSYNTHESIS

THE ABSTRACTS OF INVITED PAPERS

The physicists of the Kiev "Proton-21" laboratory of low energy nuclear physics (Dr. S. Adamenko and coworkers) claim evidence (through 5000 experiments, carried out since 1999) for an enormous number of "low energy nucleosynthesis" in a little ball of copper invested from all sides by 0.3 MeV electrons. The elemental and isotopic analysis of the reaction products done in Kiev was confirmed in laboratories of other countries (USA, Russia).

Starting from a 99.99 % pure ball of copper (0.01 % impurities) a large quantity of elements like ?, ?, La, Ce, Pt, Pb was produced. The total number of new nuclei is comparable with the total number of initial copper nuclei. The process has further amazing features: (a) The radioactivity of the resulting material is not different from the background activity and (b) transuranic nuclei are produced, including superheavy ones. The aim of the workshop is to present for the first time the Kiev results and discuss their significance, meaning and possible applications (e.g. energy producing, eliminating of radioactive wastes).

It is from: http://www.proton21.com.ua/articles/BonnAbstracts.pdf. Let me add that the website of the laboratory headed by Adamenko is: <www.proton21.com.ua/index_en.html>; the list of their publications can be seen at <http://www.proton21.com.ua/articles_en.html>. What follows is a more recent description of that work, as popularized in the online newspaper: Ukraine Now <www.ukrnow.com>. I am quoting the entire article because I do not know for how long it will remain at <www.ukrnow.com/content/view/4300/2/>. That description will probably remain important, even if the extraordinary claims (nuclear alchemy without radioactivity, etc.) turn out to be a false alarm. I would like to thank D.L. for informing me about the article shown below.

Taming a Neutron Star

Ukraine Now, Friday, April 22 2005

Ukrainian scientists claim they have tamed thermonuclear fusion.

It appears that Ukrainian scientists have made a discovery which could be as significant as the production of fire or the invention of the wheel by our ancestors. If their theory is confirmed, humanity will get a source of practically free energy which could be obtained in any quantity out of anything. This energy would be ecologically clean and result in small power plants.

The situation looks like something from a fantasy novel about an inventor of a perpetual motion machine in which a lonely enthusiast who does not care for recognized theories and authorities builds an engine of eternal action or a time

machine in a barn, or creates a life-giving potion. In real life we treat such characters skeptically. I have met dozens of them and disappointment has always been the result of such meetings. However, Kyiv scientists from Proton-21 have demonstrated results that leave one speechless.

This is a team of highly experienced experts and the equipment used in their laboratory exceeds the technical capabilities of many scientific research institutes. Bombarding a target with a relatively weak beam of electrons, they get results similar to what goes on inside neutron stars. The target collapses in on itself (shrinks), followed by an explosion and the brightest flash, nuclear transmutation (the occurrence of a great number of elements which the target lacked before) and a stream of various radiation. The energy of the explosion exceeds the initial energy of the election beam by a million times. One need only harness it, and while it appears that is not an easy task, it could be realized technologically.

I have no doubt that readers will cluck: "Thousands of physicists all over the world have been engaged in such experiments for the last 50 years, moreover, they are working with huge synchrotrons like the one at Serpuchov or the one at CERN. Countless billions of dollars have been invested in thermonuclear energy and now amateur "experts" in Kyiv have beat them all? Sorry ,but Icannot believe that !"For such educated readers we will repeat that synchrotrons have nothing to do with this discovery. Attempts to produce thermonuclear energy have been underway at Tokamak installations and laser compression systems in Russia at the Kurchatov Institute and in Saratov , as well as in the U.S. at Livermore and Los Alamos, and at a laser center in Kyoto ,Japan .

I went to a meeting with project chief Stanislav Adamenko with feeling similar sarcasm. I had taken along a stack of critical reviews of cold nuclear fusion because this project highly resembled that to me from the beginning. I cannot say that what Adamenko and his colleagues told me completely won me over, but his research has reached such a level that despite my skeptical attitude it would be negligent of me not to tell the public about the project. If their results are confirmed, if Proton-21 will achieve at least part of what they claim, the world will obtain a colossal source of cheap and clean energy. If the idea becomes a soap bubble, then we will forget it.

However, the photos of samples exploded from inside look very convincing. And the database with results of analyses based on almost 10,000 of successful experiments forces one to take them seriously.

Nuclear 'Lighter'

Here is what Adamenko says. As the scientist's speech is full of arcane terms and data which are clear only to nuclear experts, I will try to simplify his story.

Adamenko: First we have the goal of developing efficient and safe technology for using nuclear waste. We want to construct a sort of "lighter" able to force radioactive atoms to "burn down" and turn into "ashes." The first successful experiment was made on Feb. 24, 2000 , on non-radioactive targets. In a couple of months we found stable, non-disintegrating atoms of super heavy chemical substances among other particles in the screen that captures the target's fission products. Finally, in our installation which is located in a laboratory at the Institute of Nuclear Research of the National Academy of Science of Ukraine , we conducted successful experiments neutralizing radioactivity in 2002. We managed to exceed the boundaries of the initial topic.

So, why has humanity failed to tame thermonuclear reactions for almost all 60 years? Scientists are not able to find conditions to conduct a stable process. The whole world thinks that the main thing in the process is a race for more powerful ways to impact targets, and such an approach inevitably leads to a dead-end – targets exploded before a large-scale thermonuclear process managed to start. After many searches we succeeded in finding such a tool and we managed to start a reaction. In brief the idea looks like this – we punch the surface of small ball-like target with a powerful, but very short beam of electrons. The surface layer transfers the blow deeper inside, to more deeply located layers, and they in turn transfer the impact deeper. As the target has the form of a ball, the level of compression increases when the shock wave deepens into the substance. It looks like a tsunami – its wave is not too visible at the deep sections of ocean, but it rapidly increases in shallow places, rushing onto the beach with huge waves.

The shock wave in the ball behaves in the same way – starting from some layer its pressure becomes so intense that it

presses atoms of substance despite their mutual repulsion. This pressure is a million times higher than anything existing or created on Earth. The nuclear "pot" of a substance with incredible density is formed in the center and all electrons are taken away from their orbits encircling the nucleus, while the very nuclei lose their initial characteristics and mess with each other. The nuclear mix flies away and forms new atoms – many of them were absent in the initial target material. The main idea in this method is to create conditions for such an electronic blow that all surface layers of the target will start continuously shrinking inside. We dubbed it "The method of punching the compression of a substance."

For those who have a deeper knowledge of nuclear physics I will provide data and calculations. Scientists from all over the world are trying to conduct controlled thermonuclear reaction experiments with mixes of deuterium-tritium (D-T). In theory, in order to ignite it and to give way to energy which exceeds the energy spent for "ignition," one should create conditions described long ago known as the "Lawson criterion." According to this criterion, first the temperature ***T*** of plasma should not be less than 7-10 keV (70-100 million degrees Kelvin). And second, the density of plasma **n** (the number of ions in a cubic centimeter) and the time of its detention under specified temperature TAU should satisfy the following ratio:

$\mathbf{n}*TAU>10^{14}$.

The creation of such density of plasma at a specified temperature, and moreover its detention for a necessary period of time, is a task which has been an unreachable dream for physicists all around the world. According to the results published by Adamenko and his colleagues, they managed to reach the following conditions inside the core of the target:

$\boldsymbol{T} >>$ 40 keV (upper estimate of 100-200 keV);

$\mathbf{n} >> 10^{27}$ nucleus /cm^3 (upper estimate exceeds $10^{30} – 10^{33}$ nucleus/cm^3);

$\mathbf{TAU} > 10^{-8}$ sec.

So, in some of the 10,000 experiments the Lawson criterion is surely exceeded:

$\mathbf{n*TAU} >> 10^{19}$

Such density of a substance is characteristic of the nuclei of neutron stars and white dwarves. This extreme state was obtained under Earth conditions for the first time and is the result of the artificially invoked collapse of the target as described above.

It is not difficult to estimate the energy emitted during the collapse and the following explosion. We put 100-200 joules in a beam of electrons to create the initial ionization. For comparison – in order to heat half a glass of water 1 degree we need 400 joules. We take a quarter of this energy – this is an insignificant value. But the emission of the target lasts for 10^{-8} sec. So what do we obtain after the collapse? First we obtain isotopes of elements of the entire Mendeleev's periodic table from hydrogen to super heavy elements. It is possible to calculate for each nuclei how much energy such a transformation took. And it happens that to channel nuclear transformations only 10-30 megajoules are necessary! That means that the ratio of input and output energy differs by 5-6 times!

There are other ways of getting energy. If we take only the energy of a light flash, it will be almost equal to the energy necessary to launch the process. The ion component gives 1,000% and this is a low estimate.

First There Was Copper, Then Mandeleev's Entire Periodic Table

Aleksander Kochno, the director general of the Proton-21 laboratory, and another employee, Vladimir Vysotsky, a professor of physics and mathematics at the Kyiv Shevchenko University , join our conversation.

Vladimir Vysotsky: They demonstrated amazing photos of exploded targets, and it could be clearly seen that the explosions happened in their center, in the depth of the substance. I was particularly interested in a photo of a strange hemisphere imprinted on the screen with a ball clearly cut out from the center. The scientists explained that inside this ball the reaction of the nuclear collapse had happened and the explosion had taken this hemisphere out of the target and smashed it into the screen. Other tables show the results of spectrographic analyses – how many various elements were registered during explosions, for example from a copper target with 99.99% purity.

Alexander Kochno: At first we had tested methods of inertial thermonuclear synthesis which are close to classical methods. But we tested in our own way. When we received results which did not fit forecasts, we started analyzing them. And we realized that we faced entirely different physical mechanisms. We started creating theoretical models, optimizing installation and came to what we see now through iterations.

We opened door to that process and a stream of absolutely new information flew out. We simply failed to analyze everything and had to rethink these things.

-So are there any preliminary conclusions available?

V.V.: The first is that these experiments were followed by short-term, but unbelievably powerful emissions – X-rays, gamma rays, light rays, etc. The second is the formation of new elements – both the entire spectrum of Mendeleev's periodic table and such super heavy elements that nobody had ever suspected their existence. These are transuranium and rare isotopes. There is an example – the most distributed isotope of iron is Fe-56. Its proportion of the total weight of iron amounts to approximately 92%. And there is a rare isotope called Fe-57. There is a small amount of it – almost 2.2%. This is the so-called "Mossbauer isotope" which is used in nuclear physics and metrology, and its market value is $10,000 dollars per gram because it is very difficult to split it from ordinary iron. So, during our experiments we got Fe-57 in higher quantities than Fe-56. Even in this single case one could start commercially feasible production.

As for the super heavy nuclei, it is known that until now the only elements with nucleic charges up to 116 were synthesized in the best laboratories of the world. Moreover, there were reports at recent physics conferences – one famous laboratory registered the formation of 4 nuclei with a charge of 116 and rough atomic weight of almost 280. A second famous laboratory synthesized 5 nuclei during a half-year period. We can synthesize transuranium elements in trillions of nuclei and the maximum rough atomic weight we have registered is almost 4,000 units. We suspect that nuclei with a rough atomic weight up to 100,000 were formed during our experiments. It is curious, but the possibility of the existence of such nuclei was forecast 30 years ago by academician Migdal.

Adamenko: The most amazing thing is that these super heavy nuclei are either stable or very long-lasting ones. By the way, you can note that the greatest dream for all thermonuclear laboratories in the world is to provide synthesis on the basis of nuclei lightest in weight – tritium and deuterium. The system of synthesis we have developed goes on with almost similar efficiency with any nucleus (including those classified as the iron group, which is impossible in principle in classical thermonuclear synthesis).

V.V.: Third are the streams of charged particles. These are ions with great energy, electrons, protons, deuterons, fast-moving plasma. There is an abnormally high number of protons. During each explosion, so to say, a small galaxy, a new world, is born. We get interesting confirmation of this fact. The distribution of chemical elements in the universe is known – what percentage of its weight belongs to hydrogen, helium, lithium and so on. There is a curve which was built with corresponding data. And the distribution of elements which happens as a result of our experiments nicely correlates with it, no matter what we put into the "oven" – on average the "ash" has the same content. This has been checked by many experiments. As for the energy of the particles, they have from 100 keV to 5-10 MeV for protons and deuterons. Besides that, we register great numbers of particles with energy levels of up to 1 GeV.

The fourth moment is applied deactivation. As a result of mini explosions the substance under radiation gets rid of such phenomenon as radioactivity. After collapse has occurred due to the impact on the sample, the substance loses its initial content. At a certain moment a "nuclear mix" forms, where atoms (in their general meaning) are located in the center of the core, while there are no electrons around them. And the same thing refers not only to light but also to any heavy nucleus. An almost uniform electron-proton-neutron mix is formed. This concoction serves as material for the

immediate formation of a new nucleus in another "package" and this new rebirth must be maximally stable. Unstable nuclei are simply not viable and they split immediately. And in case the substance was radioactive initially, then after the explosion the newly formed substance has no radioactivity at all!

So, this method may be used to utilize various wastes, and not only radioactive ones – any poisons, even the worst ones, could be transformed into safe substances and energy may be obtained as well if scientists will succeed in making them targets for nuclear collapse.

The fifth thing is external manifestations and testing effects. In our experiments we register huge quantities of various abnormalities. For instance, the material of the reactor walls absolutely changes its structure and pores are formed. Experts in nuclear reactor testing say that when comparing our substance with material which had worked in a reactor for 20 years, our substance showed more changes in structure.

Here one can develop theories and technologies for each paragraph. The field for further research and applications is boundless.

Soccer Ball Sized Reactor

- Here is a pragmatic question – how could the effects you have discovered be used in practice?

V.V.: The easiest way is to use them to deactivate radioactive waste. Chernobyl has shown that this is a critical question. In November I was in Las Vegas attending a conference dedicated to the prospects for nuclear industrial waste. The conference was held by IAEA. Each country reported what it could do in the sphere of processed nuclear fuel elimination. Nothing new was offered – waste is still buried. Americans and Japanese are trying to develop huge proton accelerators for getting neutrons which they will use to emit at waste in hopes that as a result they will get a less radioactive substance. The first experimental installation will be built in the middle of the century. Now hundreds of million dollars are already being spent annually. Russia ,China and other countries chose the same way. Even if they are successful they will not have the ultimate utilization of fuel. Neutrons processing some types of radioactive waste will stimulate the formation of other types of waste. That means the market for our installation is wide open. However, we have many problems and we need corresponding solutions.

-Is it realistic to get electricity with the help of your installation? How can your explosion be harnessed to generate electricity?

V.V.: We may choose different paths. Each observed process – emissions, streams of particles and external effects may be potentially used for this. One should calculate which option will be the optimal one. The primitive way is to transform energy from the collapse into heat, then create vapor with heat and use it to rotate the turbines of a generator. Maybe it would be more useful to employ magnetic-hydrodynamic generators. They look like ordinary generators which produce current at the moment when conductors cross a magnetic field. Everything works in principle and can be calculated. But we have not yet come to a solution for providing our own laboratory with its own light. Now we are conducting experiments in order to understand the essence of the processes. And the main thing is to install different targets each time, to reach a vacuum, to measure all parameters, to shoot, measure everything again, to disassemble the installation, to replace the target and so on.

For efficient production of electricity the system must be automatic – it should make not one shot an hour, but, say, one or ten per second. The automatic supply of a target rod, the receipt of energy – all these are serious technological problems which should be solved first.

An approximate calculation shows that when using targets with different dimensions at 10 shots per second with a performance factor of 10%, one may hope to get 100 megajoules per second. The capacity of such an installation will practically replace a 100 MW power unit! But we have no limits, say, for increasing its capacity by 10 times and that would equal the standard capacity of a reactor at Chernobyl . Anything could be used as fuel – copper, silica and even water. And there will be no radioactivity either before, or after!

-And what do you think the approximate dimensions of such a reactor would be?

A.K.: The machine itself may be relatively small. The reactor will not be larger than table. So, in the future there will be no need to construct huge power stations. They would be compact and be easily delivered to any necessary place. However, I would like to say again – there are many technical problems and their solution will take several years.

-And what about the safety of your small bomb? Could it be used by terrorists, for instance?

V.V.: These processes are small and they could not be used to produce a great explosion. Moreover, the explosion is always directed inward.

-But as a result you obtain an outside explosion! And could this mini nuclear explosion trigger a reaction which may result in the collapse of the surrounding world?

V.V.: No! The explosion is always limited by the target which the beam is aimed at, and the entire process is going on only inside the target. Only nuclear fission products come outside and they could not trigger repetitive explosions.

A.K.: And in order to conduct a relatively serious explosion one should launch the process at a target which has dimensions of at least 1 centimeter. According to our estimates, that is not possible. One could not create a pocket-sized atomic bomb based on this effect.

The Black Hole as an Experimental Artifact

A.K.: Now we are talking about things which make ordinary physicists speechless and the existence of super heavy elements an axiom for us.

And we had a lot of such cases – after our experiments we gave our samples to other organizations and asked them to check them with their equipment. And we did not tell them what these samples were. They brought us reports and in a couple of months they admitted that they had no idea how such results might be registered, for instance during spectrographic examinations with lines which are impossible for these elements. "This is not according to textbooks!" they said. They overhauled equipment, tuned it, looked for malfunctions and obtained the same results. We told them how we got these samples and they replied: "So, why didn't you tell us!" We explained that we did it to keep the experiments pure.

But we have some things which could not be explained, for instance, "black holes."

-???

A.K.: They do not "light up" under any light.

Adamenko: There are various methods of to analyze substances. One is radiation by a beam of ions and registering reflected signals. We tore secondary ions away from bombarded substances and analyzed them. And after an explosion we saw how local sections (20-50 microns) appeared on a screen. They reflected nothing no matter how hard you bombarded them with ions. Not only did these smashed out particles of screen refuse to fly, but even primary ions did not return. These are regions which absorb absolutely everything, in any range of weight! Just imagine, you shoot a handgun and the bullets simply disappear. They are not reflected and they do not pass through. And moreover, the process of absorption has no visible manifestations. This could not happen according to the laws of classical physics. We gave this effect a temporary name – "black holes." We suppose these places contain the nucleus of some super heavy element which has "not grown yet" till its reaches its limits. A so -called "dump pit ."We spent more time bombarding these sections (up to half an hour), and only then did these "black holes" start to return some part of the ions. Probably, saturation had occurred. These are interesting subjects of study.

There is another assumption connected with these sections and it refers to cosmology. It is known that there is a great quantity of "dark" matter in the universe, and it cannot be detected by ordinary tools. It is possible that the "black

holes" we observed are part of this matter. It may be made of the nuclei of super heavy elements.

Ukraine Patents 'Eternal Engine'

-Is your method registered? Have you received any patents for it? What are the results of experiments published in scientific magazines?

A.K.: The patent is already given in Ukraine , and our claim is in different stages of registration in Europe, the U.S. and Asia . The international application PCT/UA2003/000015 for a patent was accepted on May 19, 2003 , with priority dated 14.08.02. We reported our findings at approximately 15 international conferences and published several articles in serious scientific magazines. Did they shout "hurray" or not? They did not shout, but they did not condemn our findings either. Now they are keeping silent, trying to overthrow our data. But the very fact that two theoretical articles totaling 60 pages were published in leading physics journals Foundation of Physics Letters and Foundation of Physics speaks for itself.

-Several years ago scientific circles widely discussed the theory of so-called "cold fusion." And coverage ranged well beyond scientific circles. However, supporters of the theory have failed to provide confirmation yet. I should note that your work has many similarities with this theory.

V.V.: What is general to both cases is that here one can observe processes which are going on under relatively low energy when in general they should not exist, as well as the formation of new elements. There is a difference in approaches and theories which describe these processes. We managed to create an installation which gives real results which can be reproduced with 100% certainty, while the theory of cold fusion cannot do that. The increase in energy emitted during the reaction is at the level of statistical mistakes in experiments. Yet we have increases of many thousands of percent.

-How well are your results documented?

A.K.: We have conducted almost 10,000 experiments and they were carefully documented. All targets were weighed and measured before and after bombardment. All conditions were registered – target content and screen material with an accuracy up to 4-5 digits after the decimal point. We conducted chemical characteristics of electron beams, and spectral and other analyses. We have made more than 20,000 analyses already. All targets are stored safely in their own numbered slots. They may be taken out, measured once more and we may find parameters which we had not thoroughly examined during the first analysis. Each day we receive up to 10 new samples and we simply have no time for proper analysis, leaving them for the time being. All data are entered into a database which is adjusted to conduct various correlations and calculations. We may take a necessary sample, cut a piece away from it and pass it to somebody for a control check. We have no situations in which we conducted an experiment, measured and obtained results, and the sample disappeared and we could not confirm what we had found. That could not happen. We welcome scientists from all over the world – let them come, analyze and discuss. We are ready.

Stanislav Adamenko, the science head of the Proton-21 laboratory

218) My dilemma -- to do or not to do it?

Ludwik Kowalski (5/6/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This morning I receive a message from a stranger, Walter. He wrote:

> "Oriani counted very dark tracks only" It is important to know
> whether "very dark" tracks were counted in a double-blind
> manner. Otherwise the experimenter can unconsciously --
> and innocently! -- bias the results towards what was expected.
> I.e., "very dark" might actually have to be darker for the control
> experiments. Best if the counting can be done automatically,
> e.g., by image-processing software.

I asked for the advice about the image-processing software but Walter said that it was only a general comment and that he never used such software. But his comment is highly appropriate for a situation in which the signal to noise ratio is as small as described in unit #210. The only way to decide if the signal is real (that is to decide if alpha-like particles are really emitted from the cathode) is to use photos, as described by Oriani at ICCF10. Walter's message reminded me that I wanted to use this method; here is my reply to him:

> After the first etching I will take numerous photos of the entire
> surface. This will identify "old" tracks not by their sizes or darkness
> but by their positions (with respect to recognizable scratched lines).
>The same will be done after the second etching. "New" tracks will
> thus be identified unambiguously by comparing the photos "before"
> with the photos "after."

Should I start this work right now or should I wait? I am hesitating because I know how much work is involved in photographing ten surfaces. At the minimum magnification of my microscope each photo covers the area of only 1.3 mm by 0.9 mm. Each of my CR-39 chips has the area of about 1 cm2. That implies about ~100 pictures per surface. With ten surfaces (5 for control chips and 5 for treatments) I must study about 1000 pictures. That is not trivial. Assuming I use the same exposure times (24 hours), and the same counting geometry (chips are ~5 mm away from the cathode) as Richard, I should expect, on the average, 33.6 alpha tracks per surface. This translates into about one track per 30 photos.

The purpose was to produce a simple method by which students and teachers can convince themselves about reality of nuclear particles due to a chemical process. To be useful the experiment should be feasible in three to four hours. Suppose that the rate of emission is ten times larger than what was reported by Oriani. In that case the expected number of tracks would 336 per surface. No photography, and no detailed statistical analysis, would be necessary to see that the effect is real. At the minimum magnification of my microscope the field of view has the diameter of about 5 mm. This would allow to count tracks at the rate of several minutes per surface. But now Oriani is in a situation in which photography is a must, as far as track detectors are concerned. This is not for students and teachers. In a week or two Oriani, and a nuclear physicist from the University of Minnesota, will start exploring the phenomenon with a

silicon detector. I should wait for their preliminary results before deciding what to do next. The silicon detector, if the background can be lowered, as in Jones' laboratory, seems to be (?) more appropriate than CR-39 for very low emission rates. But lowering the background might not be trivial; it calls for a set of good veto detectors.

219) Post-workshop comments

Ludwik Kowalski (5/10/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

There was an interesting workshop at Stevens Institute of Technology last week. The title was “The Applied Science Problem;” I am grateful to a neighbor, Dr. Mary Ann Hellrigel, for inviting me. It was a gathering of about forty scientists, historians of science and students. Most contributions were very interesting and stimulating. Cold fusion was not mentioned but I think that most participants would be interested in it. The essay below was e-mailed to them after the workshop.

Protoscience, pseudoscience, etc.

Ludwik Kowalski
Professor of Physics, retired
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043
<kowalskil@mail.montclair.edu>

After hearing about complex relations (linear and nonlinear) between science, applied science and technology, I would like to comment on pseudoscience and protoscience. In the linear model protoscience precedes science; it may lead to science or to pseudoscience. Someone mentioned that at least 95% of scientific publications describe research based on previous investigations. But each identifiable thread has a beginning, a seminal publication or a patent. It describes a discovery that was made, in one way or another, without an obvious connection with other studies. In science it may be a discovery of a new phenomenon, such as the piezoelectric effect; in technology it may be a gadget, or a new material. Subsequent accumulation of knowledge follows in a brick-by-brick fashion.

How are seminal contributions made? What do they have in common with other kinds of intellectual creativity, such as music, visual arts or poetry? That is a big topic and I do not want to deal with it. I am mentioning “seminal contributions” to define protoscience. A seminal contribution that has not yet been validated belongs to the realm of protoscience. The ways of validating scientific claims are based on additional explorations. The process of validation may be fast or slow. A topic becomes scientific when claims are confirmed by several recognized scientists. The process is gradual and no sharp boundary exists between protoscience and science.

But a boundary between science and pseudoscience is usually well defined. Pseudoscience, such as astrology, differs from science, such as observational astronomy, by the way in which claims are validated. Pseudoscientists only pretend to be scientists, sometimes to benefit from it materially, sometimes to satisfy their psychological needs. A large number of examples can be found in a book entitled Voodoo Science (1). Scientific error, says Robert Park, "has a way of evolving ... from self-delusion to fraud. I use the term voodoo science to cover them all: pathological science, junk science, pseudoscience, and fraudulent science. In pathological science, scientists fool themselves. Junk science refers to scientists who use their expertise to befuddle and mislead others . . . Pseudoscience has the trappings of science without any evidence. Fraudulent science is, well, fraud--old-fashioned lying.”

The author, however, was not able to recognize “cold fusion” as protoscience. I would like to focus on this point

becaus the cold fusion episode, in my opinion, will be remembered as an interesting aberration in the sociology of science. This will happen regardless of how the scientific controversy, begun in 1989, will be resolved. The major proponents of cold fusion were recognized authorities in their disciplines. Some of them, now in their sixties and seventies, have been conducting research in the field for more than 15 years. As far as I know (from reading their papers and from attending conferences) their ways of validating claims are not different from those in various areas of recognized science. How was it possible, our descendants will ask, that such people were treated in the same way as pseudoscientists? How was it possible that their publications were often rejected by editors of mainstream journals and that financial support was not available to them as easily as in other areas of "pure science?"

I have been studying cold fusion for more than two years, not only as an observer but also as a researcher. This is reflected in over two hundred items posted on my website (2) dedicated to the subject. Experiments in which I participated did not provide a clear and undeniable confirmation of claims in which I was interested. The biggest problem was absence of reproducibility. But that does not mean that cold fusion research is pseudoscientific. Irreproducibility is an indicator that researchers are not aware of major influences. Electrostatic demonstrations were also highly unreliable untill the role of ambient humidity was recognized. Science is highly bureaucratic today and many think that nonscientific factors, such as competition for limited financial resources, have played an important role in the shaping of attitude toward cold fusion researchers (3). Historians of science have a unique opportunity to study cold fusion, as suggested, for example, in (4). Do not miss an opportunity to interview major cold fusion players; it may no longer be available in several years.

Fraudulent con artists (pseudoscientists) described by Park are usually people without recognized credentials. Cold fusion protoscientists, on the other hand, at least those I met at two conferences, have excellent academic credentials. I suspect that the controversy surrounding cold fusion attracts con artists and charlatans. But such an assertion is difficult to prove. More obvious is the fact that people working in different areas of protoscience tend to attract each other. I do not know, for example, what the so-called "zero point energy" field (5) has in common with cold fusion. But research reports in that field can often be found in journals and magazines devoted to cold fusion (6,7,8). Likewise, research on hydrinos -- atoms of hydrogen "excited" to presumably-existing states below the ground states -- and on perpetual motion devices, can be seen intermixed with cold fusion papers. My definition of cold fusion, described in (9), focuses on a correlation between a chemical process, such as electrolysis, and a nuclear process, such as emission of alpha particles.

Sometimes people say that experimental validation of cold fusion would inevitably result in "paradigm shifting." I do not take this for granted. Many investigators try to understand cold fusion in terms of new theoretical models. But, as far as I know, their models are not able to identify conditions under which cold fusion anomalies (chemically induced nuclear reactions) become reproducible. Who said that the existing paradigm (the arsenal of existing models) will not be able to make sense out of reported experimental observations? On the other hand, how can a theory be validated when experimental data are not reproducible? The phrase "theories guide but experiments decide" describes the essence of scientific methodology. It implies that making cold fusion reproducible is a precondition of possible evolution from cold fusion protoscience to cold fusion science.

And here is my last question. How long can an area of research remain protoscientific without becoming pseudoscientific, by default? Yes, I know that asking questions is much easier than answering them. The main point is that the questions I am asking here belong to the sociology of science; they do not belong to science per se. I will end with a quote from wikipedia, an editable encyclopedia of science on the Internet (10). The description of cold fusion one finds there is worth reading. But keep in mind that anybody can change anything in wikipedia at any time. I can not be sure that what you will read there will be the same as I read several weeks ago.

" 1) A pseudoscience is any body of knowledge purporting to be either both factual and scientific, or of an even higher standard of knowledge, but which fails to comply with scientific method. Motivations for the advocacy or promotion of pseudoscience range from simple naivety about the nature of science or of the scientific method, to deliberate deception for financial or other benefit. Some people consider some or all forms of pseudoscience to be harmless entertainment. Others, . . .consider all forms of pseudoscience to be harmful, whether or not they result in immediate harm to their followers.

2) Pseudoscience is distinguishable from revelation, theology or spirituality in that it claims to offer insight into the physical world by "scientific" means (i.e., most usually in accordance with the scientific method). Systems of thought that rely upon "divine" or "inspired" knowledge are not considered pseudoscience if they do not claim to be scientific or to overturn well established science.

3) Pseudoscience also differs from protoscience . The latter may be defined as speculation or hypothesis which has not yet been tested adequately by the scientific method, but which is otherwise consisent with existing science or which, where inconsistent, offers reasonable account of the inconsistency. Pseudoscience, in contrast, is characteristically wanting adequate tests or the possibility of them, occasionally untestable in principle, and its supporters are frequently strident in insisting that existing scientific results are wrong.

4) The boundaries between pseudoscience, protoscience, and "real" science are often unclear to non-specialist observers. They can even be obscure to experts. Many people have tried to offer objective criteria for the term, with mixed success. Often the term is used simply as a pejorative to express the speaker's low opinion of a given field, regardless of any objective measures.

5) After more than a century of active dialogue, the question of what marks the boundary of science remains fundamentally unsettled. As a consequence the issue of what constitutes pseudoscience continues to be controversial. . . . Examples of fields of endeavor that many consider – to varying extents – pseudoscientific include Cold fusion, Pseudoarchaeology, Gene Ray 's Time Cube, astrology and homeopathy.

6) There are also young fields of science that are sometimes frowned upon by scientists from established fields, primarily because they are speculative in nature. [For example]: (a) exobiology /astrobiology, (b) Search for Extraterrestrial Intelligence (SETI) and (c) Communication with Extraterrestrial Intelligence (CETI). These fields are not considered pseudoscientific or protoscientific by most scientists, though, and they are studied at many universities and specialized institutes."

Please share your comments about cold fusion and other social topics associated with it. My e-mail address appears above. Information about ongoing cold fusion events can be found at (11).

220) Two cold fusion workshops and conferences

Ludwik Kowalski (5/13/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

It is remarkable that two cold fusion workshops are going to take place nearly simultaneously this month. One, organized by ISCMNS (International Society for Condense Matter Nuclear Science), is starting today in Siena, Italy, and another will start at MIT, Boston, next week. The Boston workshop is dedicated to Eugene Malove, "Cold Fusioneer, Investigator and MIT Graduate '69." Two cold fusion conferences will also take place this year:

1) The 12th International Conference on Condensed Matter Nuclear Science (ICCF12) in Japan
2) The 13th Russian Conference on Cold Nuclear Transmutation of Chemical Elements and Ball-Lightning (RCCNT&BL-13)

Here is the agenda of the MIT workshop (May 21, 2005):

Experimental Reports of Cold Fusion Systems (A.M.):
1) Mitchell Swartz - Introduction
2) David Nagel - Evidence That Cold Fusion Involves Nuclear Reactions
3) John Dash - Characterization of Titanium Cathodes after Electrolysis in Heavy Water
4) Peter Hagelstein - Cold Fusion
5) Mitchell Swartz - Parameter to Describe Optimal Operating Point Width

Theoretical Strides in Understanding of Cold Fusion Systems (P.M.):
6) Yeong Kim - Mico/Nano High-Desity Plasmas and Cold Fusion/Acoustic-Induced Cold Fusion
7) Talbot Chubb - Bloch Nuclei and Phonon De-excitation
8) Scott Chubb - Understanding Cold Fusion using Conventional Condensed matter Physics
9) Robert Bass - Do Current Concepts Resolve the Chief Challenge to Cold Fusion Theory?
10) Keith Johnson - Anomalous Superconducting Properties of the PdHx/PdDx System and their Possible Relationship to Cold Fusion
11) Mitchell Swartz - Absence of Bremsstrahlung is Consistent with Conventional Physics
12) Group Discussion
13) Robert Rines - Patents and Science from Cold Fusion and Other Fields
14) Peter Graneau - Alternative Energy using Latent Energy of Water
15) Ken Shoulders - Charge Clusters and the Hutchinson Effect

Poster presentations, not yet listed, will also be displayed. Responding to the suggestion made by Mitchell Swartz I prepared a poster presentation shown below. I will refer to it in the group discussion; perhaps my answers will generate some interesting comments.

Short questions and answers

1) What is Cold Fusion (CF)?
It is not pseudoscience, as many think. It is protoscience claiming that nuclear activities result from some chemical (atomic) processes (for example, in electrolysis, or when hydrogen ions diffuse through some solids).

2) Why was “excess heat” not mentioned in the above answer?
Convincing others that excess heat (generated at the rate of one watt or less) has a nuclear origin is much more difficult than validating a nuclear signature, such as neutrons, protons or alpha particles. The essence of the controversy is not the excess heat; it is the nuclear origin of that heat.

3) Why hasn’t a single truly-reproducible setup been offered (in 16 years) by the CF community to demonstrate a nuclear effect caused by a chemical process?
Because CF research (at least 100 people in several countries) is not coordinated.

4) Why don’t CF researchers criticize each other?
They probably feel "we are surrounded by enemies; mutual criticism would only weaken our fortress."

5) What is experimental protoscience?
Any new claim made by a qualified experimental scientist belongs to protoscience unless it is independently validated in at least three different laboratories.

6) How long can protoscience exist before turning into pseudoscience?
In the case of CF the controversy has not been resolved in 16 years. Unless recognized by the scientific establishment, CF might be universally perceived as pseudoscince in about ten or twenty years.

7) Why twenty years?
Because nearly all CF researchers are old.

See my CF website at <http://csam.montclair.edu/~kowalski/cf/>
Comments will be appreciated.

222) The majority of nature's treasures are still hidden

Ludwik Kowalski (5/17/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Three days ago I received a thank-you note from a person who read some of my units. Replying to this note I made a specific suggestion and I asked a general question about cold fusion. The answer was interesting and worth sharing. It is an example of healthy attitude toward science in general and toward cold fusion in particular. **Tom Benson wrote:**

"Thanks for the reply. Let me answer your questions in reverse order. No, cold fusion isn't my full-time occupation. I have a job as a marketing director for a large software firm. I do cold fusion work just for the scientific pleasure of it, I suppose, the joy of hunting for a hidden, fundamental physical process, which is very controversial and therefore even more of an adventure.

I have very much enjoyed reading your website and some of the 'motivation' type posts, so if you don't mind, let me relate to you my own motivation. I loved science as a kid. I grew up in one of those post-WWII science towns, where everyone on the block was a nuclear engineer or scientist. Seaborg and Fermi and Rutherford were heroes, and the idea of being some part of a similar discovery, however small a part, was something to dream about. But instead of science I ended up starting a software firm, going the silicon valley route -- very satisfying in many ways but you know how it is, there were always some regrets not doing science.

Anyway, a couple years after cold fusion was announced, I decided to work on it. It seemed an opportunity to do real, old-fashioned science, the opportunity to do something truly novel. The longest of long shots of course, but I had no reputation at risk, and since other more established scientists couldn't risk their reputations (and who could blame them?) then it was left as an opportunity for an amateur like me.

I felt cold fusion was possible (even if a long shot) because I had read a quote by one of the disbelievers. He said 'If cold fusion existed, we would have seen it decades ago.' That seemed completely backwards. If you know the history of the nuclear science, and if you know about the experiments done to chart the cross-sections and energies all of the hundreds of various nuclear fusion and fission reactions -- it was the fundamental nature of those experiments that, if they were triggering a cold fusion type reaction, or even if cold fusion existed in nature, it would NOT have been seen. By definition, cold fusion reactions, if they indeed exist, are reactions that only produce alpha particles and heat, and they only happen when deeply buried in a condensed matrix. So, by definition, they never produce ionizing radiation that would escape to be detected, and therefore they never produce a signature that would be detected by the equipment that nuclear scientists had been using for the past 100 years.

That was intriguing -- the realization that there WAS a blind spot in the nuclear world, and cold fusion just coincidentally fell right in that blind spot. It was a tenuous link but compelling. It made me think; well, there could be hundreds, or thousands of other types of nuclear reactions, a whole universe of reactions, happening all the time, right beneath our feet. But if they don't produce ionizing radiation, or enough energy to see easily, then how would we know? We can't see them. This is one of the most interesting things about science, how much you can miss even in years of hard study.

I also had seen a real-life example: Fullerenes [carbon molecules, such as C60]. For a hundred years, in universities all over the world, hundreds of thousands of skilled organic chemists had been studying carbon. It was one of the most

carefully studied, profitable branches of science ever; and in that time spent, they simply missed an entire class of carbon molecules, which existed in nature all the time, in every bit of smoke from a match. And now these new structures are proving to be one of the most valuable compounds in the history of science. This reminds us that the majority of nature's treasures are still hidden, perhaps right in front of our eyes. If it can happen for organic chemistry, why not nuclear physics?

The second big 'aha' was hearing Fleischmann speak, at an early conference, about the fact that the original experiment he and Pons conducted was actually designed to test a decade or more of theoretical work they had done. Their interpretation of QED let them to question whether deuterium ions, compressed tremendously inside a matrix, might spontaneously fuse in a very unusual fashion. So they did an experiment to test this hypothesis -- the original Pons-Fleischmann experiments. The result they got confirmed their hypothesis. This is classic, pure science, the kind we read about in textbooks. Very nice, aggressive, science. So when I read the opposition calling their experiments 'junk science' and 'crap' and other smear campaign-type words, I was irritated. It was highly inappropriate.

On the other hand, I can't presume to say the effect is proven. It requires much, much more evidence. It is also true that many of the experiments are very poorly done and not double-checked. But that says absolutely nothing about the existence or nonexistence of the underlying physics - it's simply the result of the fact that cold fusion experimenters are all doing work on pennies, using old scrounged equipment . . . Thanks again for your response, and sorry about the long-winded reply."

223) Karabut's papers

Ludwik Kowalski (18/5/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Alexander Karabut, whose earlier publication (see item #13) triggered my interest in cold fusion, sent me two posters for the incoming MIT colloquium. He also sent me two corresponding papers in Russian.

Click to see his Paper 1 in English (awkward in some places)
or in Russian.
Click to see his Paper 2 in English (awkward in some places)
or in Russian.

A quick comparison shows that some sentences found in the English paper, do not appear in the corresponding Russian paper, and vice versa. The impression is that English papers are more recent.

In the first paper I read that the excess heats was generated at the rates of up to 10-15 W, and that the efficiency was 150%. That is much more that 10% efficiency reported by Kar abut in unit #13. My understanding of 150% is that for every 100 J of electric energy supplied to the glow discharge tube the amount of heat generated is 250 J. (150 J of ecxcess heat). But I am not sure of that this is a correct interpretation; perhaps the amount of heat generated is 150J rather than 250J. According to my definition, this would be 50% efficiency, not 150%. But even 50% is impressive.

The highest excess power on Figure 3 is about 8 W; most data points indicate excess powers from 1 to 4 watts. Presumabaly efficiencies in the range from 10 to15 W were recorded at input powers higher than 20 W. Reading the paper carefully I was not able to find a protocol for the high efficiency. The only indication was high voltages (1000-1400 V) applied in the form of short pulses (much shorter than intervals between pulses). Can one say that this is a supervave of some unspecified fundamental frequency?

Another interesting result, also reported in init #13, is nuclear alchemy; many new chemical elements were accumulated in the cathode when excess heat was generated. The estimated rate of transmutation is reported as 10^{13} atoms per seconds. Is this enough to explain the excess heat? Suppose that, on the average, production of one atom is associated with the release of 5 MeV of heat. This would generate heat at the rate of $5*10^{13}$ MeV/s, or 8 W. The order of magnitude seems to be consistent with the actually measured excess heat power.

The second paper focuses on generation of X rays; the subject that is also mentioned in the first paper. The rays were studied, using many different cathodes, when the current was 500 mA and the voltages were in the range of 500 to 2500 V. That translates into a lot of input power; more that 1000 W, at the extreme. At the efficiency of the excess heat generation of 150% that would generate 1500 Joules of abnormal heat each second -- enough to bring one liter of water to the boiling point in about three minutes (starting at room temperature). But such exp ¡ectation is incorrect because the applied voltage was not constant. The 1000 W is the momentary power during each pulse; it is not a constant power. Durations of current pulses were between 0.27 and 10 microseconds. and periods of repetition were between 1 and 100 microseconds. Two kinds of X rays were identified:

a) multidirectional (diffused, up to $5*10^5$ bursts per second with up to 10^6 photons per burst.)

b) laser-like beams of short duration (up to 10 beams per second and up to 10 photons per beam.) Emission of laser-like beams takes place not only when the current is flowing but also up to 100 microseconds after the current is turned off. Lasing implies presence of reversed populations of metastable energy levels presumably created by deuterium ions bombarding the cathode.

Soft X-rays (photons whose energies are in the range of 1.2 to 3 keV) are referred as primary penetrating radition. Secondary radiation, presumably resulting from interactions of primary photons with cathodes, were also identified. One of these components is said to be able to penetrate 5 mm of steel. In the second paper the new technology of creating laser beams is characterized as 100% reproducible. Nothing, however, was said (in the first paper) about the reproducibility of generation of excess heat and transmutation products. I suppose that Karabut believes that the 150% efficiency is 100% reproducible. Otherwise his conclusion, at the end of the first paper, would be questionable. The conclusion is that building a new nuclear device is now possible. That device, a cube of 20 cm, powered be electric energy at the rate of 10kW, will generate excess heat at the rate of 15 KW. The main conclusion of the second paper is a possibility of building a solid-state X-ray laser. It will produce powerful pulses of radiation (10 MW) lasting 10^{-11} to 10^{-13} seconds.

Appended 5/19/05:
I am now aware of three independent cold fusion groups working with glow discharge chambers: that of Karabut (also see unit #13), that of Arik (see unit #213), and that of Tom Passell (the paper can be downloaded from the library at www.lenr-canr.org) All three are interested in excess heat. A device generating 10+15=25 kW of heat (10 kW from the electric energy supplied and 15 kW from cold fusion) is not yet a large power plant. But its 100% reliable operation would promote research on a much larger scale.

What would I do if I were a researcher able to build a device generating nuclear energy via excess heat at the efficiency of 150%? I would also try to publicize my work, as Karabut does. But instead of writing about many things (different cathodes, different gasses, different waveforms, different instruments, etc.) I would focus on what has been the most reliable and the most promising. I would describe my protocol as clearly as possible; I would provide other researchers with details needed to replicate my results. Yes, I know that this would be in conflict with desires to benefit financially from being the first in new technology. At my age I would not worry about this but I can understand those for whom commercial success is important. I do not know how to resolve conflicts between personal and general benefits. But the issue is certainly not new; Karabut is not the first scientist claiming to invent something useful. The e-mail message he sent me ends with this sentence. “I take an interest about an grant of a research work.” Will he find a grant in Russia? Will he find it in another country? It depends not only on him; it depends on success of others. The progress he made at the research laboratory Lutch, during the last three years, -- a jump from the 10% efficiency to the 150% efficiency -- is spectacular.

P.S. (5/20/05): 1) The term efficiency, (k.p.d. in Russian), in the context of an excess heat paper, can mean two different things:

a) (Thermal energy generated) / (Electric energy supplied)
b) (Excess heat generated) / (Electric energy supplied)

In my mind efficiency is (desirable output)/(input). That is why I assumed that the 150% refers to (b). But that assumption might be wrong. The excess heat would be much smaller if 150% referred to (a) rather than to (b).

2) If efficiency is defined as (a) then 100% would mean no excess heat at all. And 10% efficiency would mean that 90% of electric energy is converted into a form of energy other than heat, for example light or mechanical energy or chemical energy.

If efficiency is defined as (b) then 100% would mean that the amount of excess heat is equal to the amount of electric energy supplied. In my opinion (b) is more appropriate than (a). The k.p.d., by the way, translates as "coefficient of useful action." The useful thing, in cold fusion devices, is excess heat.

224 The MIT colloquium

Ludwik Kowalski (5/22/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The moderator of this gathering was Dr. Mitchell Swartz, a veteran cold fusion researcher. His doctoral dissertation at MIT, I was told, was in electrochemistry. He is also a medical doctor specializing in oncology. Here is how this one-day colloquium (5/21/05) was described over the Internet: "Cold Fusion - Science and Technology - plus other Clean Energy Investigations, with Special Tribute to Dr. Eugene Mallove, '69, Cold Fusion Investigator and former Chief Science Writer at MIT. Topics include: Science and Engineering; Discussions of Cold Fusion Materials Science; Review of Current Literature; Experimental Results; Understandings of Theories; Device Engineering; Discussion of Future Developments and Commercialization Potentials. Remembrances of Gene Mallove by family, friends and colleagues. Lunch included in conference fees. Free for MIT Students."

The number of participants was about 60 (my own counting); 15% of them, I was told, were students. The meeting was organized by E-club -- the MIT Entrepreneurs Club. It is an organization sponsoring workshops devoted to all aspects of science and technology. They meet weekly. The event organizer, Dr. Richard Shyndurоff, told me that the colloquium had two purposes; to commemorate Eugene, killed one year ago, and to expose interested students to the controversial field of cold fission.

The first speaker was David Nagel - the topic of his presentation was "Evidence that cold fusion involves nuclear reactions." It was a general review of results on production of helium, tritium, neutrons, new elements, and x-rays. He emphasized that formation of craters and hot spo ⁄ts on cathode surfaces (using scanning electron microscopes) should also be viewed as nuclear signatures. The second presenter was Ross George; his topic was "Acoustic-induced Cold Fusion Experiments." Ross has a company <html:/www.d2fusion.com> conducting practically-oriented research in cold fusion. He described experiments in which generation of excess heat was shown to be accompanied by the accumulation of helium (up to levels exceeding natural concentration in air). Some of his recent sonofusion experiments, generated excess heat at the level of hundreds of watts.

The third and fourth speakers were John Dash (from the University of Portland) and Peter Hagelstein (from MIT). Peter is a theoretical physicist; he said that about 150 different reaction mechanisms have been proposed, in fifteen years, to model cold fusion. In his opinion not a single theory emerged as "much better than others." John, who is a metallurgist, was describing results of his experimental investigations in the area of nuclear alchemy. Using the secondary ions mass spectroscopy method (SIMS) he was able to identify several transmutation products. He also reported on changes in isotopic ratios but these were results from literature, not from his own investigations. Kim Yeoung, Tabot Chub, Scott Chub, Robert Bass and Keith Johnson also talked about theoretical aspects of cold fusion.

Mitch Swartz talked about the electrochemical cell called Phusor. Mitch Swartz talked about the electrochemical cell called Phusor. The electrolyte used in this cell has a very low concentration. For that reason the input power is only several watts then the applied voltage is thousand volts. The highest rate of excess heat generation, according to rapidly displayed transparencies, was 3.5 watts. During the break I heard people saying that the device is now commercially available; potential users are schools willing to teach cold fusion. The most interesting part of Swartz's presentation was his discovery (already described at ICCF10) of the optimal input power. Mitch is convinced that high current (and thus intensive bubbling) is harmful. In his cells the current is very small and single bubbles on the surface of the cathode grow very slowly. But practically useful excess heat implies large output power; how can high output power be produced with a device of low input power?

The last presentation that I attended was that of Ken Shoulders. That item, entitled “EOVs and Hutchinson Effect,” can be downloaded, as a pdf file, from Ken’s website at <http://www.svn.net/krscfs/>. The presentation had three parts. The first was about Hutchinson Effect (shredding metallic structures without heat and with practically no mechanical force), the second was about the Ukrainian project of S.V. Adamenko (see unit # 217), and the third was about his own device -- the EV reactor and cylindrical mass spectrometer. Unfortunately, the amount of time devoted to the third part was very limited. The speaker before Ken was Robert Rines, the MIT patent counselor. He reminded the audience that “in old days” a patent would not be given to an inventor unless a working model were presented. That is no longer required. Then he elaborated on difficulties that patent investigators have in dealing with cold fusion claims.

226) Reading a strange patent description

Ludwik Kowalski (6/2/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This unit is the continuation of what was in unit #216. It describes a strange initiative. I plan to follow that initiative because I believe that long-lasting commercial success is as important as reproducible experiments in science. How to separate hydrogen from water? By relying on electrolysis, or on thermal decomposition. But these methods are not economically effective ways to produce a fuel. A presumably effective method was patented by Hyunik Yang and Alexander Koldamasov. A description of their Korean patent can be downloaded from www.delphion.com The text is in English but the translation is far from being good. Information appearing on the first page is shown below.

* *
The International PCT Publication Number is: WO2004/041715 A1
The title is: "APPARATUS FOR GENERATING HYDROGEN GAS"
The first inventor is: Yang, Hyun-Ik
The second inventor is: Koldamasov, Alexander Ivanovich
The initial publication date is: 21 May 2004 (21.05.2004)
The priority data is: 10-2002-0069231
* *

1) In the abstract I read that the apparatus uses highly purified water under “predetermined pressure.” The water flows through an narrow opening in the implant made from a dielectric material. I do not understand how high voltage impulses are generated in the implant by “cavitation emission” and how hydrogen atoms are separated from oxygen atoms. But I do know that separation of atoms is an endothermic process. What kind of energy is used to separate atoms? The authors refer to ions (which are magnetically separated) but the nature of ions is not clear to me. Do they refer to ionized molecules of water or do they refer to ions of hydrogen and oxygen?

2) Later I see that the dielectric material must have “tolerance to a cavitation emission phenomenon generated inside of the body.” I know that cavitation consists of formation of bubbles in a liquid. But what is “cavitation emission?” What is being emitted by what?

3) On page 4 I see a reference to “magnetic bodies.” Are these bodies magnetic monopoles? How else can I understand the following sentence? “Herein, magnetic bodies are formed at lateral sides of the channel such as a North pole of a group of the manetic bodies and a South pole of another group of the magnetic bodies face with each other.” How are H and OH ions, mentioned on that page, separated? What material is the “catalytic plate” made of? Would the answers be obvious to me if I were a chemist?

4) On page 6 I see a reference to a “high pressure wave.” But I do not understand the nature of that wave. The author writes: “Because of the high pressure wave, there are created fine cracks on the inner walls of the passage slot of the dielectric implant. Electrons are emitted from the fine cracks due to a property of the material used in the inner walls, i.e., the property that easily resulting in the cavitation emission phenomenon. The emitted electrons are dispersed within the operation fluid, thereby resulting in the Vavilov-Cheronkov effect.” I know that Cherenkov radiation consists of light emitted when the speed of electrons is higher than the speed of light in that medium. How are electrons accelerated to emit light? One thing is clear; a patent description is not a pedagogically written textbook.

5) On the next page I see a reference to “Lorentz force in a perpendicular direction to the magnetic field.” That force separates H and OH ions according to “their electric polarities, i.e. positive charged ions and negatively charged ions.” How fast must the fluid (containing ions) flow and how large should the magnetic field be to make such separation possible?

6) Please be aware that I am writing this as I read the text. The illustrations, whose descriptions begin on page 7, might provide answers to some of my questions.

7) Unfortunately, the illustrations did not help me understand the device. Figure 5, however, was useful. It made clear that “magnetic bodies” are not monopoles; they are N and S poles of two bar magnets (polarized sidewise) used to crate the magnetic field along the path of flowing water. The Lorentz force is due to that field, and to the velocity of ions formed in water. Hydrogen ions H^+ are said to be separated from the OH^- ions by Lorentz force. But how are these ions formed? How much energy is needed to separate H^+ from OH^-?

8) On page 14 I see this sentence: “ The apparatus as recited in claim 1, wherein the dielectric implant is made of one of ruby and sapphire and inner walls of the passage slot contacting the operation fluid include a dielectric layer sensitive to the cavitation emission.” What properties of ruby or sapphire are essential in this application? Why are these substances better than other dielectric materials?

9) My main question has to do with energy. The device is supposed to produce fuel. It is well known that burning one mole of that fuel (2 grams of hydrogen) generates 495 kJ of thermal energy and produces one mole (18 grams) of water. If the device can be 100% efficient, which is an idealization, then these 495 kJ of energy can be used to produce 2 grams of hydrogen. What benefits can one derive from a device using more energy to produce fuel than the energy one can obtain from that fuel?

The only logical answer, without violating the first law of thermodynamics, is to postulate that an additional source of energy is being used. What is the nature of that source? I know how some people would answer this question. They would say that the so-called “zero-point energy” allows us to get more than two grams of hydrogen from 495 kJ of thermal energy. The theoretical idea of a hidden sour úce of energy would be acceptable to me, but not before an experimental confirmation. According to what was quoted in unit #216, commercialization of the device is going to start in several months. Will it use much less than 495 kJ of thermal energy to produce 2 grams of hydrogen? If so then the iESiUSA stocks sold at $4 a share will be worth much more that $4000 per share. But I am not ready to invest in their hydrogen-making machine.

Addendum (6/4/2005):
I WAS ASKED TO REMOVE THIS ADDENDUM. THE REQUSTER REFERRED TO MY PERSONAL SAFETY. YES, I AM CONCERNED !

Addendum (6/4/05):
Browsing the Internet I found this webpage http://100777.com/node/1146. Posted on the “site for Truthseekers,” the document contains a description of something called gCell. I do not know if this cell has anything to do with the iESiUSA invention. They say that catalytic conversion of water into hydrogen and oxygen takes place in a gCell. Here is a quote from the first paragraph:

“ . . . A second process involves a thermo, electro-catalytic reaction that results in the complete separation [of hydrogen from oxygen]. In the third process, small amounts of the hydrogen and oxygen gas molecules created in the second process recombine, providing additional electrical current to subsidize the overall gas generation process. A single Genesis gCell stack (about the size of a small car battery), consisting of several individual gCells, is capable of producing hundreds of cubic feet of gas per day. In comparison, a typical American home located in cold climates consumes approximately five metered cubic feet of natural gas a day. When converted to electricity this represents a 30kW output. The eCell does the reverse reaction to create a cheaper, more powerful, more reliable, longer life, and compacter fuel cell..... ”

Unfortunately, the origin of "free energy," needed to operate the gCells and eCells is not mentioned. This can be contrasted with what is explained at another website http://www.physorg.com/news3083.html . This description makes sense to me; it offers a way of using heat from solar energy concentrators (or high temperature nuclear reactors) to produce fuel for our automobiles. Here is the description:

"The U.S. Department of Energy has awarded Clemson University a three-year, $856,000 grant to develop more efficient methods for producing hydrogen. 'The irony is that today, most hydrogen is produced by consuming the very fossil fuels we're trying to replace,' said principal investigator Mark Thies, professor of chemical engineering at Clemson. 'But, we can also produce hydrogen by splitting water into its two elements, hydrogen and oxygen. The trick is to find the most energy-efficient manner for carrying out that splitting process.'

Thies explains that proposed 'thermochemical processes' are much more efficient than the classic electrolysis method, which uses an electric current, for splitting water. The thermochemical processes require heat -- both solar and nuclear power have been proposed -- to operate and use complex chemical reactions to reduce the energy required to split the water.

These processes are still on the drawing board. Both high-powered experiments and high-powered computer calculations will be needed before hydrogen production can become a reality. Thies has assembled a diverse team of experimentalists, theoreticians and computer-aided design specialists to work on this challenging problem. The team includes Clemson professor David Bruce, John O'Connell of the University of Virginia, industrial consultant Paul Mathias of Cambridge, Mass., and Maximilian Gorensek of the Savannah River National Laboratory."

Addendum (6/5/2005):
Here is a piece from the iESiUSA website: http://www.iesiusa.com/hydrogen.html
We believe that the low-cost hydrogen-generation technology is the "crown jewel" of the company because of its potential to revolutionize the energy supply through the world. iESi's technology allows for the delivery of pure hydrogen directly to the compressor, without the usual requirements for . . . We are in the final stages of completing the manufacture of a hydrogen-generating unit. It will be available for private demonstration to licensees and investors in late 2004.

It is now June 2005; what did they demonstrate? In my opinion, selling reliable generators, under a very strong warranty, would be the best possible publicity. Many investors would buy a device if the "money-back guarantee" was formally offered for at least one year. A reliable device described on the iESiUSA website (already protected by the Korean patent) would pay for itself in much shorter time than one year. I am afraid that a demo might backfire, like the 1989 public announcement in Salt Lake City.

P.S. Units #229 and #230 (and some to be added later) are also connected with this topic.

227) Fisher's polyneutrons again

Ludwik Kowalski (5/30/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
Fisher's theory of cold fusion has been described in unit #191. The theory is based on the assumption that polyneutrons exist and that their exact masses can be calculated. It is important to emphasize that existence of polyneutrons is highly speculative. The same is true for the formula used to calculate their exact masses. John is aware of this. On the last slide of his presentation at Siena (May 2005):

http://www.markfisher.net/johnfisher/

John asks: "Do I believe polyneutron theory? Yes in concept. Polyneutrons are key agents for CF phenomena. They avoid the coulomb barrier, gamma radiation and neutrons. They offer explanations for transmutation and excess energy. Not in detail. Other choices for key parameters may be required. Should experimenters believe the theory? Not yet. But it has suggested novel experiments in the past (Particle showers in the vapor, energetic particles behind the cathode). . . . And it provides a mental framework for interpretation of results. Should theoreticians believe the theory? No. But they should have open minds. There are plenty of new theoretical questions that need attention." Fisher's model seems to be consistent with traditional nuclear physics; it respects the coulomb barrier and the law of conservation of energy. He invented polyneutrons and uses them to explain various cold fusion claims. His theory would be much more believable if it were based on universally recognized facts.

John's Siena presentation was a modified version of his theory. After posting slides of that presentation (available from the above Internet address) he suggested, in a private message, that I replace the earlier version of his theory (described in unit # 191), by his slide show. I am not going to follow that suggestion because I want to be able to compare two versions of John's theory. My task is not to justify his theory; it is to describe it pedagogically, and to share some comments. Here is how John introduced the new version in Siena: "Nuclear physics is incomplete. It can be extended to include polyneutrons. Polyneutrons explain cold fusion phenomena." In the recent private e-mail message John wrote that "for years they [theoretical physicists] had been stubbornly sticking with the idea that DD fusion was responsible for the cold fusion effects, and they were putting all their efforts into trying to find tricky ways of getting around the absence of the trademarks of DD fusion, rather that just accepting the fact that DD fusion did not occur ....."

Slides 5 and 6:
Referring to the "BCS model for polyneutron fluid" John states that "pairs of neutrons of opposite spin and momentum attract each other. Neutrons attract each other forcefully and directly. Not weakly and indirectly as for electrons via phonons. With strong interaction and full access to momentum space polyneutrons will be strongly bound. Collective binding of neutron pairs is expected to be much stronger than binding of electron pairs." I am not familiar with the BCS theory but I do know that traditional nuclear physics postulates existence of attractive nuclear forces between all nucleons. In the new version of the theory John postulates that the smallest possible polyneutron consists of 12 neutrons. I do not know why four or six neutrons, for example, can not form a polyneutron, as postulated in previously version.

The mass difference formula now has two terms, not one, as in the previous version. These are the volume and the surface terms, as used in the well known semi-empirical mass formula. John writes: " I assume a liquid drop model for the polyneutron mass excess. $\Delta(^{A}Nt) = a_v A + a_s A^{2/3}$ (A>12). The mass excess is a minimum at A =12, and for A<12 it rises abruptly toward $\Delta(^{4}Nt)$ [where it is assumed to be equal to zero]. Consequence: reactions that generate polyneutrons ^{A}Nt are endothermic for A<12. "

It is worth emphasizing that the semi-empirical mass formula for ordinary nuclei is much more reliable that the formula

for the polyneutrons. The reason is obvious. Nobody questions existence of atomic nuclei; masses of many atomic nuclei have been measured with great accuracy. Existence of polyneutrons, on the other hand, remains questionable. For ordinary nuclei modeling coefficients, such as a_v and a_s, match experimentally measured masses. In the case of polyneutrons that approach to modeling coefficients is not possible. In other words, the above formula the mass excess should not be called "semi-empirical."

Slides 7 and 8:
Here we see how to calculate D, a difference between mass excesses of plyneutrons composes of A+1 and A neutrons. Consider polyneutrons composed of 126 and 125 neutrons. In that case the value of D (in MeV) is $a_v + 0.133*a_s$. Numerical values of the modeling coefficients, a_v and a_s, are not specified on these slides. In the previous version of the polyneutron theory the a_v was 1.90 and the a_s was zero.

Slides 9 to 12:
These four slides remind us about showers of alpha particles reported by Oriani and Fisher at ICCF10. Using a cell identical to the one they used I was not able to convince myself that such showers exist. In private e-mail messages Oriani wrote that his recent attempts to observe large showers were not successful. Like many other CF researchers, he is struggling with the issue of poor reproducibility. He even tried to speculate about causes of irreproducibility. But that is a different topic.

Slides 13:
Here "composite nuclei," such as $^{16}O^{74}Nt$ are introduced. It is a system composed of an ordinary nucleus and of a polyneutron -- a "nuclear molecules." John writes that such molecules "are bound to each other by a reduction in surface energy over the area of contact. These composites must be stable (except for beta decay) if they are to participate in polyneutron reactions." In other words, he refers to stability with respect to strong nuclear forces only.

Slide 14:
In principle, neutrons can be transferred from one component of a nuclear molecule to another, for example:

$$^{16}O^{74}Nt \rightarrow {}^{15}O^{75}Nt + e,$$

and

$$^{15}O^{75}Nt \rightarrow {}^{16}O^{74}Nt + e,$$

where e, the reaction energy (third modeling parameter) is postulated to be negative and identical for both directions. I think that is not possible; if the first e is negative then the second must be positive, and vice versa. How can direct and inverted reactions be both endotermic?

Slide 15:
Introduces the third modeling parameter, E_b; it represents the energy released when a nuclear molecule is broken. The name of that positive parameter is "composite mass excess." Breaking of a nuclear molecule should not be confused with breaking of a polyneutron (see slide 17).

Slide 16:

Here I see a postulate that the reaction energy E (not to be confused with Eb or with e)
is positive for one particular kind of process:

$$^{18}O + {}^{A}Nt \rightarrow {}^{16}O + {}^{(A+2)}Nt$$

That process consists of growing on a polyneutron in the presence of ^{18}O. About 0.2% of oxygen, in air and water, contains that isotope of oxygen. John takes it for granted, as described in unit #191, that the above reaction was taking place spontaneously in the original experiments of Fleischmann and Pons (and in many other cold fusion experiments). That is why E must be positive in his theory. Accepting this postulate John shows that D (defined in slide 8) must be smaller than 1.955 MeV. Algebraic manipulations leading to this conclusion are straight forward. Note that D, defined, in slide 8, is expressed in terms of his model parameters a_v and a_s.

If one had D=1.955 then it would be an equation involving two unknowns a_v and a_s. In reality it an inequality involving these two model parameters. It is the first constrain on the values of a_v nd a_s. The second constrain appears in the next slide.

Slide 17:
Here I see a postulate that the released energy, E, must also be positive for another kind of reaction, namely:

$$^{18}O + {}^{A}Nt \rightarrow {}^{16}O^{(A-22)}Nt + {}^{12}Nt + {}^{12}Nt \text{..... (provided } A > 33)$$

In other words, large polyneutrons (A > 33), colliding with ^{18}O, can result not only in reactions described in slide 16; such collisions can also result in formations of nuclear molecules accompanied by the emission of two polyneutrons of size 12. I do not know on what bases were the values 12, 22 and 33 chosen. Accepting the positive E for the above kind of reaction John derives the second constrain involving a_v and a_s.

$$3.955 + E_b - 2*a_v + a_s*(A^{2/3} - (A - 22)^{2/3} - 2(12)^{2/3}) > 0$$

The other two constrains are implied -- neither a_v nor a_s can be negative. Two equations with two unknowns would most likely lead to a unique set of two model parameters. The inequalities, on the other hand, can only be used to restrict a region (in the first quadrant of the a_v versus a_s plane) in which the unknown solution is located. I am writing all this as I go from one slide to the next. I do not know how the inequalities are going to be used. What is clear, however, is that the above two processes are going to contribute to a chain reaction which, as explained in unit #191, can develop under favorable conditions.

Slides 18 and 19:
The possible chain reaction consist of two processes, the first consists of the growth of polyneutrons and the second, consists of production of a pair of ^{12}Nt polyneutrons. A chain reaction in air and water would generate enough thermal energy to kill everybody on our planet. Fortunately, this does not happen. What protects us? What stops a chain reaction when it starts developing? According to John, reaction products (right sides of the two equations in slide 18) have the ability to absorb polyneutrons. They are poisons in the same sense as fission products in our commercial nuclear reactors. This is illustrated in Slide 19.

* *

I WILL STOP NOW (6/3/05) AND WILL CONTINUE LATER. BUT BEFORE STOPPING LET ME QOUT AN E-MAIL MESSAGE RECEIVED THIS MORNING. IT HAS NOTHING TO DO WITH PHYSICS. I DO NOT THINK THAT THE WRITER, PAUL BOLOGNA (A BIOLOGIST AT MY UNIVERSITY) IS AWARE OF POLYNEUTRON THEORY OF JOHN FISHER. HERE IS WHAT HE WROTE, ADDRESSING ALL FACULTY MEMBERS OF

CSAM (College of Sciences and mathematics). PAUL WROTE:

“This is a multipart message in MIME format, just some fun summer reading: The Center for Applied Mediocrity of the Institute of Negativity, a major research institution, has just announced the discovery of the heaviest element yet known to science. The new element has been named "governmentium."

Governmentium has one neutron, 12 assistant neutrons, 75 deputy neutrons, and 224 assistant deputy neutrons, giving it an atomic mass of 311. These 311 particles are held together by forces called morons, which are surrounded by vast quantities of lepton-like particles called peons. Since governmentium has no electrons, it is inert. However, it can be detected, as it impedes every reaction with which it comes into contact. A minuscule amount of governmentium causes some reactions to take over 4 days to complete, when they would normally take less than a second.

Governmentium has a normal half-life of 4 years; it does not decay, but, instead undergoes a reorganization in which a portion of the assistant neutrons and deputy neutrons exchange places. In fact, governmentium's mass will actually increase over time, since each reorganization will cause more morons to become neutrons, forming isodopes. This characteristic of moron-promotion leads some scientists to believe that governmentium is formed whenever morons reach a certain quantity in concentration. This hypothetical quantity is referred to as "Critical Morass." When catalyzed with money governmentium becomes administratium, an element which radiates just as much energy, since it has 1/2 as many peons but twice as many morons.”

More Serious Insertion (6/4/05):
Polyneutrons, invented by John, offer a great explanational flexibility but their real existence is not as certain as existence of neutrons. I know of two cases in which neutral particles were first invented and then discovered. They are neutrons and neutrinos. Let me briefly summarize the case of neutrons. Their discovery was announced in 1934 by Chadwick. Beside being a good experimentalist, Chadwick was exposed to 1920s speculations that such particles (hypothetical proton-electron combinations) might exist. This helped him tremendously to recognize real neutrons. Other scientists, especially Joliot-Curie (in 1932), contributed to this discovery.

The first contributors were Germans, Bothe and Becker. They discovered highly penetrating radiation coming from a beryllium foil bombarded with alpha particles. The radiation consisted, as we know today, of neutrons but they believed it consisted of gamma rays. A French scientist Jolit-Curie recognized a contradiction between what was already known about gamma rays and properties of beryllium radiation. In studying penetrating properties of that radiation he discovered paraffin bombarded with it was emitting protons. Neither Germans nor French were familiar with earlier speculations about neutrons. But Chadwick, an English scientist was. After reading Jolit-Curie’s publication he realized that protons might be knocked from paraffin by neutrons. Then he conceived a clever experiment to confirm this hypothesis.

Will the history repeat itself? Perhaps polyneutrons do exist but Fisher’s way of thinking about them is too naive. The first way of thinking about neutrons (proton-electron combinations) was also too naive and has subsequently been rejected. Perhaps existence of polyneutrons will be discovered in experiments that have nothing to do with cold fusion. A scientist familiar with John’s theoretical model might be in a better position to recognize polyneutrons that other scientists. Theoretical speculations are useful, even when they are based on unacceptable postulates.

228) Cars running on water?

Ludwik Kowalski (6/5/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The webpage whose URL is shown below,
http://www.rexresearch.com/puharich/1puhar.htm#4394230

describes a presumably old, but never widely implemented, invention. "Dr Andrija Puharich reportedly drove his motor home for hundreds of thousands of miles around North America in the 1970s using only water as fuel. At a mountain pass in Mexico, he collected snow for water." But our cars still don't run on water. I do not think that a conspiracy of oil companies is responsible for this. To me it means that something is wrong with the US patent described on the above quoted webpage. This observation is also based on what I know about the first law of thermodynamics. The amount of energy needed to extract hydrogen from water (production of fuel) can not be smaller than the amount of energy one gets from turning that hydrogen back into water (burning that fuel).

But that is not totally satisfactory. Thermodynamics only tell us that "something is not right," it does not identify errors. To i dentify errors one has to address relevant details. Unfortunately, my familiarity with chemistry is very limited. That is why I would appreciate if a qualified electrochemist, reading this short note, could either identify specific errors (in the patent description) or argue that the explanation has no errors. I would be happy to append such input to this note.

P.S.
Figures 6 and 11 reminded me of superwaves described in unit #213. The fundamental frequencies were between 20 and 200 Hz; the modulating frequencies were between 200 and 100,000Hz. My first impression was that the author refers to matching of frequencies of atomic oscillations in water molecules. But, is it not true that such oscillations usually take place at much higher (infrared) frequencies? What kind of resonances can be matched with frequencies smaller than 0.1 KHz?

Short addendum #1 (6/6/06):
William C. Rostron, thinks that "the patent should never have been granted" to Puharich. William wrote:

No doubt there cannot be a violation of the first law of thermodynamics. If it works, then the energy for the breaking the hydrogen-oxygen bond comes from ambient heat; the process acts like a heat pump, ultimately extracting cracking energy from ambient air. In principle, there isn't anything wrong with this idea. Notice the heat fins on "Component III".

The schematic diagram showing the isolation transformer and "Component III" reaction nozzle won't work: there isn't a complete electrical circuit. Somehow, current has to flow to excite the circuit, and that can't happen if the upper winding of the transformer secondary isn't connected to something--even just a capacitor. This is critical, because there is sufficient description of the waveforms and theory to build the circuits designated by the functional boxes, but the output drive transformer circuit is shown explicitly, and it's broken. On that basis alone, the patent should never have been granted, in my opinion.

William emphasized that this is his own point of view, not of the power plant company that employs him at a nuclear

plant.

Short addendum#2 (6/7/05):
Referring to cars fueled by water a physics teacher wrote: "There have been cars driven on water reported previously. The one's that actually perform as claimed use metallic sodium or potassium in addition to the H_2O." Here is my comment on this. As a high school student, more than five decade ago, I saw a demonstration in which a tiny bit of sodium was dropped into water and reacted violently. But I did not know that sodium can be used as an automobile fuel. Looking into a chemistry textbook now I see that hydrogen is released from water by the following reaction:

$2\ Na + 2\ H_2O \rightarrow 2\ NaOH + H_2$

In other words, to produce one mole of H_2 (2 grams) one uses two moles of Na (46 grams). The heat of combustion of H_2 is 495 kJ per m
ole (247.5 kJ per gram) while the heat of combustion of gasoline is close to 50 kJ/gram. This shows that one gram of hydrogen produces about five times as much heat as one gram of gasoline. It also shows that one gram of sodium must be used to generate 5.39 kJ of heat (released when hydrogen is burned). One kilogram of gasoline (little more than one liter) will produce 500,000 kJ of heat. How much sodium is needed to produce the same amount of heat? The answer is 92.9 kilograms. (Feel free to replace the word heat by thermal energy).

Suppose the distance covered by Puharich was only 200,000 miles. A car covering 20 miles per gallon of gasoline would use 10,000 gallons of that fuel. This is equivalent to 929,000 kilograms (nearly 930 tons) of sodium. Note that NaOH is a dangerous pollutant. It is not hard to figure out that a lot of nitrogen hydroxide would be produced during the trip. How was the NaOH disposed of? How often was the vehicle "refueled" with sodium? A question I am not asking has to do with energy needed to extract 930 tons of sodium from NaCl.

Hydrogen cars of tomorrow are expected to be environmentally friendly. Production of hydrogen should also be environmentally friendly. Getting hydrogen out of water with sodium does not satisfy this condition. The iESi device for extraction of hydrogen from water, on the other hand, is said to be not only environmentally friendly but energy efficient as well. I do not think that such claim is valid. But I will be happy to be wrong. Nothing would be more convincing than long-lasting commercial success of their already existing devices, and subsequent scientific papers explaining them.

229) A Russian patent of Gnedenko et al.

Ludwik Kowalski (6/10/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Today I received a phone call from a reader. That person asked me to translate a Russian patent of Gnedenko and Goriachev. The patent, according to the caller, is linked with inventions described in units #216 and #226. I said I will do my best and post the translation at my cold fusion website.

Addendum (6/14/05). The patent description arrived today and I will start translating it. Actually it is a set of four files. The first is an abstract; it is already in English and I will paste it below. The inventors are listed in alphabetic order; the names of Koldomasov and Yang (see units #216 and #226) appear of the list. But patent holders are Gnedienko and Goryachev.

Goryachev Igor' Vital'evich (RU)

(54) **POWER PLANT FOR PRODUCING HYDROGEN AND OXYGEN**

(57) Abstract

An installation designed to produce hydrogen and oxygen, and also for generating power recovered in fusion reactions taking place in a reactor. The installation includes a dielectric housing that is resistant to a cavitating emission for receiving and transmitting a dielectric medium in the form of a mixture of light and heavy water, an insert disposed in the housing and made from dielectric material that is susceptible to cavitating emission and furnished with at least two apertures capable of allowing the dielectric medium to escape. The installation is furnished with a pulser, a pump for

supplying the operating dielectric medium under pressure, a system for deflecting charged particles, and at least two pipes that are electrically insulated from one another and connected to receptacles for collecting hydrogen and oxygen, also a stricture in the form of a Laval nozzle at the outlet from the insert in the housing, and a deflecting system on the housing downstream thereof, after which pipes are arranged. The deflecting system may also be realized by electrostatic or magnetic means. The invention provides expanded functional capabilities. 2 z.p. files, 1 figure.

(*Mixture of light and heavy water*)

FILE #2:
This is also an abstract that has already been translated. I am pasting it below. I wish the emphasis was on scientific principles rather than on the appearance of the device.

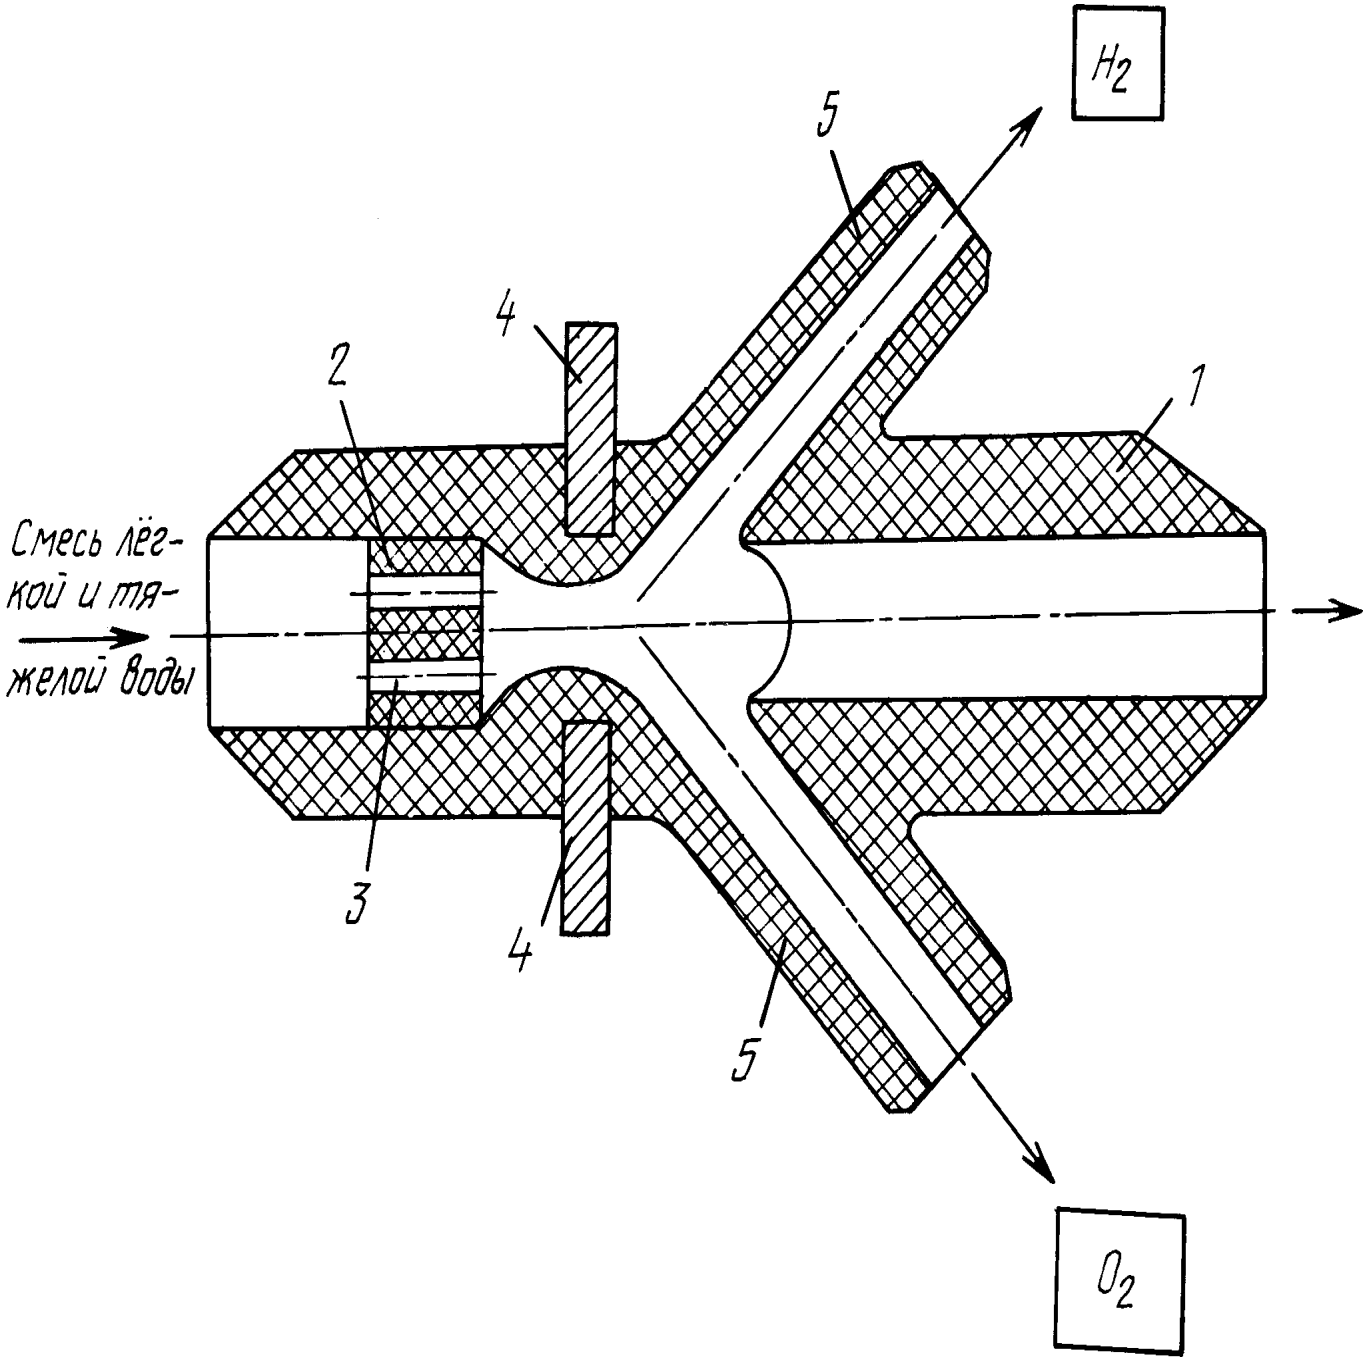
FIELD: **production of hydrogen and oxygen.**

SUBSTANCE: the invention is pertinent to electric power installations. The installation intended for production of hydrogen and oxygen, and also for production of the energy emitted at fusion reactions going in a reactor. The installation contains: a dielectric resistant to cavitational emission housing for intake and gating of the dielectric medium in the form of a mixture of light water and heavy water, an insert mounted in the housing and made out of a dielectric material susceptible to cavitation emission and provided at least with two holes allowing an exit through them of the dielectric medium. The installation is supplied with a impulsator, a pump to deliver the working dielectric medium under pressure, a deflecting system of charged particles and, at least, two branch-pipes electrically isolated from each other and linked with vessels for hydrogen and oxygen collection. At that at exit of the insert in the housing there is a narrowing in the form of Laval's nozzles, behind it along the stream run on the housing there is a deflecting system mounted, behind which the branch-pipes are located. The deflecting system may be electrostatic or magnetic. The invention ensures expansion of functionalities of the installation.

EFFECT: the invention ensures expansion of functionalities of the installation.

3 cl, 1 dwg

FILES #3 AND #4:
File #4 seems to be an illustration accompanying file #3; that is why I am showing it first. It shows how a “mixture of light and heavy water” is delivered to the body of the device (from the left input) and how molecular hydrogen and molecular oxygen are removed (up and down, respectively, as labeled).



File #3 is in Russian. It begins with the abstract (already translated -- see file #1). The abstract is followed by the text shown below. This text is not clear to me; it makes references to presumably "well known" facts and solutions. Be aware that I am going to translate without understanding. Most words are clear but I can not make sense of sentences. Some technical terms are new to me and I have no dictionary at home. For example, what is the "miezelectronnaja camera"? Literally it is a chamber between electrons. But which electrons are they talking about?

Likewise I am confused by the term "cavitational emission." I know that cavitation consists of formation of bubble but I do not know what kind of emission is associated with bubbling. What is being emitted -- particles or waves? If cavitational emission consists of particles then what is their nature and why are they emitted? If it consists of waves then what kind of waves? Is it sound? Is it light? Is it X-rays? How much energy is emitted? I hope that a reader of this translation will somehow understand it. But I would not be surprised of being accused of gobbleygooking; that is how the text appears to me, probably due to my limited background in the area of electrical water processing.

Description of the invention:

This invention, based on physics and chemistry, is related to technique of producing hydrogen and oxygen. Being

related to nuclear engineering it can also be used to produce energy liberated in a fusion reactor.

One known solution [a reference to a 1987 Russian book on water purification is given] consists of a tube through which the processed liquid is delivered to the discharge chamber (with flat and pointed electrodes) and a tube through which it is removed. Also known is a solution [US patent #3969214, 1976] containing a body with an axial opening, the fluid delivery input located in the lower section, the “miezelectronnaja camera” [see above], the anode connected to the positive terminal of the power supply, the cathode connected to the negative terminal of the power supply, and a device producing variable magnetic field.

The limitations of these known inventions is the fact that the anode and the cathode are located on the same side of the “miezelectronnaja camera” [see above]. Oxygen released at the anode is thus mixed with hydrogen released at the cathode. Mixing of these two gases is accompanied by endothermic reactions (production of hydrogen peroxide and ozone). These reactions lower the overall efficiency because they absorb part of the electrolytically generated heat.

Nuclear reactions taking place in the deutron-containing media are well known. They are described by Lipson et al. [two reference to papers published in 1990 and 1992 -- in the Russian journal “Technical Physics” -- are provided]. Continuos operation is not possible in nuclear reactors of known type because heat loses increase rapidly with plasma temperature ($\sim T^{7/2}$) and energy sources extinguish themselves. Nuclear reactions are thus not able to supply excess energy needed to overcome coulomb repulsion and sustain nuclear interactions.

The problem can be technically solved [a 1972 reference is mentioned] by inserting one or several dielectric elements into the passage of the liquid. The pump imposes fluctuations of pressure on the passing dielectric liquid and powerful resonance oscillations at acoustical frequencies (about 1 kHz) are generated in the system. positive electric charges, of high density, appear at the front face of the dielectric insertion through which the dielectric fluid if passing. The charge density depends on the intensity of cavitation, on the dielectric properties of the insertion and of the liquid. This leads to generation of quasi-stationary plasma in the liquid, in front of the insertion. The energy content, however, about 1 J/cm, is not sufficient to compensate for what is used to sustain the plasma discharge.

A known setup, using hydrogen and its isotopes, can generate energy continuously. It consists of a body through which a dielectric medium is flowing. The body should not be affected by cavitational emission; it should contain a dielectric insertion able to produce cavitational emission. The insertion should have at least one opening for the passing dielectric fluid, for example light water whose electric resistivity is about 10^{11} ohm*m. Then approximately 1% of chemically pure heavy water, with identical dielectric parameters, is added. An electrical charge of high density is then formed in the openings of the insertion. High potential due to that charge is able to ionize hydrogen atoms and accelerate them sufficiently to overcome coulomb barrier and lead to nuclear reactions. This was described in the 2000 patented prototype (see patent #2152083 of Russian Federation).

The described unit uses only part of the released energy -- excess heat. Our invention removes this limitation of analogous proposals, and of the prototype. It expands functional possibilities by increasing the intensity of plasma to a level at which energy loses (to sustain plasma) are compensated, and at which hydrogen and oxygen can be efficiently produced.

The setup produces hydrogen and oxygen. Its body is made from the dielectric material resisting cavitational emission. The insertion is made from a material able to produce cavitational emission. A dielectric fluid, in the form of a mixture of light and heavy water, passes through at least two openings in the insertion. The unit is equipped with a pulse generator and with pumps able to supply the compressed dielectric fluid. The setup is also equipped with a deflection system and with two exit pipes delivering hydrogen and oxygen. The pipes are electrically insulated from each other. After passing through the insertion the fluid is directed to the Laval’s nuzzle. The deflection system, either electric or magnetic, is situated after the nuzzle.

The attached figure is a schematic diagram of the energy setup for production of hydrogen and oxygen. Body (1) is made from the dielectric material that can not be damaged by heat and by cavitational emission. It can be ceramics, sapphire, etc. The insertion (2) is made from a dielectric material favoring cavitational emission. It can be asbo-

cement, ftoroplast, etc. There should be at least one opening (3) in the insertion. Each opening is a cylindrical channel whose length is 25 to 30 mm and whose diameter is 1 to 2 mm. The deflecting system (4) is mounted in the body of the device. After the insertion the body has the Laval's nuzzle and at least two exit pipes (5). The pipes are connected with containers collecting hydrogen and oxygen. The deflecting system can be either electric, for example, a parallel plate capacitor, or magnetic, for example, permanent magnets or electromagnets. The magnetic system creates a steady magnetic field in the region between the end of the insertion and the nuzzle.

The dielectric liquid flowing through the setup pulsates with the frequency that is close to the natural frequency of of the insertion opening. The resonance amplifies pulsation of the liquid and cavitation takes place at the entrance the of the opening in the insertion. This is associated with cavitational emission. Exposed to that emission the material from which the insertion is made starts emitting electrons; these electrons enter the flowing fluid. At the same time positive charge of high density is formed at the entrance of the opening. The difference of potential between the charged area and earth approaches one million volts. Hydrogen atoms of the working liquid are ionized when they are in the high voltage region. Positive ions (atomic nuclei of hydrogen isotopes) are then accelerated, inside the liquid, toward the axis of the opening. The concentration of ions (plasma) increases near the axis. Recombination times are sufficiently long and nuclear reactions can take place.

Impulse that ions receive from positive charges on the wall of the opening can exceed 10 keV. [Why is the term "impulse" used instead of kinetic energy?] This creates conditions for nuclear fusion reactions. Accelerated nuclei are able to react despite the coulomb barrier. The rate of nuclear processes can be regulated by changing the concentration of heavy heavy water in light water. The working model has been built; it works in the following way:

Working fluid is a dielectric -- a mixture of light and heavy water in the ratio of approximately 100:1. It is pumped into the body of the device (1) under the pressure of 5-7 MPa. The mixture of water flows through the opening (3) in the insertion (2). The insertion is made from a dielectric material, such as ftoroplast. The length of the opening is 25-30 m; its diameter is 1-2 mm. A pulsator, whose frequency is close to 1 kHz, is used to induce variations of pressure in the flowing mixture. Neither the pump nor the pulsator are shown in the diagram. The resonance frequency of the opening depends on its length and diameter; it also depends on physical parameters of the fluid. The frequency of the pulsator is changed slowly to approach the resonance frequency.

The body of the unit can be made from a transparent plastic material. The beginning of nuclear processes can then be recognized because ionizing radiation emerging from the opening ionizes the surrounding air. It can also be recognized by emission of neutrons, by the increase of temperature of the working fluid, by chemical changes taking place, and other parameters, using appropriate detectors (neutron counters, thermometers, etc.) The nuzzle (Laval's narrowing) is used to speed up working fluid after it becomes ionized. The deflecting system (4) is used to separate ionized particles. Positive and negative ions are deflected in opposite directions by either electric or magnetic field. By increasing the concentration of heavy water in light water, for example, to the 100: (3-5) ratio, a change in ionization can be observed. Production of hydrogen and oxygen increases at the same time. Ionized dielectric fluid moves rapidly through the magnetic field in the nuzzle and ions are subjected to Lorenz force. That is how positive ions are separated from negative ions. Positive ions move to one exit and negative ions move to another exit. Relaxation is difficult because the two flows are electrically insulated. In collective vessels Ions recombine and become either hydrogen or oxygen.

[The last paragraph is the summary of the invention: It is a single sentence consisting of 121 words. It would be very difficult to translate. I am going to leave this task to a professional translator. In my opinion sentences of that kind are not useful.]

Addendum (6/17/05)

The magnitude of the centripetal Lorentz force is F=q*v*B, where q is the charge of the ion, v is its speed and B is the magnetic field. The centripetal acceleration due to that force is F/m, where m is the mass of the ion. Comparing this acceleration to v^2/R one finds the formula for the radius of curvature, R=(m*v)/(q*B). The m and q are fixed, for a

given kind of ions, but v and B can be adjusted. For ions of hydrogen ion $q=1.6*10^{-19}$ C and $m=1.67*10^{-27}$ kg. Assuming, for example, that v=0.1 m/s (speed of water in the nuzzle) and that B=0.1 T (due to common magnet) one gets $R=10^{-8}$ m. That is a very small radius; I do not understand how to make it consistent with deflection of hydrogen ions in flowing water. Even when v is 10 m/s R is only one micron.

I wish a person familiar with the device could explain cavitational radiation and separation if ions in a flowing water. A student in an introductory science course would probably asked for the source of energy used to separated atoms of hydrogen from atoms of oxygen in water molecules. S/he would argue, correctly, that the separation energy, per molecule, must be equal to the energy released when hydrogen is burned in air (producing water). The authors claim that thermonuclear energy is released in the device. What evidence do they have that this really happens?

The iESi device is claimed to generate excess heat at the rate of 10 MW. Suppose that this is due to production of helium via cold fusion. How much helium would be produced in the device each day? It is not difficult to answer this question. The energy released in producing one helium atom (from two deuterium atoms) is 23.7 MeV. This is $3.8*10^{-12}$ J. The excess energy generated at the rate of 10 MW will produce 10 MJ of energy per second. The number of helium atoms produced in each second must thus be equal to $10*10^{6}/3.8*10^{-12}=2.6*10^{18}$. In one day the number of helium atoms would be 24*60*60=86,400 times larger ($2.3*10^{23}$ atoms). That amounts to easily-detectable 1.5 grams of helium per day. Air, on the other hand, typically contains no more than several microgram of helium per cubic meter. Reproducible detection of grams of helium, commensurable with excess energy, would be a highly convincing argument that the excess heat is indeed due to cold fusion of deuterium, as claimed by the inventors.

Addendum (6/19/05)

Browsing the Internet I found the website of PhysOrgForum Science. There I found a recent (6/11/05) posting in which Bearded Clem wrote: "I've been keeping an eye on IESI since I read another cold fusion thread on these boards and recently read on their website that the 2 chief scientists of IESI have come here to Edmonton where I live and I am very interested to find some unbiased proof that what they claim is real because if it is, it will be the breakthrough we need to survive the 21st century. If anyone is interested, here is the text form of a .pdf you can download of the <www.iesiusa.com> website. [See below.] It's a little vague for a skeptic like me but compelling none the less.

White Paper On Plasma Heat and Hydrogen Generator

By Dr. Norman L. Arrison

iESi has acquired the most significant technology of the 21st century through Dr. Hyunik Yang and his team from around the world. Their technology draws on the energy of the atom and converts that energy into useful energy in the form of heat in one device and the splitting of the water molecule into hydrogen and oxygen in another device. Dr. Yang's team has varied in size and composition over a ten year period of research. The consistent aspect of the team has been their international stature and dedication to hard work under the leadership of Dr. Hyunik Yang. Dr. Hyunik Yang is 47 years of age and has a distinguished record beginning with his B.Sc. in Engineering from Korea followed by his Ph.D. and post doctorate degrees at Columbia University in New York. He then had a successful career with Hyundai where he was contracted out to NASA and where he won the Eastman Kodak Award for the best paper and an ASME conference. Dr. Yang then went to Russia where he became a member of the Russian Academy of Science. With the distinguished scientists Dr. Yang had worked with, they decided to build a unit to produce power for mankind based on the energy in the atom.

The approach they used was brilliant. They used resonate harmonic frequencies to expose the nuclei of atoms so they could put the nuclei together to obtain the energy from the fused product. Their system is inexpensive, safe, and easy to operate and construct. The first plasma device will produce heat by taking water and converting it to steam. This device is expected to be working by late 2004 and an early prototype is already functioning. the early prototype produces 14 times the energy put into it and the final product is expected to produce 200 times the energy going into the unit. The second plasma device is expected in early 2005 and it will use it's energy to split the water molecule into hydrogen and oxygen. This device is already working in an old prototype which produces the hydrogen and oxygen and immediately recombines the two in a hot hydrogen and oxygen flame. The old hydrogen-oxygen device was the first proof that the team had successfully tapped the energy of the atom. It only produced 50% more energy out than went into the device but showed that the energy of the atom was being drawn upon.

iESi got control of this technology through the special relationship which exists between Dr. Hyunik Yang and Mr. Patrick Cochrane the founder of iESi. Mr. Patrick Cochrane is married to a Korean attorney and through her got to know of Dr. Yang's work. Mr. Cochrane was so fascinated

with the technology that he helped Dr. Yang with his funding which up to that time had been carried by Dr. Yang and his immediate family. Because of Mr. Cochrane's assistance for Dr. Yang's work, a close relationship blossomed which has resulted in the formation of iESi as it exists today. We at iESi feel very proud that we are the ones bringing this historical changing technology to the world. Plasma heat generation alone guarantees that the cost of electricity will be stable for all mankind. The hydrogen and oxygen producing technology guarantees a clean planet for humanity. The result is that iESi should be the most significant company of the 21st century.

Quoting a well know cold fusion researcher Clem wrote: "he had reason to believe that a commercial cold fusion device would be marketed within a year by a group out of Edmonton, Canada." I am not surprised that a person from that town is so excited about what is going on. In a 6/14/05 message another contributor (Panthom) wrote: "Since the MIT CF Colloquium, both Professor Peter Hagelstein and Martin Fleischmann have personally witnessed this cold fusion technology in the facility in Edmonton where IESI has their scientists sequestered. These two men are providing the unbiased proof the world needs that what they claim at IESI is true. But Patrick Cochrane at IESI is in legal trouble with the securities authorities in Alberta, so he's being forced out of the company by their investors, which can only help the company."

I do not know how reliable this information is. But, as some cold fusion researchers know (from a recent e-mail message sent to them by X), Martin Fleischmann was invited to participate in the demonstration of the device. The author of that message, X, was also invited. I would be happy to append a description of the last week Edmonton demonstration.

230) Two Russian papers

Ludwik Kowalski (6/20/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Please be aware that my unit #229 now has two added sections, at the end. They were not there when the unit was posted, several days ago.

2) It seems to me that **we really need a forum for discussion**, among cold fusion researchers. Unfortunately, the discussion list of ISCMNS, promised at ICCF11, did not materialize. And what happened to the online journal promised one year earlier? Let me make Éa suggestion. I have an idle discussion list at the university server; it can become a forum we need. To be a participant simply send me a private message whose subject line should say: "Discussion of CF." The first line (in the body of the message) should show your name (first, then last) followed by the e-mail address. The next line (or lines) should say why you consider yourself to be a cold fusion researcher. Participation in at least one of the ICCF* conference, for example, is a sufficient reason, as far as I am concerned. My e-mail address is <kowalskil@mail.montclair.edu>. The list will be activated as soon as the number of participants exceeds 20. Please, send this invitation to serious CF researchers you know; not everybody will see it here. Cut this paragraph and paste it into messages you sent.

3) **Today I received two Russian papers** from ∞ one of the readers. They seem to be related to the device invented by Koldamasov and Yang. (see units #216, #226 and #229). These papers prompted me to start this unit. I will try to translate them and make some comments. The copies of pages mailed to me do not identify the place of publication. But the sender wrote that the papers were "published in 2001, following the 2000 Sochi conference."

Paper 1: Studying of thermal and radiation effects in Koldamasov's cell;" by D.S. Baranov.

Paper 2: An experimental setup based on Koldamasov's cell;" by A.P. Andreev, D.S. Baranov, A.K. Molodov, A.K. Pokrovski and N.N Sikavatkin.

The authors of these papers are from Moscow (Scientific Institute of Crystallography, Russian Academy of Science, and MRTI (?)).

Translation of sections from Paper #2

Abstract: A temperature increase of short duration ø was observed in Koldamasov's cell when heavy water was locally added to the working fluid. The temperature did not changed when ordinary water was added, under analogous conditions. Adding lithium chloride to water resulted in registration of radiation in the scintillation detector.

This study was undertaken to reproduce previously reported results (1,2) and to enlarge the scope of a more recent investigation (3). The central element of that installation, the Koldamasov cell, was made from the transparent organic glass. Bright glowing discharge (plasmoid) was observed in front of the opening in the insertion when cavitation was taking place. The insertion changes the cross section, available to the fluid, by two orders of magnitude. Pressures in cell were changed in the range of 10-40 atmospheres at the frequency of ~1000 Hz.

The working fluid was oil whose temperature was ~33 C. At that temperature the viscosity of Δ heavy water exceeds

the viscosity of ordinary water by ~20%. This, however, could not lead to a significant increase of friction (resulting from addition of heavy water) because the viscosity of oil is ~20 times higher than that of water. Sensitive calorimeters were used to measure difference in temperatures between the input and output of the cell. The electrical diagram is shown in Figure 1. It is essentially a Wheatstone bridge in which R1 and R2 are thermistors. Medical injectors were used to introduce heavy or ordinary water at the entrance of the pump. The injected volume was one cubic centimeter and the time of each injection was ~10 seconds. The time was sufficiently long to mix the injected water with ~ 1000 cubic centimeters of oil.

In the first experiment heavy water was injected first and ordinary water was injected later. In the second experiment ordinary water was injected before heavy water. Figure 2 shows that difference fls in temperature occurred after injections of heavy water only. [In that figure changes in difference of temperatures are expressed in volts but the bridge was calibrated]. According to calibrations, changes shown in Figure 2 were the same as from the injection of one cubic centimeter of water at 100C. Trying to optimize generation of excess heat one observed cases in which no excess heat was generated and cases when changes in temperatures were sufficiently high to melt ftoroploast insertions. Destruction of the insertion was observed three times, but only when oil was mixed with several cubic centimeters of heavy water. Insertions were never destroyed when oil contained no heavy water (even at much higher temperatures and pressures).

Radiation emitted by the cell was measured by using a 5 cm by 5 cm cylindrical NaI detector. The detector was ~8 cm from the insertion. Radiation entering the detector had to pass through an aluminum foil of 0.5 mm, 5 cm of organ flic glass and a 5 mm layer of ftoroplast. [In other words it consists of gamma rays.] The setup was calibrated by using the annihilation line (511 keV) and a sodium line of 1460 keV. The multichannel analyzer spectra are shown in Figure 3. ..... [The background does not change significantly when the motor of the pump is turned on to off. A significant above-the-background component appears (in the gamma ray energies up to 250 keV) after 0.8 cubic centimeters of the water solution of lithium chloride, concentration 4 N, is injected into oil. The conclusion is:] Radiation measurements and temperature effects due to heavy water are with Koldamasov's findings and show that nuclear processes do take place in the cell.

[I am certain that scientists who prepared the last week demonstration in Emonson did not miss an opportunity to show, using a widely available detector, that gamma rays are indeed emitted from their setup. The setup generating excess heat at the ra Ëte of 10 MW must be much larger than the setup used by Baranov. When will the results of the last week demonstration be announced?]

3. A.P. Andreev et al. (see paper 3 below).

Translation of sections from Paper #1
Abstract: A compact experimental setup, analogous to that described by Koldamasov (1,2), was built. It shows that stable glowing discharge (plasmoid) is produced in the liquid under the influence of cavitation. [Does this mean that what was called "cavitational emission," in unit #229, stands for sonoluminescence?]

According to (1,2) a new approach approach is possible to generate thermonuclear energy. An independent confirmation of this could lead to a broad investigation of that approach. Direct c onfirmation of Koldamasov' work is difficult because the working fluid in his device was pure (double distillation) dielectric water. The reason is simple; the dielectric properties of pure water change drastically after it passes through the cell. Changed water must be purified before it can be reused.

In this investigation we tried to use a different working fluid -- organic oil. Dielectric properties of oil are more favorable but that substance is about 20 times more viscous than water. We were able to find conditions under which bright glow discharge (plasmoid) is formed in oil. The diagram of the setup is shown in Figure 1. [I shows a loop in which oil is forced to circulate under pulsating pressure. Numerous technical details (pump rpm, pressures,

frequen Ocies, etc. are provided. A set of three dots in the part of the article that I decided not to translate. Set of three dots below stand for was not translated] . . . The central element of that installation, the Koldamasov cell, was made from the transparent organic glass. It has a dielectric insertion with a narrow opening (cross section being 100 times smaller that in the tube through which the oil is supplied to the cell). Stable glowing discharge was observed at the entrance of insertions made from organic glass, ftoroplast and polysterol. It was observed when the insertion was made from vinoplast. Ftoroplast turned out to be the most effective when the pressure was ~30 atm. Appearance of plasmoid must be due to cavitation..... Characteristic speed of the fluid through the insertion opening (radius 0.5 mm) was 50 m/s. .....~

The total volume of working fluid was ~6 liters. It is remarkable that oil was not spoiled during its prolonged (`10 hours) circulation through the loop. An attempt to use less fluid liquid, a mixture oil and kerosine, also resulted in formation of plasmoid. But the pump deteriorated rapidly when that fluid was used. The setup is sufficiently compact to be used in practical applications.

4) Post scriptum:
This piece shows how main players of the company were described in the 5/23/05 “news and information” section of PRNews <http://sev.prnewswire.com>. The title of the article was “Esteemed Quantum Energy Physicists Dr. Hyunik Yang and Dr. Nahm Cho Arrive in Edmonton.” They will certainly become famous if the company’s offerings (“Direct Electrical Power Generation, low-cost Hydrogen Generation and low-cost Heat Generation, all three of which were developed by Dr. Yang”),turn into commercially successful technology.

Innovative Energy Solutions, Inc. (iESi) today announced the arrival of the Company's co-founder and Chief Technical Officer, Hyunik Yang, Ph.D. and Dr. Nahm Cho in Sherwood Park, Alberta, just southeast of Edmonton. The recent relocation of Dr. Yang and Dr. Cho should expedite the efforts that are already well underway on the Direct Electrical Power, Heat and Hydrogen Generation units and allow the Company's team of scientists to advance the impressive work they accomplished for iESi while in South Korea. "Much of iESi's proprietary intellectual property is based on the research in the field of quantum energy generation authored by Dr. Yang," said Patrick Cochrane, CEO, iESi. . . .

In his career, Dr. Yang has also held positions as professor at Hanyang University and as senior research engineer at Hyundai Electronics. Dr. Yang has designed several new inventions in the field of quantum energy and cold fusion. Dr. Yang received his Engineering B.S. from Hanyang University in South Korea, and completed his Engineering M.S., Ph.D. and post-doctoral work at Columbia University in New York. He is a member of the American Society of Mechanical Engineers, Society of Automobile Engineers, Korean Society of Mechanical Engineers, Russian Academy of Natural Science, Korean CAD/CAM Society and the Korean Society of Machine Tool Engineers. Since 1997, Dr. Yang has been listed in the Who's Who in the World, and in the Who's Who in Science and Engineering since 1998.

Dr. Cho also held positions as professor at Hanyang University. Dr. Cho is the author of four patents in South Korea and is an expert in the field of Nuclear Transmutation and Fusion. Dr. Cho received his Precision Mechanical Engineering B.S. and M.S. from Hanyang University in South Korea, and completed his Ph.D at the Tokyo Institute of Technology. He is a member of the Japan Society of Mechanical Engineers, Japan Society of Precision Engineers, Korean Society of Mechanical Engineers, Korean Society of Precision Mechanical Engineers, Korean Society of Manufacturing Engineers and the Micro Biochip Center.

231) Gold from carrots?

Ludwik Kowalski (6/26/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

A reader made me aware of a much older "revolutionary invention" that has never been explained scientifically -- Papp's engine. Google brings many descriptions of that extraordinary device. In 1968 Bob Said <www.rexresearch.com/papp/1papp.htm> wrote:

". . . Let's take a hard, skeptical look at this engine. It was designed by a Hungarian-born inventor name Joseph Papp. He and financial backer Don Rosen, who have set up a firm called Environetics, Inc., to develop the engine, are saying mighty little about the details of what makes it work until their patent applications have been granted. But this much they will say:

The engine operates on a charge of gas blends, hermetically sealed inside each cylinder above the piston. A charge of low-voltage electricity, which can come from either a 12-V or 24-V source common to light aircraft, is used to create an electrical field in or around the cylinder. This causes the gas to change from its original form to a new form which requires m /ore space. As it expands it does two things: pushes the piston down and creates --- they aren't saying how --- the conditions for returning to its original form. The heat generated by its expansion is absorbed by its contraction. When it is contracted, another charge of electricity causes it to repeat the expansion-contraction cycle, and so on ad infinitum. When this sequence of events occurs in an orderly phase among 4, 6 or any convenient number of cylinders, suitably connected to a crankshaft, you get useful work.

How much work? It's pretty much a paper solution at present, but the developers say any amount you want, from the amount necessary to drive a lawnmower on up through automobiles and airplanes to the amount needed to power a locomotive or a battleship..... Rosen stressed that what Papp has done is design a fuel, not an engine. The secret blend of gases is the key. Using a power source to move pistons and a crankshaft is old hat to reciprocating engine technology. And Papp's "key" can be applied to turbine technology as well. . . .

Moreover, any reasonably sophisticated reader will wonder about safe, tidy little scientific ideas like entropy, conservation of energy and one or two others. Because they are unwilling to divulge hard details on the concept until patent protection is complete, Papp and his associates leave us nibbling at these annoying problems. But then, the scientific community thought Edison, Marconi, the Wright Brothers and Robert Goddard were out of their minds, too. And look what they did for us. So don't scoff too soon. After more than two decades fas reporter and editor for newspapers and magazines from coast to coast I have been exposed to more than my fair share of perpetual motion machines, miracle cancer cures, devices for communicating with poltergeists, methods of extracting gold from carrots and similar schemes. I do not recall one which caused my reporter's instinct for a good story to resonate more strongly than Papp's engine does..... "

Some interesting comments on this never-commercialized invention were made in 2003 by Eugene Mallove; his article is in the compilation posted at the above website. Even more interesting is the piece attributed to Richard Feyman. The posted articles are worth reading and thinking about. Was Koldomasov (see my units #216, #226, #229, and #230) inspired by Papp's work? It would be great if devices described at the iESi website could perform as outlined by promoters. Our polluted world is in urgent need for "clean energy" inventions. Such inventions should be explained and used immediately. Small scale applications, if they work, would be rapidly scaled up and used all over. Secrecy

seems to be working against desirable things. Without secrecy the premature death of Papp would not prevent others from working on the fuel he invented.

In a long run, technology cannot develop without scientific understanding. I think that “tidy little scientific ideas like entropy and conservation of energy” should not be ignored by inventors.

232) Free energy and its impact

Ludwik Kowalski (28/6/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

An piece about an inventor:

Arthur A. Axelrad (MD, PhD, FRSC, Emeritus University Professor University of Toronto) is a friend, and a biomedical coworker, of Dr. Paulo Correa. In an interesting article:

http://www.aetherometry.com/axelrad_letter.html

about Correa (April 3, 2002), entitled "**PAGD, Aether Motors, and Free Energy**," he wrote:

"I would like to tell you what I know about Dr. Paulo Correa and his partner and wife Alexandra, two people who have recently done something marvelous. What they have done is to make a series of startling discoveries in basic science - beginning with their work in plasma physics, a field that is almost certainly going to have a major impact on our world in the near future.

. . . One day, Barbara, my wife, and I witnessed a demonstration by Paulo and Alexandra Correra of this 'Aether Motor' - it was an electrical generating system that could deliver electrical power without any external power input save its connections to two 'orgone accumulator' boxes or to either our insulated bodies or a ground pipe. Since the device moved a motor and drove a circuitry, it had to consume some power; this appears to have been provided by the environment. The event occurred with incredible calm - no explosion, no noise even, no sudden heat, no bright light, just the quiet pulsation of a discharge tube and a quiet turning of a small rotor. Save for the driving of the motor from contact with our bodies, the effect was almost disappointingly banal. It has not always been that way. There were occasions during the evolution of these discoveries when accidental electrical discharges did threaten the lives of our intrepid pair. Fortunately, these accidents never deterred them.

The realization of what we were looking at was mind-boggling. Here before our eyes was what I was brought up to believe to be absolutely impossible! The implications were also enormous - a world of literally free energy without pollution by a 'product readily producible by available equipment and processes at a cost that allows mass marketing for multiple applications'. You would have expected a scene like a Boxing Day Sale in Toronto. But nothing like that happened. Why? I have given a lot of thought to that question.

When an investigator presents the scientific community with a concept that challenges previous beliefs, there follows a series of stereotyped responses: 'He (or she) is wrong.' 'He can't be right because it goes against what has long been accepted as true by everyone.' 'He is self-deluded but wants so desperately for his concept to be widely accepted that he unconsciously selects the data that fit and rejects the data that don't,' or - 'He's lying!' Or 'This isn't even his field, what right does he have to challenge the work of many years by highly trained experts?' Or 'He doesn't work out of a renowned university or institute or major company. How could he be doing anything like what he claims to be so important?' Or 'If we support a thing like this and it turns out to be a fraud, we'll have wasted our company's money

and we'll be considered fools.'

Once all of these responses have been uttered and evidence overwhelmingly shows each to be unable to account for what is actually being seen, then it is time for a paradigm shift. I believe that this is what has been happening in the case of Paulo and Alexandra Correra. Despite all the exciting developments, however, money to commercialize these discoveries has not been forthcoming from anywhere. This has not been for lack of trying by the Correas, nor for lack of interest by potential backers. Many have come to them from all over the world and have seen striking demonstrations of the XS NRG TM PAGD reactor, the motors it drives and the batteries it charges, or of the Aether Motor developed at ABRI. These inventions are solidly protected by world patents. They are extensively documented in the patents themselves and recently on the Internet. Nevertheless, the Correas are, at the present time, in the process of shutting down their laboratory for lack of funds."

I see no evidence that Correas' inventions, or inventions described at the iESiUSA website, have anything to do with fusion of atomic nuclei.

An old piece written by a physics teacher:

In a 1993 book, entitled "Uncommon Sense: The Heretical Nature of Science," I found a section devoted to cold fusion. The author, Alan Cromer, is a professor of physics at Northwestern University. I remember that name because, many years ago, I was using an introductory physics textbook he wrote. Cromer's description of cold fusion is worth reading; it represent a typical point of view of a mainstream scientist.

"..... It thus is clear that cold fusion is possible if two deuterium atoms can be squeezed together closer than they are in a deuterium molecule. It is also well known that many metals, including palladium, absorb hydrogen. Therefore, isn't it reasonable to , suppose that if deuterium were forcibly incorporated into palladium by using an electrical current, deuterium atoms could be squeezed together close enough for their nuclei to fuse?

No, it isn't. The palladium atoms are themselves three times farther apart than are the two deuterium atoms in a deuterium molecule. The palladium is able to absorb deuterium molecules because the spacing between the palladium atoms is larger than the diameter of the deuterium molecule. No squeezing is involved. In fact, the deuterium molecule breaks apart inside the palladium, and its two deuterium atoms end up being farther apart in the palladium than they were in the free deuterium molecule.

Furthermore, Fleischmann and Pons claimed that their fusion reaction generated a large quantity of heat. A simple calculation shows that if the heat they claimed was due to fusion, there would have been enough neutrons generated to have killed the experimenters. They interpreted the absence of the neutrons as the discovery of a new type of nuclear reaction.

Scientists weren't immediately aware of all this when the announcement was made at a press conference. So when reporters asked scientists for their assessment of the Utah experiments, there were mixed responses. Philip Morrison observed, 'Based on the information I have, I feel it's a very good case." He said his confidence in the reality of the reaction was "high, but not conclusive.' The Nobel Prize-winning physicist Sheldon Glashow said, 'I don't believe a word of it' (Chandler, 1989a, p. 5). The amusing comment by Kim Molvig -- 'I am willing to be open-minded, but it's really inconceivable that there is anything there' (Pool, 1989, p. 1661) probably reflects the ambiguous use we often make of 'openminded.' Most alarming were the comments from scientists that put extraordinary confidence in Fleischmann and Pons: "I'd be extremely surprised if they've done anything stupid. They have a very good track record in electrochemistry. I am pretty excited about this" (Chandler, 1989b, p. 29). In fact, stupidity in science is far less surprising than is the radical overthrow of well-established doctrine.

I was one who was convinced from the beginning that the results were bogus. You could say I was closed-minded on the subject in the sense that I had a deep inner conviction that the experiments were wrong. Within days of the announcement, we had an impromptu meeting in my department to discuss the matter. By then, prepublication copies of the papers of Fleischmann and Pons and the Jones group had arrived over the fax machine. As I examined them, I judged the first unsuitable for publication and the second an interesting and publishable work that was probably

wrong. My judgments at that time were more negative than those of my colleagues but were in accord with those of the reviewers at Nature, who rejected the Fleischmann and Pons paper while accepting the Jones group's paper.

In their original press conference, Fleischmann and Pons stated that they had been working on cold fusion ‘in secret’ for five years. This tipped me off at once. Science isn't done in secret. It's too easy to make a mistake. This is true for electrochemists doing electrochemistry and even truer for electro chemists doing nuclear physics. A theoretical nuclear physicist myself, I have a small idea how hard my experimental colleagues work to get everything right. It's a process of constant refinement in which comments and criticisms of other scientists play a vital role. To me, Fleischmann and Pons were acting like a couple of alchemists for whom the scientific revolution had never happened. The public, on the other hand, and many scientists as well, were taken by the romantic notion of two chemists working alone to defeat the billion-dollar hot-fusion physicists. The chemists ate it up.

As soon as [saw the Fleischmann and Pons paper, I knew my worst suspicions were correct. The paper lacked any references to nuclear physics and, indeed, had hardly any references at all. References are used in all scholarly writing to establish the author's knowledge of the relevant work in the field. A typical scientific paper has about thirty citations, most to recent related work. Fleischmann and Pons had five references, three to their own work and two to works on hydrogen absorption in metals. (One of these was to a 1940 Russian paper.) There was no reference to the huge literature on fusion. A scientific paper differs from a nonscientific one by the requirement that it be consistent with the previous work in the field. This means it must acknowledge the existence of this previous work and show how the new results fit in with the old. A paper may challenge previous work, but it can't ignore it.

The Jones group's paper has eighteen references. They indicate their knowledge of the unlikelihood of cold fusion, but argue that something unusual happens when the hydrogen is absorbed into matter. They interpret some geophysical data as indicating that cold fusion is going on inside the earth. This connects their work to the rest of science. They also give their raw data-the number of neutrons they detect when their cell is off and when it is on. The difference, if any, can be attributed to fusion. Their data are shown in Figure 8.1. The vertical bars on the points indicate the probable error; that is, the true value is likely to lie somewhere on the bar. To accept cold fusion, you have to believe that the positive results around the lOO-channel mark isn't a statistical fluctuation. This 1 find very difficult, given the Jones group's claim that the neutron production "dropped dramatically" after eight hours. Statistical fluctuations are well known to produce dramatic changes in small numbers; that's what makes gambling so exciting. Many other laboratories have since tried to duplicate the Jones group's result. Although some claimed to see a few neutrons, none of these results has held up over time."

= =

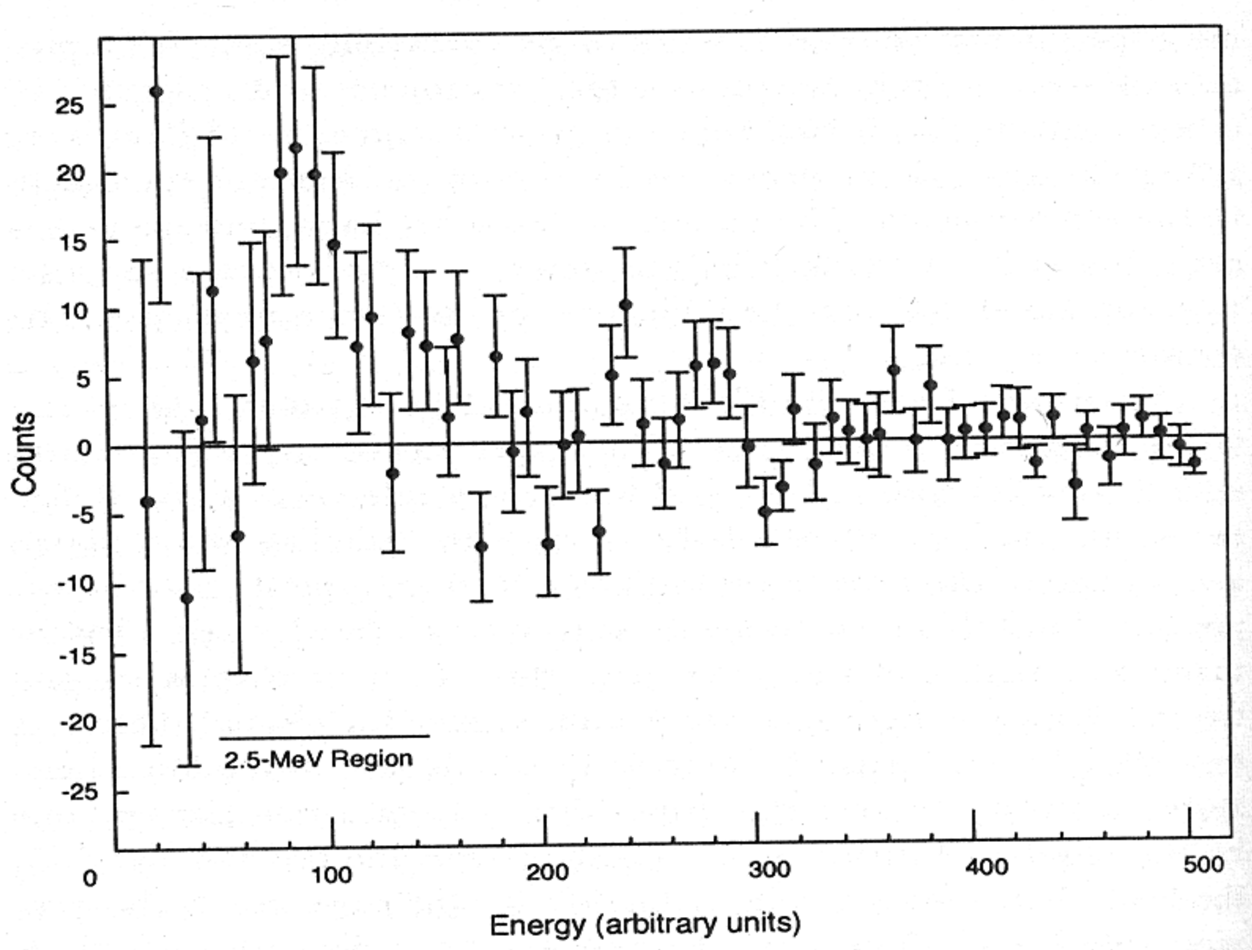

Figure. 8.1 The number of neutrons of different energies detected by Jones et al. with the electrolytic cell on, minus the number detected with the cell off. There is a positive difference in the energy region expected for fusion neutrons (2.5 MeV). Although this difference is statistically significant on its face, such results are sometimes found to result from a bias in the way the data are handled. (Reprinted with permission from S. Jones et al., 'Observations of Cold fusion in Condensed Matter,' Nature" 338 [1989): 737) [I do not know what kind of "bias" was Cromer referring to. Emission of unexplained neutrons was confirmed in subsequent experiments of Jones, as described in units #113 and #131.].

= =

The fact that two Utah research groups both had reported cold fusion at the same time greatly confused the picture, as they seemed in some way to confirm each other. However, the most casual reading of their papers, or of the newspapers at the time, clearly showed that the two results were highly inconsistent with each other. The small fusion rate indicated by the neutrons detected by the Jones group, though inconsistent with current nuclear and solid-state theory, isn't as inconsistent as the trillion times higher rate reported by Fleischmann and Pons without the production of the necessary neutrons.

The Fleischmann and Pons paper, for all its extravagant claims, offers no data. Although Fleischmann and Pons measured the temperature change in their fusion cell, they give none of their raw readings. They report only highly processed numbers, without giving any indication how they were calculated. When they saw only one-ten-trillionth (10-13) of the neutrons that their claimed fusion rate should have produced, they claimed the discovery of 'an hitherto unknown nuclear process or processes.' When they came in one morning and found their cell burned out, they claimed that fusion did it.

I was surprised how many scientists were prepared to relax their usual skepticism in the face of such an unscientific paper. The chemists were particularly excited, and at a meeting they had great fun claiming that two of theirs had done in five years and with a few thousand dollars what hundreds of physicists with billions of dollars haven't been able to

do in forty years. A little team spirit is a good thing, but this was ridiculous. Back home, I was lecturing my physics students on the absurdity of the Fleischmann and Pons claims while their chemistry professor was excitedly expounding on the importance of the Utah result.

There are many lessons from this episode. First, scientists themselves are often poor judges of the scientific process. This isn't as surprising as it seems, since their training is purely technical. Many don't appreciate the seriousness of violations of procedures, such as giving a press conference before publication. More surprising, many took Fleischmann and Pons's incredible conclusions about their own work at face value, even before reading their paper.

Second, scientific research is very difficult. Anything that can go wrong will go wrong. For instance, Fleischmann and Pons forgot to stir their cell while measuring its temperature, thereby totally invalidating their measurements. Stirring is a routine procedure, taught to freshman in their first heat experiment, but neglected by a Fellow of the Royal Society working with the chairman of the Chemistry Department of the University of Utah. This isn't to criticize their professionalism; it would happen to any small group working in isolation on a fixed idea. No one, no matter how experienced, can do a complex experiment without the guidance and criticism of others. Isolation is the death of science.

Third, science isn't dependent on the honesty or wisdom of scientists. As a collective enterprise, it rises above individual shortcomings. It will survive Fleischmann and Pons, but only after the wasteful expenditure of hundreds of man-hours of work and at least one death."

The third conclusion is worth thinking about. Science is a collective enterprise with more or less well established rules of validation. One of these rules states that, in principle, theories guide but reproducible experiments decide. That does not mean that irreproducible experimental observations, reported by qualified people, should be ignored. In the present state of its history cold fusion research is guided by not-always-reproducible experimental observations. All by themselves such observations are not in conflict with theoretical models, they are in conflict with other observations. Conceptual conflicts appear when attempts are made to explain experimental data. The model of two fusionning nuclei, for example, is in conflict with the well established theory of tunneling effect. Attempts to interpret irreproducible "excess heat" results turned out to be counterproductive.

History of the excess heat discovery would probably be very different if the phenomenon were labeled as "anomalous heat," rather than "cold fusion." Premature interpretation, implied by the term cold fusion, combined with highly unconventional press release, were partially responsible for the prevailing attitude toward Fleischmann and Pons. But all this would probably become inconsequential if experiments became widely reproducible. Promoting technological applications of irreproducible science does not make any sense to me. The emphasis, at this time, should be on science not on technology. Scientifically unjustified claims of "great inventions" hurt the reputation of honest research. I do not know why a working model of a "free energy" device is not required before a patent is granted to an inventor.

What will do more harm to real cold fusion research, scientifically unjustified claims or negatively-biased attitude of scientific establishment? Inventors should respect scientific explanations, editors of our journals should not deny the peer review process to qualified cold fusion investigators. As a novice-part-time-cold-fusion researcher I would like to dissociate myself from those whose claims are not validated. Saying that something is a cold fusion device, without giving any evidence for it, makes no sense to me. What would be the best evidence? Working devices independently produced (as described by inventors) in at least two or three shops. Theoretically inclined people will certainly find ways to explain reproducibly performing gadgets. Emission of alpha particles, neutrons or gamma rays, from an apparently non-nuclear device, would also be a strong indication that something highly unusual is taking place. Words and promises alone, like "gold from carrots" or "cheap hydrogen" from water, are not sufficient. When will the iESiUSA devices be available on the marketplace? Why is there so much secrecy about them?

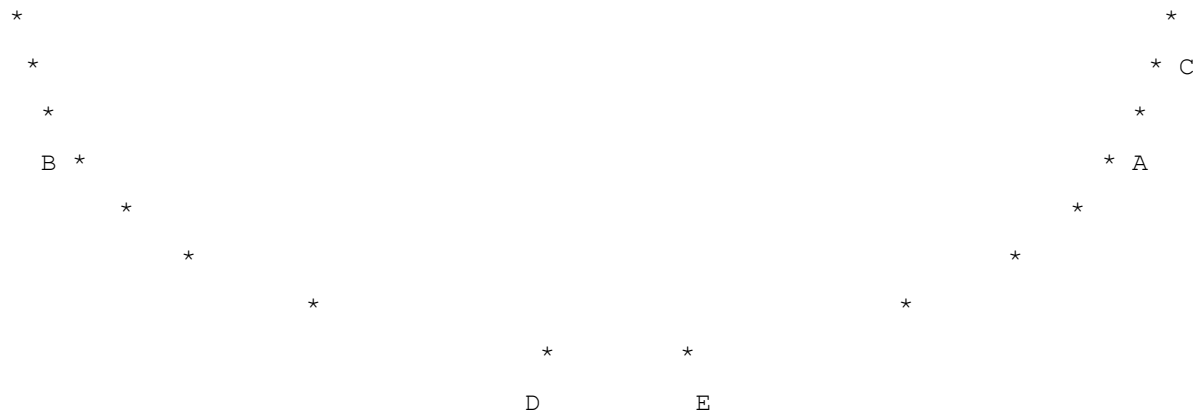
233) Free energy

Ludwik Kowalski (5/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The term “free energy” is often used to describe gadgets presumably delivering more benefits than seems to be possible according to laws of physics described in our textbooks. Some refer to it as zero point energy, vacuum energy, black matter energy, etc. How can this concept be described to a layman? One way is to use a simple hypothetical illustration. Imagine a valley between two mountains. The slopes are covert by ice and an object is placed at a point A as illustrated below.



It starts sliding down gaining speed. Then it slides up loosing speed. Without friction it would slide to the point B (located at the same elevation as A), then back to the point A, then to B again, etc. etc. That is an ideal situation. In reality some friction is always present and consecutive round trips would become shorter. This happens because mechanical energy of the sliding object decreases and is converted into thermal energy (heat). The assumption is that no external energy is supplied. Under that assumption our object would never slide above the elevation AB.

But suppose that some energy is received during each round trip, for example, from a push (or blow of air) at the bottom of the valley. It is not difficult to imagine, for example, that pushes occur only when the object travels from D to E. In that case the object will be able to slide higher and higher during consecutive round trips. The same result would be observed if chemical energy, for example, in the form of fuel, were used to gain additional speed during each cycle. The mechanical energy gained can be used to perform some useful work, or to generate some heat. Free energy is similar to synchronized pushes and blows (in the above illustration) except that it cannot be identified with any known source or agent.

Now consider an inventor who invented a device that, according to a patent description, delivers excess energy at a steady rate. He is selling shares for the device and people buy them. Why do they buy shares without seeing a working device? Because they think that the claim is valid. The patent granted to the inventor is the basis of that belief. Naive investors assume that the patented device have been examined by experts; they do not know that working models are not required by patent laws. My impression is that even impossible-to-build devices can be patented, provided they are new. A patent is not a guarantee that a device will perform as described, it is only a document whose purpose is to protect the inventor, if the device turns out to be successful.

The law of conservation of energy, also known as the first law of thermodynamics, makes a clear distinction between what is and what is not possible. It tells us that some energy must be responsible for the excess heat or excess work. In the case of cold fusion that energy is believed to be thermonuclear. The best proof of this, from the scientific point of view, is accumulation of helium at the rate commensurable with excess heat. Unfortunately, that proof has not been accepted as valid by all scientists who evaluated cold cold fusion recently, on behalf of the DOE.

My impression is that the term "free energy" is used to provide a justification for perpetual motion devices of all kind. Entering this phrase into Google I had 962,000 hits. By adding "Antigravity" I got 17,800 hits. Adding "paranormal" I got 595 hits. In one of them I found this promotional description (by Tom Valone):

". . . Now at the start of a new millennium, new technologies are emerging that create "'free energy' (electricity without an electric bill), 'free propulsion' (drive for miles without paying for fuel) and 'anti-gravity' (leaving the surface of the road while you are driving). With diagrams, pictures, and video clips, this report details electrogravitics, inertial propulsion, free energy, magnetic motors, N-machines, the Searle effect, the Hutchinson effect, nuclear batteries and much more. Learn what these 21st century technologies will allow you to do. See demonstrations of anti-gravity and inertial propulsion that defy explanation. Become an expert on the new realities of free energy. K401 • VHS Video Tape • 90 min • $24.95 " As you can see, the term free energy a justification for all sort of science-fiction devices. The impression I got was that authors of most messages have no familiarity with conventional science.

Some authors, on the other hand, try to explain free energy in terms of physics that is too advanced for me. Instead of blaming authors for not explaining things I blame myself for not being educated enough. The net result is the same -- dissatisfaction. Those who really understand zero-point energy, for example, inventors, should be able to explain it, at least partially, to students and teachers familiar with basic physics. The "believe me; I know better" attitude is not helpful. Cold fusion is not the same thing as free energy. Cold fusion processes, when they becomes universally reproducible, will probably be recognized as nuclear reactions; free energy, on the other hand, is still a general mystery concept invented to turn impossible into passible.

What is being offered to the world by the iESiUSA company? Are they offering us cold fusion devices or a free energy devices? Unfortunately, as far as I know, no scientific explanations are available. Why is it so? Why those who were invited to see the demonstration do not share what they saw, and heard, with the rest of us? What do they think about emperor's cloths? Their silence is highly undesirable, as far as I am concerned. For the time being I have no other choice but to assume that iESiUSA devices, all three of them, belong to science fiction run on free energy.

234) About levels of complexity

Ludwik Kowalski (7/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I would like to describe a paper, "Physics and the real world," published by George Ellis in the most recent issue (July 2005, pages 49 to 54) of Physics Today. The blue text below consists of quotes from his article.

"Physicists reduce matter first to molecules, then to atoms, then to nuclei and electrons, and so on, the goal being always to reduce complexity to simplicity.....The extraordinary success of that approach is based on the concept of an isolated system. . . . The problem is that no real physical or biological system is truly isolated.....Consequently, reductionism tends to ignore the kinds of interactions that can trigger the emergence of order, patterns, or properties that do not preexist in the undergoing physical substratum..... Physics might provide the necessary conditions for such phenomena to exist, but not sufficient conditions for specifying the behaviors that emerge at those higher levels of complexity."

That is why biologists, for example, can do their job without knowing as much physics as physicists. Likewise, economists can do their job without knowing as much about human bodies as biologists or medical practitioners. And people can write programs in high-level languages without knowing what happens at the level bits and bytes. In principle, everything in the world depends on atoms but each discipline has its own laws (such as "supply and demand") and its own rules. One does not have to know chemistry to be a good cook. "Unique properties of organized matter arise from how the parts are arranged and interact, properties that cannot be fully explained by breaking that order down into its component parts. You can't even describe the higher levels in terms of of lower level language."

That is interesting. But let me emphasize that general rules of scientific methodology apply to all levels of complexity. The most basic rule: "theories guide but experiments decide" is valid not only in physics but also in chemistry, biology and economics. Experimental data gathered by qualified researchers should never be rejected on the basis of discrepancies with existing theories. Another basic rule is equally important. It states that experiments should be reproducible. Only reproducible experiments should guide us. That is why situation in cold fusion is so tragic. After sixteen years we still do not have a single everywhere-and-every-time reproducible nuclear signature associated with a chemical process. And we know what effect will it have on mainstream science when those of us who take some irreproducible results seriously are no longer alive. Discovering essential "hidden realities" behind such results should be the first priority of researchers. Promoting a practical application makes no sense unless the underlying phenomena are reproducible.

"Many lower-level states could correspond to the same higher level state. Higher level states are thus relatively insensitive to details of the lover-level states of a system. ..... When I move my arm, for instance, it moves because millions of electrons attract millions of protons in my muscles. ..... Laws of physics beget laws of chemistry, which beget laws of biochemistry, and so forth. But conversely, higher-level variables can control what happens at the lover levels. When I move my arm, for instance, it movers because I have decided to move it. My intentions thus instruct many millions of electrons and protons to behave in certain way." ..... Similarly, social constructions drive what happens in our everyday lives. Rules and regulations govern health care systems, housing policy, and how games such as football and chess are played. Money, another convention..... is vital for constructing bridges, jumbo jets, and most other manufactured objects in our world."

After these introductory comments Ellis focuses on the role of the feedback control systems and on the limits of

physics. In the section about limits of physics he criticizes those who believe that "predicting human intentionality is difficult only because we don't know enough about brains to make the calculations. Physics is all there is. Despite its appeal to some, that kind of claim is an unprovable philosophical supposition about the nature of causality; the claim is without predictive power -- that is, no observable consequences follow from it -- and without experimental support. . . . Predicting probable outcomes of the working of the brain would be possible only if we were to take into account the higher-level entities that shape its outcomes -- including abstractions such as the value of money, the rules of chess, local social customs, and socially accepted ethical values. These kinds of concepts influence what happens in the world but are not physical variables -- they all lie outside the conceptual domain of physics . . . Furthermore, you cannot understand or predict a mind's behavior without taking into account its interaction with other minds."

How can one disagree with such observations? Life is much more than just physics. "We should also recognize that the enterprise of science itself does not make sense if our minds cannot rationally choose between theories on the basis of available [experimental] data. A reasoning mind able to make rational choices is a prerequisite for the discipline of physics itself." Ellis' observations can be applied to cold fusion. Unlike hot fusion, cold fusion is not a simple collision between two isolated positive ions. It takes place in metallic crystals. The level of complexity of cold fusion might be responsible for some of its reported peculiarities. This is often emphasized by theoretically inclined cold fusion researchers. They say that what is nearly impossible in low pressure plasma become possible in crystals. I view this as the effect of complexity similar to those discussed by Ellis. Cold fusion, practically impossible in an isolated system of two particles, becomes observable in condensed matter.

The irreproducibility of experimental results, however, cannot be blamed on collective effects involving millions of interconnected ions and electrons. It can only be blamed on our ignorance. "The higher, many-body levels are more complex and less predictable than the lower levels; we have reliable phenomenological laws of physics and chemistry, for instance, but not at the level of psychology and sociology. [Social aspects of cold fusion, due to unfortunate 1989 events, constitute another level of complexity. One has to deal with it to make progress] "Higher-level variables are often aggregates of lower-level variables, and determined by them. But [they also] reveal important properties of the hierarchy that are otherwise hidden." Yes, something essential, as often emphasized by Edmund Storms, is still not under control of experimentalists. I hope he is right in predicting that the discovery of hidden factors, probably by material scientists, will eventually lead to desirable applications of cold fusion. Trying to promote practical applications, without understanding what is going on, is likely to become counterproductive.

235) It was only one year ago

Ludwik Kowalski (7/9/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Due to collaboration with Dennis Lett (and his team) I was highly excited one year ago. I was convinced that their results, reported by me at the 11'th cold fusion conference in Marseilles, were the beginning of something that should turn the controversial field into just another area of mainstream science research. My findings were described in units #182, #183 and #184; they will also be described in the ICCF11 proceedings. What I did not know one year ago was the footnote that had to be added to my report at the stage of its galley proofing. Here is the footnote:

On May 2005 Ludwik Kowalski sent an e-mail message to Dennis Letts. He wrote: "I am going to galley proof our ICCF11 presentation in Marseilles. This puts me in an awkward situation. If I were reporting on my own work I would add a short paragraphs, something like this: 'No additional experiments were conducted to confirm observations reported 6 months ago. The unexpected delay is due to . . .' But in this case I was only a messenger; you are real players. A reader is likely to be interested in the current status of our investigation. I think that it is not right to report positive results only and keep negative results hidden. Do you agree? . . ." The following reply was received several hours later.

"No additional experiments were conducted to confirm observations reported 6 months ago. The unexpected delay is due to the fact that experiments seldom work on a schedule. The MOAC had to be modified slightly to re-store design stability and precision. Also, we have not observed laser-triggered excess power since August 2003. Of course I agree [with your last statement] – since changing metals at the end of 2004, my success rate has been zero. This is compared to a success rate of 87% during the years of 2000–2004. Other than changing Palladium stock, I don't know what has caused the sudden loss of the laser effect. Experiments have been conducted in a high quality calorimeter (MOAC), in a moderate quality calorimeter (my Avanti) and on the open bench. The laser effect has not re-appeared under any of the above calorimetric conditions.

Experiments are being conducted now to re-establish the laser effect or to explain why it stopped working. You may use this information in any way you wish, including an addendum. With regard to reporting negative results, consider this: Cravens and Letts discovered the laser effect in September 2000 and reported the positive results publicly in August 2003. We spent 3 years testing the credibility of our result before reporting publicly. We anticipate behaving in a consistent manner now – we have negative results but we're not in a rush to report until we're sure that we have negative results and try to provide some reasons why the results are negative. I believe that reporting results formally by 2007 will be consistent with our previous work and should not be considered 'keeping negative results hidden'."

I agree that one should not jump to conclusions too rapidly, and that negative results should be investigated as thoroughly as positive results. And I admire his courage to continue researching. Let me share another piece of disappointing information. On June 20, 2005 a reader wrote to me: "As far as I know, the only Japanese CF laboratory still in operation is Mizuno's lab. ..... Iwamura is closed down because of the opposition and because the company is in a crisis. Spring8 and some others are supposedly working to verify Iwamura, but I do not think this involves experiments. The other researchers have all retired as far as I know." Another line of cold fusion research, supported by Toyota -- Fleischmann's laboratory in Southern France -- also ended suddenly two years ago, in spite of presumably positive results. This was said to due to death of the supporter.

Iwamura's findings (see unit #123) dominated last two cold fusion conferences; they were said to be confirmed in other places (see unit #105), but not independently. Why did two automobile industries stop productive scientific research? Probably because they are more interested in short-term benefits from research than in its long-term scientific significance. Let me also mention Oriani effects. I started investigating them after the 11th cold fusion conference, as reported in unit #188. This work was also described in units #189, 192 and 197. Unfortunately, what was highly reproducible is no longer reproducible, as reported to me by Oriani three months ago. Like Dennis Letts, Oriani is not giving up; he believes that the cause of irreproducibility can be found. Somebody hinted that fluctuating solar activity might be correlated with negative results of some cold fusion experiments on earth. That is an interesting idea but its validation would be even more difficult than validation of cold fusion claims.

I have no doubt that researchers with whom collaborated in the last year (Jones, Letts and Oriani) are component and honest. That is why I am not yet discouraged by negative results. I still want to find somebody who can help me to produce a student-oriented cold fusion demonstration on the basis of a scientific research claim. Please contact me if you have something feasible, and not very expensive, to suggest. Keep in mind that my background is nuclear physics, not chemistry and not calorimetry. But I would be willing to work on an excess heat demo, provided the rate of generation of excess heat, at least 10 W, is significantly higher than the rate at which energy is supplied to the unit. Aside of this pedagogical project I would like to have a chance to observe an interesting research work and write about it at this website. My email address is <kowalskil@mail.montclair.edu>.

236) Promises promises

Ludwik Kowalski (7/9/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The iESiUSA website has an item that I do not remember seeing several days ago. It is a one-year-old paper entitled " Alternative energies are looking good again." The author, Michael Kanellos, is a writer. Here is the first sentence: "Companies promoting solar power and other alternative-energy concepts are rapidly attracting venture funding, research grants and, just as important, the interest of many of the tech industry's deep thinkers and influential figures." This is followed by comments on the oil crisis, terrorism and "Enron-related" blackouts in California. Then I see a section about enormous profits of companies that benefited from investments in new technology fields.

Contrary to my expectation, the article turned out to be devoted to technologies of photovoltaic cells; I expected it to shed some light on the iESiUSA technology. That is why I am disappointed. When will we hear from people who witnessed the June, 2005 demonstration in Edmonton? According to the Internet rumors, Martin Fleischmann was only one of several qualified witnesses. When will the revolutionary devices be described on the company's website? When will company scientists share with us what they understand? The longer I wait the more pessimistic I become about the three iESiUSA promises. As far as In know, it was a fraudulent claim. The company no longer exists and millions of dollars were lost by naive investors. Here is a quote from "Understanding Phisics;" by Kowalski and Hellman (a textbok published in 1978, by Dickenson Publishing Company). "Getting more out of a physical system than is put into it has been a persistent dream of humankind. Those who have tried to do this honestly -- by inventing their own 'perpetual motion' machines -- have invariably failed. The only people who have come out ahead in his area are those who claimed success and then got others to pay to see it. That it seems, was not difficult to do. In 1812 Charles Redheffer traveled through Philadelphia and New York, charging a dollar admission (a dollar was a lot of money in these days) to see his perpetual motion machine made up of wheels, gears, and pulleys which kept moving continually with no apparent source of energy. He did very well until someone discovered a little man in a back room turning a crank.

Another method of making money is to 'invent' such a device and then get people to invest in it. So gullible are some people, and so anxious to get something for nothing, that they will put money into all kinds of money-making schemes." The iESi company was certainly not the first instrument to get money from greedy people; and most likely not the last one. Even people who studied science are not always immune to preposterous claims. They know that many ideas that turned out to be good were initially rejected as nonsensical. The germ theory of disease, for example, was ridiculed when it was first introduced by Pasteur. Today bacteriology is an essential part of medical science.

Or think about Wright brothers' idea of airplanes. It was ridiculed by those who believed that only balloons "lighter than air." could fly. But the brothers did not give up and their persistence paid off. How can one deny this today when heavier than air machines fly all over the world? Dismissing an idea which seems to be in conflict with what is already known may or may not be justified. That is why scientists are often reluctant to reject unreasonable claims. Sometimes it pays off and sometimes it leads to disappointments.

Inserted on 7/15/07
Scientific people behind the iESiUSA technology are A.I. Koldomasov (from Russia) and H. Yang (from Korea). A set of essays, including my own, about their work can be found at:
http://www.rexresearch.com/koldomsv/koldomsv.htm .
This reference was sent to me this morning, from Google.

237) A very important report

Ludwik Kowalski (7/10/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I have several pieces of information connected with the story of current interest. THESE PIECES CONTAINED NAMES AND PERSONAL MESSAGES WHICH SHOULD NOT HAVE BEEN MADE PUBLIC. APOLOGIZG TO THOSE WHO WERE INVOLVED I AM REMOVING THIS INFORMATION NOW (7/14/05).

Added on 7/11/05:

I like the idea of making working iESiUSA devices available to independent investigators, as suggested in the report shown below. Peter is a leading theoretical cold fusion researcher and I think that his report is worth preserving; it will become an important part of history of science. The report is already a "very nearly public document." The blue text is his; black insertions, such as [*1] and [*2], are mine; they refer to comments that follow the report. As indicated above, Hagelstein's report was sent to me, and to other people, by Jed Rothwell.

"This letter is to provide a brief report on the iESi site visit that took place on February 13, 2005. This company has developed a new energy generation technology that is based on a highly unconventional approach, and I was requested to evaluate it to see whether I thought that it was suitable for investment purposes. As you know, I have been involved in research in the area of cold fusion for nearly 16 years, and was the conference chair of the Tenth International Cold Fusion Conference held near MIT in 2003. I was also involved in the recent DoE review of cold fusion that was held last year. This is relevant as the new technology developed at iESi appears to be related to, or make use of, cold fusion phenomena **[*1]** as the basis of its operation.

I note that a previous site visit was done, and that iESi provided a demonstration of their technology at that time. This earlier report provides a detailed description of physical parameters associated with the test. The numbers in that report are similar to the numbers presented to me during my visit, so I will not overly belabor points that were covered earlier **[*2]**. I was interested in understanding some of the issues about how the technology works, as well as understanding the level of expertise of the researchers involved. For example, measurements of current, voltage, temperatures, and flow rates are reasonably straightforward, and the effects under discussion are not small. It was possible to verify by touch the presence of a sizeable temperature increase, and one could see discharge phenomena consistent with the production of significant charge imbalances. Hence the basic claims of energy and charge creation correspond to massive effects that are readily observable independent of any of their diagnostics. **[*3]**

Real or Faked?

It would be reasonable to ask whether the results presented might have been faked in some way. The production of excess heat would require roughly a 4 kW heater somewhere in the flow stream, along with a power supply from somewhere to drive it. If someone wished to simulate a large heat effect by cheating in this way, it could have been done with the apparatus presented under the conditions of the test. Let me be clear that I do not believe it was, but this cannot be ruled out by any tests or observations that I made.

An electrical discharge was readily observable inside the cell. The breakdown strength of the cell and oil are likely in excess of 100 kV/cm, with breakdown clearly evident, and 2-3 cm distances involved. I would not be surprised if internal voltages on the order of 500 kV were present. Had one been determined to fake this, one could have put in a charge source somewhere in the flow stream, and then taken advantage of an internal Van de Graaf effect to make a discharge. Once again, I do not believe that this was done, but the possibility cannot be ruled out by my observations.

I note also that in the course of my review, essentially no scientific data was presented. In this I was disappointed. **[*4]** However, Professor Yang provided me freely with many helpful pieces of information that were helpful in learning about their work and observations.

Focus of the Review

It would have been a simple matter to determine whether their system operates as claimed if it worked according to well known operating principles that one could look up in textbooks. As the research effort involves cold fusion effects, there are no textbooks explaining basic operating principles. Nevertheless, there have accumulated a fair amount of understanding of cold fusion systems and how they work over the past 16 years, and my goal was to try to understand how this device might be operating based on previous knowledge of the field. **[*4]**

Hence, my approach to the review is as follows. Since some of the experiment is inaccessible the possibility of being tricked is ever-present (once again, I do not believe that iESi is engaged in tricking people. The ultimate defense against such things is for an independent lab to construct a version of the device themselves and see it work.), I wanted instead to understand what it is they did and what they saw. Instead of reporting on temperatures and voltages, which has been done previously, I was more interested in understanding what the device was doing and why, based on iESi's experience, it was doing it. I note that within the scientific community, scientists interacting with other colleagues on experiments usually learn about the experiments over time from discussions, from papers, from data, and from working with the experiment. Over the course of a one-day visit **[*5]** and review, it is not possible to come away with a complete understanding, but one can make every attempt to learn some of the basics of an experiment.

Essential Claims

To make life simple, I will boil things down to a small number of basic claims:

The iESi team claims that a very large amount of energy is being generated as its primary claim, and that energy gain on the order of a factor of five is observed at a maximum temperature on the order of, but less than 100 C. By itself, this claim would seem to be amazing, but it is actually neither unique nor overly interesting for applications. Within the area of cold fusion research, several groups have reported higher gains, or experiments where the gains could easily have been higher with minor design modifications. A heat boost of a factor of five might be interesting for commercial applications were electricity priced lower. **[*6].** Thermal to electric energy conversion below 100 C through conventional means is sufficiently inefficient that it would be difficult if not impossible to run the system with its own converted power done this way. Highly significant is the amount of power being generated, as there have not been previous reports of excess power generation at this magnitude. Even more highly significant is the power per volume ratio that one might associate with the working area of the cell, which is on the order of a few kW per cubic centimeter **[*7]**. similar to power generation densities obtained in cold fusion cells. I note that the iESi team claims that power gains of 20 or more can be produced with their technology.

Also claimed is a very high rate of reproducibility, approaching 100%. The system was demonstrated successfully three times during my stay in Edmonton. I have no reason to doubt that it is reproducible in their hands.

Perhaps the most significant claim is one of an ability to generate large amounts of voltage, current, and electrical power. It was claimed that the team had observed DC electrical power production at a level of 200 kW [4 Amps at 50 kV] with the device under consideration, with a much lower electrical input power. To support this claim, the system was run under conditions where rather memorable discharges were generated, and voltages between 10 and 40 kV were measured on an electrode that extended out from the cell. The discharges were seen to dig tracks through more than an inch of Plexiglas surrounding the active chamber of the cell, which is consistent with the presence of high voltage as mentioned above. I note that a device that can produce electrical power gain significantly greater than unity would be of large commercial value. The iESi team did not demonstrate such a conversion during my visit, but was building up toward such a demonstration for the near future. **[*8]**

Excess Energy Generation Issues

As discussed above, the excess energy generation claimed, and demonstrated, is on the order of a few kW with an energy gain of about 5 [thermal energy out over electrical energy in]. I asked Professor Yang how he thought that the system produced energy. His explanation involved ideas about proton-proton reactions, and that he was creating conditions similar to that in the outer part of the sun in the discharge areas inside the cell. I will not go into an explanation here as to why such thoughts are not going to be helpful (Professor Yang's area of expertise is in mechanical engineering) **[*9]**. Consequently, I came to the conclusion that while the research effort has discovered the effect, their understanding of what is happening is not very good. In essence, they have no relevant models for what is occurring within their cell **[*10].**

After reviewing their cell design, and after thinking about things, I have tentatively come to the conclusion that the basic operation of their cell is ultimately very similar (?) in many regards to that of a conventional cold fusion cell **[*11]**. The iESi design, viewed from this perspective, has present all of the elements that, according to my understanding of such devices, are required. There is fuel, there appears to be appropriate local matter conditions within the cell, and there is vibrational stimulation. Moreover, aspects of the operation of their cell appear to be consistent with such a picture. The cell appears to turn on and off in accordance with the presence of stimulation, as expected. A proprietary external stimulation increases the heat effect, also as expected. **[*12].** The cell seems to give a higher output at increased temperature, which is consistent with expectations associated with the availability of the fuel. Discussions about their experience with different local matter conditions appears to mesh with expectations. The power density associated with excess heat production appears to be very similar to those observed in a conventional cold fusion cell. The ``ash'' expected from this kind of experiment would be ^{3}He, and the iESi team is claiming to have observed ^{3}He from this kind of experiment in experiments elsewhere. **[*13].** My present view is that they probably are seeing a very large excess heat effect that works very similarly to other experiments in terms of mechanism, and that the design of the iESi cell in this regard is very good, allowing practical access of a high power operating regime which has not been reported previously.

Verification: Energy

One would always like certainty, especially in matters of science and financial investments. Thinking about things after the visit, I was wondering what kinds of things might be done in order to verify the energy claim. How can one be certain that it works as claimed? How could one prove that the device operates according to one principle or another? The normal way these things are done in more normal scientific circumstances is to do tests of one sort or another. For example, sending a test unit out to a trusted independent lab for an independent measurement of the energy gain would be a simple way to arrange for a confirmation. **[*14]**. A measurement of ^{3}He in quantitative measure to the energy produced would not only provide a confirmation of the underlying reaction pathway, but would provide an independent measurement of energy production. Simply measuring an anomalously large amount of ^{3}He would be provocative; as such an observation has so far eluded everyone that has tried within the cold fusion community (whereas quantitative ^{4}He has been measured in other experiments). There are a host of more subtle tests that can be done which could shed light on the underlying physical mechanisms. I would recommend that iESi seriously consider the possibility of an independent test in the relatively near future from a respected laboratory. Other tests and experiments should probably be part of a research effort devoted to understanding the device in the months and years to follow.

Charge Generation: Issues

The consequences of the appearance of electrical charge can be seen in the discharge effects associated with the experiment. I asked Professor Yang whether he understood how the charge was produced, and my understanding is that this has not yet been clarified in this experiment. Charge generation is known in association with cold fusion experiments. The effect appeared in a number of gas-loading experiments that I was involved in at MIT in the mid-1990s, and has been reported by some of my colleagues elsewhere **[*15]**.

There are several things that are interesting about the charge generation in the iESi experiment. The charges are probably generated with reasonably high associated energies. This I conclude from observations that Professor Yang reported in which voltages on the order of 1 MV were measured **[*16]**. In addition, the iESi team reports the observation

of a blue glow that can be seen in the oil and Plexiglas when charge is being generated **[*3]** when the lights are turned down. I was not able to see this effect during my visit, but the device was run during the daytime and there was no way to block incoming light from the outside. A nuclear radiation detector brought near the cell registered counts when the cell was running, but much less or none when the cell was off, consistent with the absence of accessible long-lived beta emitters in significant quantities **[*17]**. I asked whether they had attempted film exposure after their runs, and they had not done such a test. Apparently x-ray or gamma-ray measurements have been performed on the cells elsewhere, and a signal of some kind has been seen. One would expect a Bremsstrahlung signal in the presence of fast charged particles. It would be fun to see data of this kind.

In my view, this charge **emission [*18]** effect is probably real. I think that it is a cold fusion phenomenon that has been made to be dominant in this experiment. What is special about this device is that it has been pushed to maximize the charge emission effect **[*18]** so that it has become a primary reaction channel, such that it dominates the energy budget. This innovation allows for direct in-cell cold fusion to electrical energy conversion. **[*19].** This is really interesting, and probably makes obsolete other cold fusion electricity-generating technologies that require an external thermal to electrical energy conversion step.

Verification: Charge generation

The test that would have been nice to see would have been the application of the electrical output from the load to drive an electrical load. Such a demonstration is planned for the near future. Once again, the standard way that a confirmation is normally arranged for in scientific circles in such a situation is to arrange for an independent laboratory to run a test. There are a variety of tests that are possible that would help clarify the physical mechanisms involved, but these should more properly be part of a research effort devoted to understanding the device **[*14].**

Summary

The primary functionality claimed for the new iESi technology that I reviewed in Edmonton is excess heat generation and electrical energy generation. The level of power generation in the demonstration was several kilowatts for about 15 minutes, and an energy gain in excess of 5. **[*20]** . Higher power generation and energy gain was claimed in experiments carried out previously. The presence of high voltages was demonstrated, and the ability to drive electrical loads at high power levels (200 kW) with high energy gain was claimed in earlier experiments**. [*21]**. The usual route to confirm such claimed results would be to send a unit to an independent lab for verification, in this case, of the excess energy generation and electrical output.

The goal of my review was primarily to try to understand what they had done. Thermal and electrical energy generation in this device is due to new physical processes not found in textbooks. In my view the iESi team has managed to get the technology to work in spite of a lack of understanding as to why it works **[*22]** . The thermal energy generation appears to be closely related to energy generation effects reported in smaller scale cold fusion experiments, with a comparable excess power density, but with a much larger operating volume than done previously due to an innovative design. The electrical energy generation also appears to be closely related to charge generation effects **[*15]** observed in a smaller scale in cold fusion experiments. In the development of the device, the iESi team has maximized the efficiency of the charge emission, resulting in the direct generation of electricity without a need for external thermal to electric conversion." **[*23]**

My comments and questions:

[*1] Nuclear activity constitutes the essence of CF claims. I see not evidence of nuclear activity. Emission of X-rays, mentioned at the end is not necessarily connected with a nuclear process.
[*2] Who visited the company and when? Why is Peter assuming that the customer knows about that visit. Where can learn about these details?
[*3] I suppose that "charge creation" should be replaced by "separation of positive and negative charges," as in frictional experiments. How can a retired physics teacher miss an opportunity to make this correction?
[*4] I am also disappointed that "essentially no scientific data was presented." How can this be explained? The purpose

of the visit was to convince an MIT professor that technical claims are valid. Why was he treated as a layman by another scientist?
[*5] Who set up the time limit and why? If I had to travel from Boston to Edmonton I would request at least three full days.
[*6] Am I missing something or is there a typing error here? I am thinking about devices producing hot water in the areas where electricity is very expensive, for example, above the polar circle in Northern Canada or Russia.
[*7] Cubic cm of what?
[*8] Should we expect this to be done in several months or several years?
[*9] Yang introduced to investors (by the company CEO) as quantum physicist?
[*10] What part of the device is called cell?
[*11] Similarity is not a t obvious to me.
[*12] I suppose that, in this case, expectations are not based on a theory; they are based on what has been reported by other cold fusion researchers.
[*13] Was the rate of generation of ^{3}He consistent with the rate at which excess energy was produced?
[*14] Yes, this would be a normal way to convince, if one was certain that the claim is valid. Avoiding this way of convincing might indicate that they know that the claim is not valid. In my opinion a reliable operation of a device is more convincing that an attempt to explain its operation. Both components of convincing seem to be absent.
[*15] Is this a reference to generation of alpha particles reported by Jones, Lipson and Oriani? I would be happy place CR-39 detectors into their operating cell and look for presence of charged nuclear particles.
[*16] Voltages between what and what?
[*17] What kind of detector was it and what was detected?
[*18] Emission from where?
[*19] Yes, that would be highly desirable.
[*20] Was it excess heat or was it electric energy?
[*21] I am glad that Peter makes a clear distinction between what was actually demonstrated and what was claimed. I am also glad that possibility of fraud is not excluded by him.
[*22] Somebody would help them to understand science if a clear description of experimental facts were made available to other scientists and engineers.
[*23] Please, be aware that, according to Peter's message to me (see above), something has to be added at the beginning of the report. I guess it would be a reference to earlier inventions made by Russian researchers.

239) What is cold fusion?

Ludwik Kowalski (12/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Two physicists commented on unit #237; they asked for anonymity. Yes, I will respect such request, except in situations in which statements are "already very nearly public." One physicist made an interesting observation about a simple way of convincing others that a very large excess heat, in the iESiUSA device, is real. That device consists of circulating fluid (water, or oil). What can be more simple than to compare the temperature of a unit volume before the cell and after the cell? That would show how much heat is generated.

James Joule would insist on this kind of test. I am thinking about his experiments at Niagara Falls (comparing the temperature of water after the fall with the temperature before the fall). In the case of the iESiUSA device, the task should be much easier, because changes in temperature are said to be much larger than a fraction of a degree. Those who were invited to witness the device demonstration -- "Hagelstein, Fleischmann, McKurbe, etc." -- should have asked for a calorimetric test. If I had a large excess heat device to promote I would certainly make such test an essential part of a demonstration. The costs would be negligible in comparison with other investments. And I would not be secretive about the demonstration; I would not ask invited guests to sign an NDA (a legal non disclosure agreement).

2) The 11th issue of New Energy Times,

http://www.newenergytimes.com/news/NET11.htm

published yesterday, has a link to the result of a recent survey conducted by Peter Gluck and Steven Krivit:

http://newenergytimes.com/Reports/2005GluckKrivitSurvey.htm

It is an interested compilation of answers to the following four questions: (a) What Is cold fusion? (b) How Does It work? (c) What chances does it dave to be scaled up to a technology? and (d) What must we do in order to attain this? Here are some answers to the first question.

I wrote that cold fusion (CF) "is protoscience claiming that nuclear activities result from some chemical processes, such as those taking place in electrolysis, or when hydrogen ions diffuse through some solids." **Gimpel** wrote: "Electrolysis and other chemical processes can supply enormous pressure that compresses and crowds atoms. It can also supply very energetic particles (electrons, protons, and deuterons from heavy water) near the surface of the cathode of electrolysis for example. Some of these particles find there way toward the nucleus of neighboring atoms. If penetration is deep enough, there is remote possibility (but a reality how ever small) that the particle may find itself on the other side of the coulombic barrier."

And **Li** said that CF "is a kind of a nuclear reaction inside the condensed matter at low energy. It is a nuclear reaction without strong neutron or gamma radiation." **Biberian**, just next to me on the list, puts emphasis on the excess heat. "During loading of metals like palladium with hydrogen and-or deuterium, under some unclear conditions, more heat is produced than energy introduced in the system. This occurs in such a way that chemistry or other traditional

reactions can be excluded. The only alternative being nuclear reaction." According to **Spaandonk** CF is "any process generating heat beyond normal chemistry, &/or resulting in transmutation of elements, that happens at near room temperature." **Haffner,** on the other hand, mentions that heat may or may not be generated in "a loaded lattice environment."

These answers compliment each other. I am saying that CF is protoscience (because phenomena are not reproducible), Li puts emphasis on the unusual nature of reaction products while Biberian reminds us about unexplainable amounts of excess heat. **Dufour** writes that in cold fusion "the enthalpy is in the order of keV per atom, intermediate between chemical reactions (eV) and nuclear ones (MeV). This reaction has none of the characteristics of a nuclear reaction." **De Nino** writes: " In condensed matter the coulomb barrier is modeled and weakened by the dynamic of the plasmas of palladium d- electrons and deuterons. Such a mechanism envisages the existence of a threshold in the deuteron concentration in order to sufficiently modify the potential barriers.

The fusion between two deuterium nuclei creates an excited (hot) helium nucleus (2+2=4). In vacuum, this nucleus will break in pieces (^{3}He+n or T+p) that will carry away the excess energy, or, with a very lower probability, it can emit a very energetic photon (gamma ray of 24 MeV). In condensed matter, however, the electromagnetic fields acting in the medium can drown away the energy of the excited nucleus and convert it into thermal radiation. It is worthwhile to note that here we are talking about classic electromagnetic fields, not about quantum fields, that is, many low energy photons instead of one high energy photon, such as a gamma ray." **Storms** defines cold fusion as "the initiation of various nuclear reactions within special solid structures without the need to apply an amount of energy normally required to overcome the Coulomb barrier." **Lietz** thinks that biologically assisted nuclear reactions, reported by some researchers, are part of cold fusion.

T. Chub writes that cold fusion "combines mainly nuclear physics, condensed matter physics, and surface science, but also includes inputs from physical chemistry and thermodynamics, quantum mechanics, atom Bose condensate studies in optical lattices, etc." Likewise, **Beaty** thinks that "there may be more than one fundamental energy-producing phenomenon involved." **Kozima**, for example, thinks that cold fusion reactions are due to neutrons. **Miles** puts emphasis on "coherent field effects provided by the solid state" while **Gluck** thinks that the field "is immensely complex and difficult to comprehend. .....[It is] nanoscience at its best and worst." And **Krivit** starts answering the question by saying that "Cold fusion is clean nuclear energy."

239) A dangerous cold fusion identity theft ?

Ludwik Kowalski (7/4/15)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Tonight I sent the following e-mail message to about 100 members of the cold fusion community:

I was one of those to whom a message received yesterday was sent. A reader wrote: "I've tried to retrieve [without success] patents given on the iESiUSA web site:

<http://www.iesiusa.com/intellectual.html>

. . . Was anybody successful in retrieving any of the patents given on that website?" Replying to this another reader wrote: "iESi is in 'stealth mode' at the moment and not taking any inquiries . . . I have some, very limited, contact with them at the moment, though they are not giving me any answers at this time."

It is clear that researchers from the iESiUSA company are not using scientific methodology of convincing. Secrecy might be consistent with trade but not with true science, except in military research. To the best of my knowledge, cold fusion community is guided by rules of scientific methodology. That is why I think that we should disassociate ourselves from iESi claims. They say that their excess energy comes from cold fusion but refuse to justify this to our satisfaction. If we do not criticize them openly people will associate us with unpleasant consequences of making probably-not-valid commercial stock market claims. I feel that somebody is stilling our identity. How can we protect our reputation for honesty and hard work? Please write to me what you think about the iESiUSA claims. I would be happy to summarize your points of view on my CF website:

http://blake.montclair.edu/~kowalskil/cf/

And I would be glad to protect anonymity of those who ask for it. It is a serious matter; we are in a dangerous situation. Am I the only one who feels that way?
Ludwik Kowalski
P.S.
Items #216 and #226, #229, etc., on my website, are connected with iESiUSA claims, and with related patents.

The space below is reserved to replies. Anonymous senders will be identified by X. I will wait for at some messages before posting this unit. Then I will update it from time to time by appending additional messages, or comments about messages. Replies will be numbered to simplify referencing.

Appended on 7/13/05:

1) X wrote: Since there is no public discussion I don't feel it is necessary to start one. As far as I know they have approached the CF community (Hagelstein, Fleischmann, Krivitt). We could accept their way of operating, since this is indeed a very slippery terrain.

2) X wrote: It stinks; people promising great commercial benefits to investors should first demonstrate the setup.

3) X wrote: It seems to be a game with iESi shares at the highly speculative Canadian stock market.

4) Scott Little wrote: In my experience a significant fraction of the folks involved in CF research don't follow ordinary scientific methodologies. It does hurt the overall credibility of the field but that's pretty well shot anyway by now. I suggest you just distance yourself from those guys whenever the subject comes up. But don't go out of your way and make a big deal out of it. That would actually draw unwanted attention to them. If they've got something that works, we'll all find out about it soon enough. Meanwhile, if they don't want to play scientists, there's nothing we can do about it. (BTW, judging from their stupid website, I'd guess they're all smoke and mirrors).

Even we have not bothered to publish any papers describing our work. Basically we're looking for a successful commercial venture and, when the experiments don't show excess heat, we don't bother writing them up. However, I am planning to write a paper describing our new flow calorimeter and submit it to Review of Scientific Instruments. I hope such a publication would attract some people to submit their cells to me for evaluation. (1406 Old Wagon Road, Austin TX 78746).

6) John Coviello wrote: Given the history of alternative energy, which is littered with exaggerated claims and broken promises, iESiUSA's claims of a revolutionary energy technology based on a creative use of the cold fusion reaction must be greeted with deep skepticism by cold fusion proponents (as much as we'd all like to see it work). Cold Fusion proponents do not want to be associated with iESiUSA if they are ultimately proven to be a fraud; it would be a setback for the field of cold fusion. Therefore, until more concrete scientific evidence is provided to prove their technology works as described, iESiUSA's claims must be treated with a healthy skeptical approach.

It is troubling that iESiUSA is taking the path of secrecy and limited demonstrations. These are hallmarks of fraudulent technology schemes of past decades. However, since a revolutionary energy technology that would replace the current fossil fuel energy regime would be literally worth Trillions of dollars, it is somewhat understandable that a company, such as iESiUSA, would want to keep their technology secret until they are ready to go commercial with it. It is encouraging that they have invited credible scientists to review their technology, even if they aren't revealing all that they need to reveal at the moment to prove it beyond a doubt. I guess it is best to treat iESiUSA as just another alternative energy company making an unproven claim, until they give us reason to think otherwise. I would be in the camp that advises ignoring them until more substantial evidence or a commercial product is provided by the company. There is no harm in ignoring them, but there would be harm in endorsing them prematurely only to find out later that they are frauds.

7) Jed Rothwell wrote: Do not worry about iESi. Every year, dozens of strange secretive groups pop up claiming they are doing cold fusion. This has been happening since 1989, but it has not hurt the reputations of actual CF researchers. You are correct when you say iESi is doing business-style R&D, not academic science. The people at iESi would agree with you. I doubt that any substantial progress in CF can result from secretive research, because I think not enough is known about the basic physics yet, and we are still at the stage when fully open, traditional academic science is called for. Perhaps I am wrong about that . . . we shall see.

The iESi claims may actually be real. It is impossible to judge today, but we might find out 9 months from now, when the secrecy period for the latest patents expires. Some of the people who have visited iESi have been impressed, although not so impressed they are willing to say with certainty that the effect is real. Obviously that will have to wait for independent replications.

8) X wrote: I was not aware that cold fusion community had many recognized intruders who did not use scientific ways of validation. Are the episodes of criticizing them recorded somewhere? Books about cold fusion focus on its conflicts with mainstream science; they do not mention, as far as know, conflicts within the CF community. That is why one is inclined to think that the iESi episode had no precedents.

9) Dennis Cravens wrote: I know that others have said iESi has claimed cold fusion events, but I never saw anywhere where iESi have made such claims. (for example I have seen allegations by Clem that iESi claims cold fusion, but nothing from iESi about it). I do see where iESi has said Yang has worked on cold fusion systems. I do not see where they have claimed that they are making excess with a cold fusion system. Having been in this game a long time I know that there is often a big difference between what is said about you and what you say. I see all kinds of comment about iESi from you but I have yet to see any link to iESI where suchCF claims are made. Perhaps they have made such claims, it is just I see not primary evidence that they have. I see all kinds of patents about H generation and such but nothing to the CF point.

I will wait for evidence before I judge them. Right now it just looks like rumors and talk about them from others. I have asked both iESi and those who have visited the lab. I get no information. Perhaps they say nothing now because they are still working and verifying and do not what to misslead anyone. I think it is best to just wait for a report by them and ignore the rumors by others. If it is real it will eventually come to light. Even the so called visit reports are not posted by those that visited the site but by those that have not. If it is just talk by others who do not know what is going on - it will pass.

Appended on 7/16/05):

X wrote: I hope to see a proper scientific presentation of aspects of the work in an appropriate forum in the near future.

Ludwik Kowalski wrote: No scientific ways of validation of hard to accept claims has been offered. That is why I agree with those who suspect fraud. Another reason for being suspicious is based on putting myself in a position of an inventor who, without understanding basic science, was lucky to invent and build a highly desirable, and not very complicated, device.I am thinking about an invention similar to that of Volta or Roentgen. How would I proceed to benefit from the invention? Suppose that several million dollars have already been gathered from inventors; as posted on the iESi website. Being absolutely certain that my claim is valid I would sell one or two devices to a reputable firm; such firm would certainly not hesitate buying a device if a very strong “money back” guarantee was offered. The guarantee would state that “the device will work as described for at least one year.” Immediately after that I would apply for a patent. An application based on the working model would certainly be granted. Then I would start looking for new investors. Such strategy would work much better than promises on the iESi website.

I do understand why an inventor might want to keep things secret before being protected by a patent. If I were a “quantum scientist”, as Yang and Cho are said to be, I would probably start thinking about Nobel Prize, the ultimate scientific recognition. This would motivate me to write a paper, perhaps in cooperation with a more qualified scientist. The paper would be submitted to a reputable journal, such as Physical Review. Knowing about working models (and possibly given a chance to communicate with independent users, reviewers would be convinced that experimental data are not based on “wishful thinking” only. Perhaps such work is in progress. But seeing no evidence I prefer to remain skeptical. Yes, seeing “a proper scientific presentation” would be very helpful. But nothing would be more convincing than lasting financial success, based on well performing devices.

P.S.

iESiUSA is not the only company promising to deliver very attractive clean energy devices without telling us how they are supposed to work. For more information go to this website:

http://www.zpenergy.com/modules.php?name=News&file=article&sid=1357

You may also click on the ”published” link there to see how little the company has to say about the product that is said to be nearly ready for commercialization. I see no attempts to validate the too-good-to-believe claims. Being a physics teacher I am highly dissatisfied.

Captured from www.iesiusa.com on 24 Oct., 2005

The intellectual capital within iESi consists of expert industry leaders in engineering, finance and marketing.

Patrick Cochrane – President & CEO

Patrick Cochrane has over 25 years of experience working in the Petro-chemical,Pulp & Paper and the energy technology industry. Prior to co-founding iESi, he founded and served as the chief operating officer of the engineering company Canadian Environmental Equipment & Engineering Technologies Ltd/Genoil Inc. in Edmonton, Alberta. In his career, Cochrane also held senior-level positions overseeing large industrial complexes & projects with water, petrochemical, oil and gas at Husky Oil, Daishowa Canada Co., Zeotec Ltd. and Fidinam Canada Ltd. Cochrane spent four years in the Canadian Armed Forces and attended Fairview College and the Northern Alberta Institute of Technology for formal training in industrial electrical technology and Power Engineering. He has authored numerous patents in the heavy oil industry, environmental and energy technologies. Cochrane was awarded a prestigious award form Cetac - West and nominated for the AsTech awards (Alberta Science and Technology Awards) in 1999 in Calgary Alberta Canada, recognizing his achievements in these areas.

Ronald Foster –Vice President of Business Development >BR> Ronald Foster is a co-founder of iESi and currently serves as the company's chairman of the board of directors. His primary responsibilities include finance, compliance and business development. In his career, Foster has held a number of senior-level executive positions with several publicly traded companies, including ValCom Inc., SBI Communications, Inc., EL-Phills Inc., Golden American Network and ROPA Communications Inc. He created and produced "Stock Outlook 87, 88, 89", a video presentation of public companies through Financial News Network (FNN), a national cable network. Foster has a tremendous amount of experience with mergers & acquisitions and the operations of publicly traded companies. He founded and served as president of a publicly traded marketing company that had annual revenues of $60 million. iESi's Scientific Advisory Board consists of world-class physicists and scientists in the area of quantum physics.

Hyunik Yang, Ph.D.

Much of iESi's proprietary intellectual property is based on the numerous patents in the field of quantum and hydrogen energy generation authored by Hyunkik Yang, Ph.D. Dr. Yang co-founded iESi and serves as the company's chief scientific officer. In his career, Dr. Yang also held positions as professor at Hanyang University and as senior research engineer at Hyundai Electronics. He has published dozens of international research papers on revolutionary quantum energy generation and anomaly effects of science. Dr. Yang has designed several new inventions in the field of quantum energy and cold fusion. Dr. Yang received his Engineering B.S. from Hanyang University in South Korea, and completed his Engineering M.S., Ph.D. and post-doctoral work at Columbia University in New York. He is a member of the American Society of Mechanical Engineers, Society of Automobile Engineers, Korean Society of Mechanical Engineers, Russian Academy of Natural Science, Korean CAD/CAM Society and the Korean Society of Machine Tool Engineers. Since 1987, Dr. Yang has been listed in the Who's Who in the World, and in the Who's Who in Science and Engineering since 1998. **Norm Arrison, Ph.D., P.Eng.**

Dr. Arrison is a senior scientist who worked for Atomic Energy of Canada Ltd. (AECL) at the Whiteshell Nuclear Research Establishment as a Research Officer and at Sheridan Park as a Design Engineer and rose to the position of being in charge of all safety systems for all CANDU Nuclear Reactors for AECL. He was first appointed to the Science Council of Canada by Prime Minister Trudeau and served from 1983-1986 at which time he was next appointed by Prime Minister Mulroney and served from 1986-1989. Dr. Arrison has authored several patents and been involved in numerous inventions, most of which have been related to the solving of environmental problems that make life better for people all around the globe. In his career, Dr. Arrison served as the director of research for Global Thermoelectric Power Systems, Ltd. and worked as an international consultant in the development of patented energy conversion processes that are utilized in Europe, Asia and Australia. He has consulted and helped develop specialized coatings products for specific industrial applications that are utilized extensively in North America and are gaining acceptance around the world. Dr. Arrison received his Ph.D. in Chemical Engineering from the University of Calgary. He is a member of the Association of Professional Engineers of the Province of Ontario and The Association of Professional Engineers Geologists and Geophysicists of Alberta.

Dumitru D. Fetcu, Ph.D.

Much of iESi's proprietary intellectual property is based on the 11 patents in the field of energy conservation, heat

transfer and waste heat recovery authored by Dumitru Fetcu, Ph.D. In his career, Dr. Fetcu has held positions as professor at the University Transilvania of Brasov in Romania and holds the chair of thermodynamics and fluid mechanics at that university's Department of Mechanical Engineering. Leveraging the new legislation that took place in Romania during the late 1980s, Dr. Fetcu founded the company Transterm. He is the author of two books and more than 60 publications in the field of heat exchange and heat recovery and has conducted over 45 scientific research contracts. Dr. Fetcu received his Ph.D. in thermodynamics from the University Transilvania of Brasov in Romania.

Board of Directors

Patrick Cochrane –President & CEO
Ronald Foster –Vice President of Business Development, Director, Board Chairman
Frederick S. Dornan –Director
Thomas Bugg –Director
Dr. Hyunik Yang –Director
- - - - -

iESi Ltd. - United Kingdom
Mark Boocock – Managing Director
Mr. Boocock has over 22 years experience delivering critical business systems and technical consultancy to blue chip clients across a range of sectors in the UK. After graduating in Computer Sciencess from the University of Glamorgan Mark commenced his career with BT. Here he developed a range of customer service and accounting systems used to run BT's then £20Billion a year business. In 1990 Mark joined Syntegra where he became involved in the development of Import Export systems for the British government. Prior to establishing iESi (UK) Mark held senior client & programme management positions with a global business service and consultancy provider. Clients have included major UK energy providers where Mark was closely involved with the de-regulation of the UK electricity market. Mark also co-founded a Facilities Management Company set up to deliver environmentally friendly cleaning and maintenance services to the UK commercial property sector and has interests in a recently established IT outsourcing business.

David Muxworthy – Marketing Director
After graduating from University in Bristol with a BA (Hons) Accountancy and Finance, Muxworthy a qualified Chartered Accountant started with Price Waterhouse with responsibility for the provision of audits to water companies; major banks and subsidiaries of major multinational groups such as Courtaulds, as well as many smaller and medium sized companies. David moved to the Welsh Development Agency in 1992 starting in Corporate Audit, undertaking independent reviews and appraisals on the operation and effectiveness of any aspects of policies, programs and procedures over the entire spectrum of the Agencies activities. In 1995 David became the agencies International Project Manager, Far East, with responsibility for attracting inward investment from the Far East (Hong Kong, Singapore and Malaysia primarily) to Wales. In 1998 David was promoted to Vice President, Business Development – Asia Pacific responsible for the smooth operation of the ASEAN office, based in Singapore, attracting inward investment from ASEAN and India, previously Hong Kong, China and Australia and growing indigenous Welsh business through joint ventures with ASEAN partners. David returned to Head Office in January 2003 to establish a division within the WDA responsible for attracting companies with converging technologies. This work took him into the Energy and ICT/Healthcare space and specifically the use of innovative technologies and services in delivering solutions for the energy and automotive industry. David is responsible for attracting a number of alternative energy companies to invest in Wales. More recently David has left the WDA to focus more closely on ICT/Healthcare and clean energy through his involvement with IESi (UK) Ltd.

Andrew Williams – Client Services Director
Mr. Williams is an experienced Chartered Engineer & Nuclear Engineering specialist, with a wide ranging but deliberate civilian & military career progression, built upon a strong foundation of engineering design & subsequently developed across a full spectrum of operational nuclear engineering & associated disciplines. His early experience as a Design Engineer with the United Kingdom Atomic Energy Authority, provided a springboard for his subsequent operational military career within the UK Royal Navy's (RN) nuclear submarine programme. His engineering credentials are also complimented by extensive Oceanography and Training Management skills developed during his

naval career. He has operational, engineering and safety management expertise in nuclear power electricity generation and marine propulsion technologies, coupled with an understanding of the impact of such technologies on the physical and in particular marine environment. Since leaving the forces in 2001 Andy has continued to develop his nuclear and maritime expertise, working in the nuclear safety, security, decommissioning and environmental management fields, again reflecting his interest in the sensible management of the Physical and in particular Marine Resource.

Hywel Rees – Sales & Partnerships Director
Mr. Hywel has over 25 years experience of servicing the needs of UK business and domestic consumers alike. After an early career in property sales and consultancy in and around South Wales, Hywel joined London based Merrill Lynch. At Merrill Lynch Hywel was responsible for looking after the relocation and housing needs of blue chip company directors throughout the United Kingdom. An opportunity arose back in Wales and over the next 10 years Hywel was able to grow his own corporate relocation company, SRMS Relocation. SRMS Relocation now provides services to blue chip companies and their staff throughout Wales and parts of England. Recently SRMS has taken over some of the provision of relocation work for the regional economic development authority whilst at the same time acquiring the largest competitor within Wales.

240) Helium is produced in spent CF cathodes

Ludwik Kowalski (15/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Searching for something else over the Internet I discovered an interesting paper published in 2002 by Robert Bass. That paper, a file in the pdf format, is automatically downloaded, as a pdf file, when one clicks on the first link that appears after the following URL is specified in the browser.

http://www.google.com/search?hl=en&q=donquixote%40radix.net&btnG=Google+Search

The title of the paper is "Five frozen needles CF protocol;" it appeared in Journal of New Energy, 2002. **6**(2): p. 30. The protocol is designed for a layman who, presented with data, would be convinced, with 95% certainty, than helium is produced in a cathode during the electrolysis (in a Fleischmann type cell). In the last paragraph Bass wrote: "I showed my one-page proof to an internationally reputable expert in Statistics and he agreed that it was correct and said that if the experiment turns out as I *predict* then he will give me a Certificate that the Confidence Level is that asserted and be willing to testify in Court as an Expert Witness that according to accepted principles of Statistics the preceding protocol is definitive as stated."

The emphasis in the paper is on statistics. But experimental details for the proposed experiments are worth paying attention to. The difficulties, as we know, are often in details. I see no evidence that the experiment has been actually performed by the author. Here is what would be required:

1) Having a strip-shaped cathode of cold-fusion-suitable Palladium. As emphasized by Bass, recognizing suitable cathode material is not a trivial task.

2) Loading the strip with deuterium up to a level of about one atom of ^{2}H per one atom of Pd. This task is also not trivial. Quoting E. Storms Bass lists four methods of measuring ^{2}He/Pd ratios.

3) Keeping the foil at the liquid air temperature till five main experiments can be performed (to minimize losses of ^{2}H due to diffusion).

4) The foil should be cut into five narrow strips, called needles. These needles should then be used in five nearly identical experiments (k=0, 1, 2, 3 and 4). The only difference between the experiments is duration of electrolysis, t_k=k*T. If T=2 hrs, for example, then the durations of consecutive experiments, would be 0, 2, 4, 6 and 8 hours. The difference of potential between the electrodes should be 17.7 volts (I do not know why) and the current should be kept constant. The k=0 experiment would be a control.

5) All five cathodes should be sent to a laboratory specializing in measurements of the amounts of helium, A_k. Using the results -- A_0, A_1, A_2, A_3, and A_4 -- one would calculate statistical parameters defined by Bass. Unfortunately, I am lost in the conclusive part of the paper. And I am puzzled by the fact that random errors, associated with individual A_k, are not being used in the analysis. Plotting A_k versus t_k, and showing the bars of A_k errors, is likely to be more convincing. I saw that kind of a plot in several cold fusion reports; the most recent was a paper describing a real experiment performed by Russ George.

The issue that Russ had to address was presence of helium in air. The challenge was to show that helium from air, or from something else, was not confused with helium from nuclear reactions in the cathode. Those who remember the 1989 DOE report know that absence of nuclear ashes (such as He), in the amounts commensurate with the amount of excess heat, was one of the decisive arguments against the claim of Pons and Fleischmann. The topic was discussed by pannelists of the second DOE report, several months ago. This time some of them were convinced that generation of He in cold fusion experiments is real.

Appended on 7/18/05:
The protocol described by Bass should not be viewed as applicable only to generation of helium. But the title of this unitis is "Production of helium." It is therefore appropriate to quote what Michael McKubbre wrote on that subject meny years ago. His paper on the subject is in the compilation of articles publishe in Infinite Energy. That compilation, a file named samplearticle.pdf, can be downloaded from <www.infinite-energy.com>. The method used by McKubre was not electrolytic; generation of ^{4}He was reported to occur in foils that were kept in a vessel filled with duterium (at high temperature and pressure). Here is the quotation:

". . . we submit a sample of gas from each of the cells for analysis to the mass spectrometer, a high-resolving, low-mass mass spectrometer. We're capable of separating the two masses of species, deuterium ^{2}D and ^{4}He.....On the monitor you see displayed, in fact, the mass spectrum from one of these samples. This is a relatively high level of helium-4. The peak here is the helium-4 peak, the deuterium peak would normally appear here; it's completely absent. This particular example shows 10.5 ppm helium. We compare the samples each day that we perform the analysis, we compare the samples of gas from the various active cells and blanks with a sample of room air, which we have measured many, many times and know to be 5.22 ppm. And we have some standards, which we typically use—that is, gas samples of helium in deuterium and argon which we submit to the mass spectrometer for the purpose of calibration.

The mass spectrometer simply sweeps a mass from low mass to high mass, in this case from 3.96 mass units to 4.06 mass units, which encompasses the range in which helium is to be found. In fact, this peak is helium, and deuterium D2 is to be found which will be found somewhere in this region. We use a liquid nitrogen cooled carbon trap in order to remove D2 so that we're able to see quite low levels of helium. We're accurate to probably 0.1 ppm helium and we can clearly resolve the presence of ^{2}D and ^{4}He. This spectrum is, in fact, the sum of a number of spectra that the mass spectrometer simply sweeps for the period of time that we pre-program, and this is the cumulative signal representing the integral of all helium which was present in the sample when we submitted it for analysis. To acquire this spectrum takes us about five minutes.

It's clearly not possible to produce helium from a chemical process. If we observe helium in our experiments it's either because it leaked in from the atmosphere—we can rule that out by the blanks that we do and the fact that the helium signal that we have seen is larger than the helium in the ambient. It's possible that the helium pre-existed in the sample and was simply released to the gas phase with long term exposure. We can rule that out largely because we've analyzed the catalyst that we're using and found that it contains no measurable levels of helium. The only possibility that remains, and remains to be checked, is that the helium is produced by a nuclear process. If the helium is produced by a nuclear process, then necessarily there will be an associated release of heat....."

Recognizing the major problem in the entire cold fusion field McKubre wrote: "One of the difficulties in the cold fusion field is the apparent apparent lack of replicability of experiments: many people performing the same experiment get apparently different results; different experiments performed in the same laboratory give apparently different results. So it's obvious that if you do the same thing you must always get the same result. What this is telling us is that there are some important parameters of our experiments that are not under our control. Some of them I know and understand, and still [we] can't control some of these parameters we don't know about yet. We just don't know what the process is that we are studying, so we don't know what parameters we need to control in order to yield a consistent result. An experiment which always gives the same result --can be performed in several different laboratories to yield the same result--would be very valuable to us, in part in helping to convince the remaining skeptical scientists in the world that there is a phenomenon to observe. But, in fact, in order to use the scientific method to observe scientific results, we have to be able to reproduce the results of our own experiments so that we can see what the effects of small

changes are on these experiments.

One experiment which has been reported to produce consistent and reproducible results is that of Professors Arata and Zhang, both of them are very, very experienced and very well recognized scientists in Japan. They performed a very careful experiment, reproduced it apparently a number of times in their own laboratory—producing both anomalous excess heat in fairly significant levels and helium-4 and, perhaps more interestingly, helium-3. The helium-3 to helium-4 ratio that they observed in their experiments is different from that in the air that we're breathing. Sufficiently different to indicate that there is clearly an anomalous nuclear reaction occurring. The difficulty with Arata and Zhang's experiment is that it's only been performed by them and only in their laboratory. What we're attempting to do here is to produce their same results with their apparatus and with their help. This is a collaborative effort between Arata and Zhang and the SRI group, to produce in *our* laboratory the same results as they have obtained repeatedly over the years, which would indicate that we have some degree of mastery over the experiment.

The experiment that we have running here, in fact, is relatively young; it hasn't been operating for very long. One of the difficulties with Arata's experiment is that it requires many, many months to produce a result, and quite literally we're not very experienced with Arata's methods, so we've had some difficulty getting his experiment set up and operational. Certainly, it's caused me to have an increased level of respect for Arata and Zhang's technical competence. They are very, very good scientists. Within a month or two, we hope to have reproduced their experiment faithfully and reproduced their result."

It should be clear that factors mentioned by McKubre are not at all addressed in the statistical protocol described by Bass. His protocol was not designed to deal with systematic errors; it was designed for experiments in which all uncertainties are due random fluctuations about mean values.

241) Simulating experiments described in unit #240

Ludwik Kowalski (7/17/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Important clarification have been made in inut #242. It was added after Dr. Bass commented on what is shown below. Please consider the next unit to be the continuation of this unit.

1) Introduction:
In unit #240 I wrote about a paper of Robert Bass. Since then I found that the peper can also be downloaded from the library at . Here I am summarizing observations based on computer simulations of experiments described by Bass. My cathodes, like his idealized cathodes are assumed to be made from a CF-suitable material. I was motivated by desire to verify Robert's statistical protocol. Instead of relying on his mathematical derivation I decided to use the brute-force approach -- the Monte Carlo method. Like Bass, I assumed that the only uncertainties result from random errors of measuring five quantities: A0, A1, A2, A3 and A4. These are amounts of helium produced in five experiments. The percentage errors. E0, E1, E2, E3 and E4, presumably independent of each other; are standard deviation for the corresponding value of Ak (k=0, 1, 2, 3, and 4). For example, if A2=1,000 units, and if the standard deviation associated with this result is 100 units then E2 =10%. I tested Robert's protocol and tentatively found it to be not reliable.

Let me begin by describing basic assumptions. Each atom of helium, produced from fusion of two atoms of deuterim is known to liberate 23.6 MeV of nuclear energy. Assuming that this energy appears in the form heat (and not photons of gamma rays) I know that excess heat generated at the rate of 10 watts ($6.24*10^{13}$ MeV per second) would produce $2.25*10^{17}$atoms of helium per hour. That quantity, helium generation rate, allowed me to calculate exact values of A_k for experiment durations of t_k= 0, 2, 4, 6 and 8 hours. The theoretical results were:

A0=0
A1=$0.45*10^{18}$ atoms
A2=$0.90*10^{18}$ atoms
A3=$1.35*10^{18}$ atoms
A4=$1.80*10^{18}$ atoms

The experimentally reported results are expected to fluctuate around these numbers and my Monte Carlo program confirms this, as expected. Sizes of fluctuations are controlled by changing desired values of E0, E1, E2, E3 and E4. The program can rapidly simulate thousands of measurements. Parameters of Robert's protocol are calculated, for each set of five measurements.

2) Bass' protocol:
Robert claims that, as stated in the abstract, his protocol was designed to "instantly reject any doubt that the electrical pulse was creating ^{4}He from some form of nuclear-chemistry process." A pulse is simply one case of the Fleischmann-like dc electrolysis going on for a fixed length of time. In unit #240 I wrote that those who actually performed experiments described in the paper used more convincing graphical displays. But that might be a matter of taste. The main issue has to with validity of the proposed numerical protocol. Would it be confirmed or contradicted by simulations of experimental results?

Robert's protocol consists of calculating three parameters (P1, P2 and P3) from available experimental data (from A0, A1, A2, A3 and A4). By definition:

P1 = 3*(A0 + 2 * A1 + A2 - A4) / 5

while

P2 = (A3 +2 * A4 -2 * A0 - A1)/10

Note that without random fluctuations of A1, A2 and A4, the value of P1 would be zero. This is simply a consequence that, under ideal conditions A2=2*A1 and A4=4*A1. My simulations, as expected, show that P1 approaches zero when bars of errors advance toward zero. This shows that P1 depends on precision of measurements of A1, A2 and A4. I find it strange that, according to the above definition, P1 is not affected by changes in A3. This conflicts with the idea that P1 is an indicator of the overall accuracy. Also note that P2, under ideal conditions, is positive. This too is a consequence of conditions imposed on durations of experiments. Once again I am puzzled by the absence of A2 in the definition of P2.

The third parameter is defined ambiguously; it involves k and Ak

$P3 = (1/3) * (Ak - P1 - k*P2)^2$

where k is the integer between 0 and 4. In what follows I will assume that (1/3) has to be multiplied by the sum of five quadratic terms, one for each k. In other words,

$P3 = (1/3) * \mathbf{SUM} (Ak - P1 - P2)^2$ (Bass confirmed this on 7/20/05)

Perhaps there was a typing error and the symbol SUM was omitted. Note that I am avoiding Greek symbols because they are sometimes changed into nonsensical characters over the Internet.

3) My results:
Simulated sets of five Monte Carlo experiments are always successful, by definition. Knowing this I calculated P1, P2 and P3 from the simulated values of A0, A1, A2, A3 and A4. The results from five simulated sets are tabulated below. The first four sets refer to situations in which E0=E1=E2=E3=E4; the valus of assumed percentages are shown in the first column. In the last set I used a mixture (mx) of arbitrarily assumed percentages: E0=3%, E1=12%, E2=7%, E3=30% and E4=4%.

%	A0	A1	A2	A3	A4	P1	P2	P3	sqr(P3)
1	0	4.59e17	9.06e19	1.36e18	1.81e18	-2.04e15	4.54e17	1.52e31	3.90e15
10	0	4.53e17	9.61e17	1.39e18	1.91e18	-2.04e16	4.88e17	1.52e33	3.90e16
30	0	4.61e17	1.09e18	1.49e18	2.31e18	-6.14e16	5.65e17	1.36e34	1.17e17
60	0	4.71e17	1.27e18	1.62e18	2.82e18	-1.22e17	6.81e17	5.48e34	2.34e17
mx	0	5.51e17	9.82e17	1.36e18	1.85e18	-6.14e15	4.61e17	1.36e32	1.17e16

I see that P1 is negative in all sets. This might be due to the suspected typing error (ommision of A2 from the definition of P1). Journal of New Energy, as far as I know, does not filter publications through the peer review process. The last column shows square roots of P3. In the published paper that parameter is labeled as sigma; it does not differ from P2 by as much as P3 does. According to Bass, the experiment is successful when P1<<P2 and when sigma<<P2/2. I cannot comment on these inequalities without knowing that published definitions do not suffer from typing errors. For the time being I simply observe that, in the 60% set, sigma is NOT MUCH smoller than P2. I am confident that the trivial Monte Carlo code (shown below) has no errors.

If I were asked to peer-review Robert's paper I would first insist on the removal of the ambiguity from the definition of P3. Then I would ask for the confirmation that printed definitions of parameters P1 and P2 contain no typing errors. If I were assured that definitions of P1, P2 and P3, in the Monte Carlo code below, are consistent with the protocol then I would suspect that the protocol is not reliable. My recommendation (to the editor of the journal) would be to

send the manuscript to a statistician able to examine the mathematical derivation of the protocol.

4) Final comments

a) My guess about the definition of P3, as used in the code, might not be valid. If this is true then I would like to receive the correct definition. It will not be difficult to modify my code and to generate a new table of simulated results. I would be glad to do this.

b) Note that Robert's protocol does not depend of explicit values of E0, E1, E2, E3 and E4. My results, on the other hand, show that relations between P1, P2 and P3 do depend on the imposed random fluctuations. This troubles me. But I cannot take anything seriously without being certain that definitions of P1, P2 and P3, in the Monte Carlo code, have no errors.

c) My Monte Carlo code, in True Basic, should be readable by a person familiar with programming in any procedural language, such as Fortran or Pascal. That is why I am listing the code below. Be aware that in True Basic exclamation signs identify comments. The tiny code was written to emphasize readability, not compactness. Comments concerning simulations would be appreciated.

242) Monte Carlo validations of two protocols

Ludwik Kowalski (7/20/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Be aware that his unit is the continuation of what was described in units #240 and #241.

1) After posting units #240 and #241, I wrote to Bass: "I want you to know that the two last units on the my CF website are based on your 2002 paper. Your comments will be appreciated, especially about how the three essential parameters should be defined in my description of the protocol. You will see that I suspect typing errors in the pdf file (your paper). In the immediate reply Robert wrote: " . . Moreover, it seems to me that you have entirely 'missed the point.'. . . In the version [of the presented to ICCF10, the formulae are concise and elegant. For all I know they may already have been published in some standard book, but the expert, (who is a 'household name' in the field of Statistics) who told me that my derivation was 'correct' did not give me any literature reference. Therefore I shall stick with my own 'de novo derivation from first principles' as explained sufficiently adequately in the Abstract to be verifiable by anyone who knows undergraduate calculus. To suggest that these rigorously derived formulae are 'unreliable' is ludicrous."

In a message received today Bob stated that all three parameters (P1, P2 and P3; see unit #241) were used correctly in my Monte Carlo code. My suspicion of typing errors, in P1 and P2, was not justified; my assumption that the summation symbol was omitted turned out to be correct. I will return to the issue of reliability later in this message. Before addressing that issue let me show another quote, also from the immediate Bob's reply.

"Ludwik, Thanks for pointing out what you have posted in your items #240 & #241 regarding my presentation to ICCF10 in August 2003. You once told me that you can post documents in MSWord or ".doc" format; therefore I would much prefer that you post the attached ICCF10 Abstract, which is a great improvement by Mike McKubre over my original 2001-published version (in that numerous constraints have been relaxed without detriment to the main idea). .....Also I would appreciate it if you would refer to this protocol as the 'Bockris/Bass/McKubre Protocol' or the 'Bockris-Bass-McKubre Protocol' because the main idea is something I learned from publications of John Bockris. Moreover, it seems to me that you have entirely 'missed the point.' ....."

2) Following the suggestion I am going to display the description of the BBM protocol in the appendix, at the end of this unit. You will see that it is quite different from the first protocol (described in units #240 and #241 and downloadable from the library at <www.lenr-canr.org>). For that reason I prefer to address the issue of validity of each protocol separately. I will try to do this a little later. Let me point out that the adjective actually used was "tentatively unreliable;" not simply "unreliable." Instead of trying to validate the protocol mathematically I decided to explore it numerically. What is wrong with this? A Monte Carlo simulation, if done correctly, is also a powerful tool of validation. Here is an illustration. Suppose a claim is made that by following an X protocol a person would be a casino winner, in a long run. To check this protocol one may decide to play many games and see what happens at the end. But that might be very expensive. Instead of following this approach one can play virtual computer games and see what happens at the end. Presence of a hidden error in the derivation of the protocol could be revealed by playing virtual games. But a reliable Monte Carlo code, like a reliable derivation, must be based on realistic assumptions.

The main issue, in this particular situation, has to do with my code, not with the idea of using the Monte Method of

validation. What is wrong with my code? What am I missing? I am going to discuss this privately with Robert. Expect to see my conclusion in several days...

3) Appended on 7/22/05:
Messages from Bass are interesting and useful. Our discussion is in progress; I will probably write my conclusions it in two or three days. Meanwhile let me make another general observation. According to what Robert wrote (see above), a layman is expected to "reject any doubt." Any doubt about what? That person, I suppose, knows the meaning of the term proportional; s/he should have no doubt that the term is used correctly when doubling, and quadrupling the duration also doubles and quadruples the amount of helium produced. But here are two questions that a critical thinker might really have:

a) Why should the stated values of A0, A1, A2, A3 ad A4 be taken for granted?
b) How can I be sure (after taking stated facts for granted) that helium was produced in nuclear reactions taking place in cathodes?

The purpose of statistical protocols, as far as I know, is not to answer that kind of questions. Such protocols are designed to deal with random experimental errors. For example, is a relation inferred from experimental data real or apparent (caused by randomness)? Robert's protocol, in step 9, mentions the confidence level of 95%. What does the concept "level of confidence" mean? Statisticians deal with samples but their pronouncements refer to populations from which samples are taken. Levels of confidence tell us how reliable such pronouncements are. Samples of larger sizes usually correspond to more reliable inferences than samples of smaller sizes.

The important point is that statistical protocols are used to validate statements about populations, not about samples. In the situation described by Robert samples (experimental values of A0, A1, A2, A3 and A4) are taken for granted. His protocol can then be used to validate the claim of proportionality. Is the amount of helium really proportional to the duration of electrolysis (under specified conditions) or is the inferred proportionality apparent? After all, other kinds of relations, such as quadratic, cubic or exponential, are also possible. In that context a statistical protocol could be useful. But questions (a) and (b) above are not statistical. I do not think that a statistical protocol would help me to answer them. To decide about (a) I would ask about work of other scientists; do they also observe similar facts? To decide about (b) I would ask about other indicators of nuclear processes, for example, about excess heat, or about tritium. Experimental data are usually easier to accept when they are consistent with confirmed theories. But, according to scientific methodology, theories should be justified by experimental data, not the other way around.

4) Appended on 7/23/05:
A newspaper may refer to a confidence level while describing a gallup poll. Suppose that a random sample consists of 15,300 questioners collected from a very large population of potential voters. After using a protocol a statistician makes a prediction (an inference based on the sample) that the election will be won by X. The level of confidence, such as 95%, refers to a particular prediction about the entire population; it does not refer to the sample.

Suppose that 8307 of questioned voters said that they will vote for X. The statistician would probably assume that only a negligible error, if any, was made in extracting this number from the pile of returned 15,300 questioners. Numbers, like 15,300 and 8,307, are assumed to be exact. But the inference made from the sample might not be very reliable. In that respect the situation described by Robert is different. Each of the five numbers (five laboratory measurements: A0, A1, A2, A3 and A4) is always associated with random errors, such as 5% or 25%. The bar of error associated with a single laboratory measurement depends on the instrument used; it can be determined by a technician after performing measurements on many samples containing the same amount of helium. Systematic errors can be minimized, if not totally eliminated, through frequent calibrations of laboratory instruments. But random errors are always associated with results of single measurements. That seems to an important difference between samples of physicists and samples of sociologists.

Suppose the goal is to decide whether or not the true relation between the amounts of helium (A_k) and durations of electrolysis (t_k) is linear. That is an inference and the concept of level of confidence is applicable. Results of five laboratory measurements of A_k, when plotted against durations, usually do not fall on a straight line. That is why bars

of errors, associated with numbers, become important. The initial hypothesis is that the relation is linear. But then it is either accepted or rejected, acccording to known error bars. It is impossible to be 100% certain that the true relation is linear (or quadratic, cubic, etc.) when error bars are very large. Yes, I know that most readers are familiar with all this.

Before finishing these observations let me focus on another well known fact. Physicists make inferences about laws of nature. Such laws are either deterministic or probabilistic. The field of cold fusion has no laws; only working hypothesis, based on irreproducible data. Are these hypotheses deterministic or probabilistic? How can an error bar be associated with the result of a single irreproducible measurement? I do not know how to answer that question. But I can think about a similar situation in sociology. Suppose a survey is conducted to predict the result of an election. A social scientist uses a protocol and makes a statement that 57% (plus or minus 5%) people support X. The level of confidence of that inference, is said to be 95%. Then a scandalous revelation about X appears in the news and less than 1% of people actually vote for X on the election day.

Does this mean that the protocol was faulty? Not at all. The protocol is based on the assumption that the conditions influencing people to vote, one way or another, do not change significantly. Behavior of social groups becomes unpredictable when such conditions change frequently. Essential conditions on which successful observations of cold fusion phenomena, such as generation of helium, depend have not yet been recognized. Presumably these conditions change frequently without our ability to control them. That is how irreproducibility is usually interpreted by cold fusion researchers. In my opinion inferences (based on logically derived protocols, or on Mont Carlo codes, are useless when one is dealing with irreproducible data. Identifying essential conditions, and finding ways of controlling them, should be the number one priority of cold fusion researchers. Everything else, including attempts to commercialize "magic devices," should wait till experimental data become reproducible. Yes, I know that everybody knows this.

5) Appended on 7/24:

I have no doubt that both Robert's protocols were written under the assumption that experimental data are reproducible. That would certainly apply to generation of oxygen (rather than helium) during ordinary electrolysis of water. In one of my messages about the first protocol I wrote that the "much larger than" seems to be too vague to be associated with the single level of confidence. The reply is worth quoting.

Ludwik, Thanks for pointing out that there is some vagueness in the original 2002 Bockris-Bass-McKubre (BBM) Protocol <http://www.lenr-canr.org/acrobat/BassRWfivefrozen.pdf> as published in JNE by me alone, before Mike McKubre suggested the improvements in generality leading to our ICCF10 version [attached], which would benefit from clarification. I was tacitly assuming that any randomness in the errors is a Gaussian stochastic process. Also I should not have assumed that dA > 0 so I should have written |dA| instead of dA in the first test. In that case, if one accepts the approximate sample value of sigma as an "estimator" for the Standard Deviation sigma, then One Sigma gives a 68% Confidence Limit and Two Sigma gives a 95% Confidence Limit, and Three Sigma gives a 99.7% Confidence Limit, etc.So, my first test

```
|dA| << delta-A
```

should be understood as a preliminary test to ensure that sigma has a good chance of being a fair estimator, i.e. the "bias" dA should be negligible in comparison to the real quantity of interest, namely delta-A. Therefore by " << " I mean "an order of magnitude", i.e. I would HOPE that

```
        2*sigma  <  delta-A
```

and in order to claim that the confidence is much "greater" than 95% [as I said] one would HOPE that

```
        2*sigma  <<  delta-A  in the sense that 3.sigma/(delta-A)  <  1,  or
        sigma/delta-A   <  1/3  =  0.33
```

In retrospect, my 2002 paper would be more clear [since sigma & dA & delta-A all have the same dimension {in the original case, energy}] if I had formulated the conclusions as:

```
Test 1:
        (|dA|/delta-A) < 0.10   ==>   estimator of sigma is OK
Test 2:
        (sigma/delta-A)  <  1.00   [68.3% Confidence]
        (sigma/delta-A)  <  0.50   [95.4% Confidence]
        (sigma/delta-A)  <  0.33   [99.7% Confidence]
```

If anybody ever performs the BBM Protocol, then I would take that as an opportunity to similarly clarify the test at the bottom of the Bass-McKubre Abstract for ICCF10 [attached]; the reason for its lamentable brevity is that I ran out of space and didn't wan't to go onto a second page. ..... but my REAL intent is that any layman (like a Senator who had studied humanities & law) who can merely count on his or her fingers will need only to see a ROUGHLY linear fit to the data and instantly conclude that "this is not an accidental correlation; this is a physical Cause & Effect which should be further researched because of its self-evident immense potential benefit to humanity!" Thanks again for your interest, Bob

a) So much about the first protocol; I would be happy to check the validity of the BBM protocol (with another Monte Carlo code) after learning more about how to turn the inequality shown in the last line of the appendix into confidence levels of specific inferences.

b) Personally I would not rely on a protocol to convince a layman that a relation is linear; I would simply plot A,sub>k versus t_k. But that is only a matter of pedagogy and taste.

c) A relation, by the way, does not have to be linear; a positively exponential relation, for example, would likely to be more desirable, from practical point of view.

d) As you probably know, from the 2004 document at:

http://powermarketers.netcontentinc.net/newsreader.asp?ppa=8knpq_ZknqphiqYUok%22EN%26bfej%5B!

a Canadian company, iESi, made a difficult-to-accept claim: "The new clean energy plant will enable Norwood Foundry to generate six times (12 MW) more electricity than it consumes (2 MW) at its foundry located in Nisku, Alberta, Canada." Please write to me what you know about the present status of that plant, and about the origin of excess energy. I would be happy to post a unit containing what you write, unless I see a clear indication that the message is confidential.

APPENDIX:

Generalized Cold Fusion Demonstration Protocol

Robert W. Bass, Michael C. H. McKubre

==========

Greek mathematical symbols were changed (by Ludwik Kowalski) when the good-looking MSWORD document was turned into the web page. This was necessary to compensate for his limited familiarity with html tags. Saving the original document as a webpage produced a monster that was hard to edit. That monster displayed different symbols (in the same equations) when viewed in different browsers.

Lower case sigma was replaced by **SIG**
Capital sigma (summation) was replaced by **SUM**
Lower case delta was replaced by **DEL** (also note that **DEL**E stands for deltaE)

Lower case alpha was replaced by **ALP**
Lower case beta was replaced by **BET**
Lower case gamma was replaced by **GAM**

Multiplications are indicated by asterisks. In the inequality (LEFT << RIGHT), in the last line, the LEFT is simply either **SIG** or dE, depending which is larger. That what the max is for. The RIGHT, in the same inequality, is the product of **DEL**E by the smallest value in the {Ck} set. That what the min is for.
==========

This is a generalization of the protocol proposed by Bass [1], which is more realistically flexible in several respects. An arbitrary number N <= 3 of similarly prepared samples is allowed, and neither the voltage nor the current is required to be constant. However, the previous protocol may be recovered as a special case when N = 5.

Let N >= 3 denote the number of similarly prepared samples. Let the suffix k denote any particular sample, k = 0, 1, 2, ... , (N -1), where the suffix k = 0 is reserved for the case of a control blank. Let { Ck }, k = 0, 1, 2, . . . , (N -1), denote the hypothesized causal inputs, where, as in Bass & Gleeson [2], each Ck may be e.g. the result of continuous monitoring of the input electrical power [product of instantaneous voltage & current] and its numerical integration over the complete duration of the preparation of the kth sample to give the total amount Ck (0 of electrical work done on the sample, or the total energy input. By definition, C0 = 0. Similarly, let {Ek }, k = 0, 1, 2,. . ., (N -1), denote the measured effect outputs. Three possibilities for the output effects { Ek }are:

(1) Ek = amount of excess enthalpy;
(2) Ek = amount of Helium-4;
(3) Ek = amount of Helium-3.

Now define the estimator of variance **SIG**^{2} by the sum over all k of

SIG^2 = [1/(N-2)] * ({ (Ek - dE - Ck *(E)2 })

where dE denotes mean effect-bias error, and where (E denotes mean effect-increment factor. Next, again summing over all k, define

ALP = **SUM** { Ek },

BET = **SUM** { (Ek *Ck.) },

GAM = **SUM** { Ck },

DEL = **SUM** { (Ck)^2 },

and verify by setting to zero the gradient of **SIG** with respect to the vector [dE, **DEL**E]^T that a necessary & sufficient condition for sample standard deviation **SIG** to be minimized is that

dE = (**DEL***AL - **GAM***BET) / DENOM

DELE = (N***BET** - **GAM***ALP) / DENOM

where DENOM stands for the N***DEL** - **GAM**^{2}

The confidence in cause/effect correlation is great if

max(**SIG**, |dE|) << |**DEL**E|*min {Ck}.

243) Another rejection by Physics Today

Ludwik Kowalski (7/31/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Physics Today rejected my "Open letter to the DOE, and its team of 18 scientists." No explanation of any kind was given. That is not appropriate. I have been a member of APS for many decades and I find the absence of the explanation not appropriate. What did the reviewers say? Why did they decide not to publish my letter? They received my piece on February 7, 2005. Why did it take so long to decide? Here is the emailed letter of rejection (receive on 7/15/05): "Dear Dr. Kowalski, We have completed our review of your letter dated 7 February 2005, which you titled "Open letter to the DOE, and its team of 18 scientists." We have decided not to publish it. I apologize for the length of time it has taken to completed this review and get notification to you. Thank you for writing and for your interest in Physics Today. Sincerely, Marty Hanna Letters Editor Physics Today."

And here is my immediate reply: "Dear Dr. Hanna: I suspected that this would happen, considering the delay. Last time you mentioned that many people commented on the second DOE review. Are some letters to the editor, on that subject, going to be published? If so then when? Strange things seem to be happening in the cold fusion field; I continue observing them. After the retirement it became my full time occupation. I am considering going to the 12th international cold fusion conference near Tokyo. Too bad that my chances of sharing what I know and think can not be shared in Physics Today. I guess it has to do with factors that neither you nor I can control. Cold fusion is going to be remembered as a strange episode in the history of science. Best regards, Ludwik Kowalski" Will this letter, e-mailed more that two weeks ago, be answered?

My two questions were based on the reply I received on April 12, 2005, after asking about the status of my letter to the editor. At that time Dr. Hanna wrote: "Your letter, along with approximately 60 others that I currently have in house, is still in review. As soon as our review is completed, I will notify you of the outcome. Your continued patience is appreciated." I was happy that sixty readers of Physics Today had commented on the DOE report and expect to see some of them in print. I suppose that most authors were APS members with high credentials. Why did editors decide to block timely contributions? Those interested in other records of rejection should look at units # 154. I think that rejections of CF papers are worth recording, for benefits of future generations. Cold fusion will be viewed as an interesting event in the history of science, regardless of verdicts about validity of numerous CF claims.

My Open Letter to the DOE was posted in unit #196. In unit #211 I commented on what Charles Beaudette wrote about that review. His paper can now be downloaded from the Library at <http://www.lenr-canr.org>: I think it is worth reading and thinking about. Was Beaudette one of those whose letters to the editor were rejected by Physics Today? I do not know.

244) Coulomb barriers etc.

Ludwik Kowalski (7/30/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

A discussion list, CANA, has been created for members of ISCMNS (International Society of Condensed Matter Nuclear Science) four days ago. The purpose is to discuss scientific and technical aspects of cold fusion. Several interesting messages have already been posted. What follows is my own message. I hope that other nuclear physicists will comment on it. Will this generate some food for thoughts? I hope so. And I will write about this here, accordingly.

I read the paper recommended by Dennis with great interest. The phrase -- "the effective target area" -- made me think about the coulomb barrier. Why about the coulomb barrier when the bombarding particles are neutral? I will explain this shortly. But before going ahead let us look at something else. The 1 / v law, mentioned by the authors, implies that the apparent size of a nucleus depends on the projectiles with which a nucleus is bombarded. This fact has been known since the beginning of nuclear era. The unit of cross section "barn" was introduced to recognize unexpectedly large cross sections. In the first nuclear reactor (Fermi's pile, 1942) blocks of pure graphite were used to slow down neutrons to benefit from large cross sections at small v. Yes, most CANA members know this; but being a retired teacher I can not miss an opportunity for lecturing.

If the term "effective target area" is accepted then the term "effective coulomb barrier" should also be accepted. I am saying this because the height of the coulomb barrier and the size of a nucleus are intimately related. To justify this one must go back to the well known definition of the coulomb barrier, CB. Coulomb barrier is the value of potential energy (of two interacting positive particles) at a certain distance between their centers. The potential energy, V, consists of the sum of two terms, V1 and V2. The positive term, V1, called coulomb potential, is due to electric repulsion, the negative term V2, called nuclear potential, is due to attractive nuclear forces. The dependence of V1 on d (distance between the centers of two particles) is of the 1/d type, according to Coulomb's law. The dependence of V2 on d is usually much more complicated. In textbooks that dependence is often represented by deep potential wells.

Let me take a crude rectangular well (rather than a more realistic well introduced by Yukawa, by Saxon and Wood, etc.). In that model V2=0 everywhere outside a volume of radius R. At d<R the absolute value of V2 suddenly becomes much larger than the absolute value of V1. In other words, CB is the value of V1 when D=R. For many of you this hint is sufficient to see why CB would go down rapidly if R (the effective radius) were allowed to become larger. But let me illustrate this numerically for a two body system -- a Gd nucleus and an alpha particle. For a gadolinium R is close to 7.5 F. The potential energy of the system, at d>R, can be calculated on the basis of Coulomb's law (where k stands the familiar 1/4*Pi*epsilon-zero):

$$V = V1 = k*Z1*Z2*e^2 / d = 9*10^9 *2*64*2.56*10^{-28} / d$$

where d is in meters and V is in joules. In practical units (F and MeV) one has:

$$V \text{ (in MeV)} = 1.44*Z1*Z2 / d \text{ (in F)}$$

Replacing d by R=7.5 F, and knowing that Z1*Z2 is 128, one finds that CB = 24.5 MeV. A more realistic potential would give a lower CB, perhaps slightly below 20 MeV, but that is not important in the context of this message.

What would happen to CB if R were doubled? In that case the coulomb barrier would be reduced by the factor of two. The paper mentioned by Dennis refers to much larger changes in the "effective R" (several orders of magnitude). That, according to the above speculation, would nearly eliminate the coulomb barrier. Yes, I know that the speculation is silly; the value of R (beyond the region occupied by neutrons and protons) is determined by the range of nuclear forces. The large effective R, as far as I know, does not correspond to unusually large range of strong nuclear forces. Cross sections of nuclear reactions induced by charged particles, even for gadolinium, are never as large as for reactions induced by slow neutrons.

So what is the point of all this? In my mind this speculation is connected with the 1/ v law. That law describes cross sections induced by slow neutrons in the non-resonance regions of v. The common explanation -- "effects of interactions become stronger at small v because times of interactions become longer" -- does not satisfy me. Why not? Because i know that alpha particles approaching a nucleus, in central collisions, also have very small v. In fact, v becomes zero when the distance of minimum approach is reached (alpha particle starts bouncing back). That kind of slowing down does not result in high probabilities of fusion. Why do slower neutrons fuse much more frequently than faster neutrons? Why slowing down of charged particles (for example, at d<10*R) does not increase probabilities of fusion with charged particles? These two questions must be related. "Spending more time near the nucleus" should have the same effect on all projectiles, charged and uncharged.

I would be happy to know how to solve the puzzle without leaning on theoretical concepts beyond classical physics. Please, be aware, that I am not addressing the issue of tunneling effect; nobody ever tried to explain this effect, as far as I know, by using classical physics. But the explanation of the 1/v law, for example in the article chosen by Dennis, appears to be classical. That is my main point. Let me end with a quote extracted from the <http://focus.aps.org/story/v4/st29> article. "A slow-moving neutron spends more time near a target nucleus than a fast-moving neutron, so it is more likely to interact. That makes the cross section -- the nucleus's effective 'target area'--larger for slower neutrons." Thanks for providing this URL, Dennis.

A saying "one picture is often worth more than many words" is applicable. But CANA messages cannot contain pictures; they are for text only. To create a picture follow these steps:

a) Using the last formula above (and several values of d between 2 F and 20 F), plot positive V1 (in MeV) versus d.

b) On the same graph plot negative V2 versus d, according to a rectangular well potential. In doing this assume that R=7.5 F and that for d<R the absolute value of V2 is "moving toward infinity."

c) Calculate V = V1 + V2, for several values of d (also between 2 and 20 F), and plot V versus d, for example, in red.

The red curve will have a peak at d=R. The height of that peak is called coulomb barrier, CB. It is not difficult to see what effect a change in R should have on CB. For much smaller R, the CB would be much higher; for much larger R, the CB would be much smaller. Coulomb barriers are often compared with gravitational barriers associated with mountains and hills (as illustrated in Figure 1 of unit # 40, on this website).

245) What can be done to avoid a global disaster?

Ludwik Kowalski (8/2/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Discussing energy-related issues (on phys-L, a website for physics teachers) one contributor asked three questions. The replies posted by another teacher (see below) are interesting and worth showing here.

1) By how much would the emission of CO_2 etc. be reduced if 100% of US electricity were from nuclear reactors?

Not likely to happen. Currently we get over 60% of our electricity from coal and about 15% from nuclear. We would need on the order of 300 new nuclear plants to take over the coal burden. It is also the case that our energy demand for electricity is increasing (as a percentage of total energy use) even though the electrical usage is only on the order of 20% of total usage [actual values depend on whether you look at gross or net usage.] Even with the incentives of the new energy plan, it could be 10 years before the first new nuclear plant would be built.

2) By how much would the emission of CO_2 etc. be reduced if 100% of US vehicles were powered from rechargeable electric batteries (using nuclear electricity)?

Not likely because of the lack of progress in battery technology. Fuel cells (run on hydrogen separated by electricity from water) are a possibility, but current prototype vehicles run hundreds of thousands of dollars. There is the whole infra-structure, chicken & egg thing here too--you can't sell hydrogren powered cars (combustion or fuel cell) until there is a wide spread network of hydrogen 'filling stations' and who will build those if there are no hydrogen powered cars to buy the fuel.

3) By how much would the emission of CO_2 etc. be reduced if we used trains and busses instead of automobiles?

The infra-structure cost of mass transit (other than busses) is just too prohibitive to expect to see much happening without some kind of major federal program feeding billions of dollars into such a project. [New urban rail project go for 50-500 million per mile.] Getting people to ride busses is not going to be easy either. However, one CAN reduce gasoline usage by 30-40% just through car-pooling [70% of our driving is done commuting to work]. Agressive programs could do a lot with this without any infrastructure costs. However, there will be GREAT opposition to any reduction in 'driving freedoms.' We've built an entire culture (and a large chunk of our economy) based on the automobile, and moving away from such will be very difficult and disruptive to the economy (short term at least).

Conclusions:
For actual numbers the web. <http://www.eia.doe.gov/> is the place to find all the information you would need. The bottom line to all of this is that there won't be any quick and drastic cuts in CO_2 emmissions from the U.S. or from the world for that matter. Weaning our energy systems off of the fossile fuels (currently 90% of supply) will take 50 year at best and more likely will take most of this Century to accomplish. However, it is by no means certain that we can

actually totally replace our fossil fuel energy with 'green technologies' and even less certain that we could do this for 9 billion people all living at a 'western' standard of living. There are money, land usage, and materials problems with scaling up any of the current 'clean' energy technologies to really take over from coal, oil, and natural gas. . . .

Try one of my newer Energy Management Simulators to get a feel for the problem--see web site below.

Appended on 8/3/05:

The discussion is going on. Teacher #3 wrote:

Some discussion of energy reserves and the exhaustion thereof can be found at:

http://www.av8n.com/physics/fossil-resources.htm

which is based on a calculation that can be found at

http://www.av8n.com/physics/energy-reserves.html

This concludes that "switching to coal" is not much of an "alternative". Extrapolating current usage suggests that coal will last longer than oil, but not much longer .... and switching doesn't solve the main problem, namely exhaustion of the *total* fossil energy reserves. U235 doesn't change the story very much, either, because there's not enough of it.

IMHO this is a methodical and dispassionate analysis. If you disagree with the raw data, please provide better data. If you disagree with the method of analysis, please present a more-meticulous analysis. I've presented my evidence in detail. I see no reason to consider it a paranoid fairy tale. If you have evidence to the contrary, let's see the evidence.

And here is what Richard Tarara wrote to me in private, after I asked him if it is OK to show his name and affilation on the CF website.

You can use my name and affiliation AND my web page (see signature below). Actually, what my simulators and my class project seem to show is that we CAN change over to green tech on a 100-125 year schedule, at least some countries can. It will be expensive, but according to an economist (Kevin Laws--Pricilla's son) who frequents the PhysSoc list, not unreasonably so. The big problem for some will be land--Japan can afford the technology but has no place to put it. Western Europe can afford it, Eastern Europe has the land -- seems like a marriage proposal to me. Russia and India can't afford it.

The model is primarily one without a Deus Ex Machina--no cheap fusion (hot or cold)--no other rabbit from the hat [recognizing Nuclear as the only new energy technology of the 20th Century suggests the strong possibility that we are stuck with what we've got.] The scenario is to eliminate oil and natural gas in 100-150 years. Coal and Nuclear can play a role, but ultimately should be phased out as well. That leaves Hydro (minor contribution), Geothermal (likewise), Biomass (land intensive), Wind and Solar. The latter two must carry most of the load, but neither are energy on demand resources. In our model, besides the direct use of electricity from each, additional wind and solar sites are used to produce hydrogen which is piped (a $5 trillion infrastructure upgrade) throughout the country to be

used in place of natural gas, as a portable fuel (combustion or fuel cell), and perhaps to power traditional HIGH DENSITY thermal power plants. The latter would be very convenient in say the East Coast corridor with the high population density, but suffers from ending up at about 25% efficiency considering the initial output of the wind generators or solar cells then taken through the hydrolysis process, piped hydrogen to the east, then the 33% efficiency of a typical thermal-electric plant.

The bottom line for the U.S. is it will cost $200-400 billion per year and end up using maybe 20% of our land area to provide the current per capita energy levels (with corrections for efficiency and conservation changes) for a population of 450-500 million people. All that can be done with the will to do it. The model works for other areas as well--Europe for example--but fails in places like Japan, Indian, and Russia.

246) Manipulating nuclear decay rates

Ludwik Kowalski (8/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
The major controversy of cold fusion is whether or not nuclear processes can be influenced by processes taking place at the atomic and molecular level. The prevailing view, based on reproducible experimental data, is that what happens in atomic nuclei (containing at least 4 protons) cannot be influenced by chemical changes. The half life of ^{137}Cs, for example, is the same in chemically pure cesium, in all compounds of cesium, in atoms located in air, in the vacuum, in digestive systems of living organisms, or in sources located near crystal screens. It is probably the same for strongly ionized cesium atoms in our sun and other stars. That point of view has been challenged when the discovery of cold fusion was announced in 1989. According to Fleischmann and Pons, nuclear processes of some kind can be triggered by chemical processes taking place in some electrolytic cells. Other cases, contradicting the prevailing view, have been reported since that time. Two such cases are described below.

Microbial destruction of a radioactive cesium
Members of the International Society of Condensed Matter Nuclear Science (ISCMNS) now have a restricted Internet discussion list named CMNS. At the 11th International Conference on Cold Fusion (ICCF11, September 2004) a Ukrainian scientist, V.I. Vysotskii, presented a paper on microbial decomposition of radioactive cesium. This morning I referred to that paper in a reply to a message from another member. I wrote:

Thanks for the second message about the BT (bacterial transmutations). I have some questions and comments.

1) How do recognized authorities in microbiology react to BT reports? Do they dismiss them as pseudoscience or do they take them seriously?

2) I suspect that most of us here are not competent enough to either validate or criticize experiments to which you refer. One has to know the metabolism of various living organisms and be a good analytical chemist.

3) I had some difficulties with what you wrote; probably because I am neither a biologist nor chemist. For example, in one place you write: “With the germinating wheat he reported [Hg] -200%; for oats [Hg] -2000%, [Zr] -700%, [Pd] -300%; both were analyzed by ICP-MS.” How to interpret such percentages? What is ICP? Should I assume that MS stands for a mass spectrometer?

4) In the reply to your first message I referred to the ICCF11 paper of V. Vysotskii et al. He reported that radioactive Cs-137 (half-life of about 30 years) can be turned into something non-radioactive in several days. Most CMNS subscribers are probably aware that rapid deactivation of Cs-137 and Sr-90 would simplify radioactive waste disposal problems (dealing with spent reactor fuel rods) by at least one order of magnitude. Many objections against nuclear electricity would no longer be valid.

5) Vysotskii report on bacterial decomposition of Cs-137 is listed in our <www.lenr-canr.org> library. Unfortunate, unlike his other ICCF11 report, it is not downloadable. Was it published in a biological journal? The paper was based on experiments which many physicists (working with biologists) can perform by using a widely available NaI gamma spectrometer. The microbial transmutation would be recognized as real if radioactivity was destroyed rather than

transferred, for example as a metabolically produced gas escaping a culture flask. Another potential error would be to ignore a drastic redistribution of Cs within the flask (leading to a very significant change in counting geometry). V. Vysotskii, who supervised the biological experiments, seems to be fully aware of such potential traps. I was highly impressed by precautions taken by the team to avoid trivial errors.

If my memory can be trusted they had about ten identical experiments (and ten controls) occurring at the same time? Rapid decrease of radioactivity (in days instead of 30 years) was observed in each tube. That was about one year ago. What is the situation today?

6) Suppose you find a microbiologist willing to replicate Vysotskii's experiment. The first question would be "where do I get the Cs-137?" A science supplies catalog for teachers will show you where a Cs-137 source of ~ 1 microcuries can be ordered. No license is needed for a source of such activity. Other option is to use dry wild mushrooms. Let me tell you a story about this.

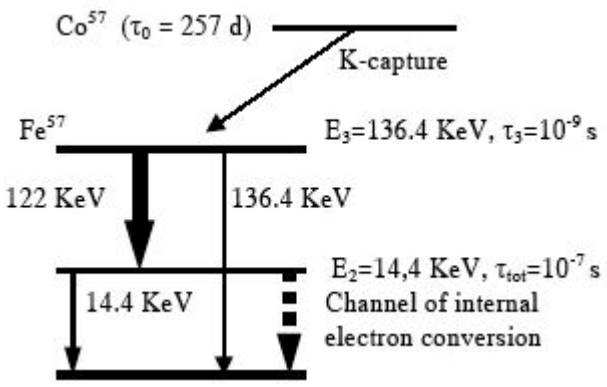
7) More that ten years ago a biology teacher from my university visited his family in Poland and brought back dried mushrooms. Knowing about Chernobyl I suggested that we put about 200 grams of them next the NaI spectrometer. The peak at 660 keV became clearly recognizable after about one or two minutes. But we wanted to be sure that this was due to Chernobyl. So we obtained similar mushrooms gathered in the USA and repeated the experiment. To our surprise we discovered the same 660 keV peak, but the activity (per gram of dry mushrooms) was about 3 times lower. Cs-137, mostly from nuclear explosions in 1960's, is all over the world. Our findings were published in a biological journal. Wild mushrooms are likely to be a good source of Cs-137 for your experiments.

Nobody responded to my reply, so far. This, however, does not surprises me, people who I expected to comment might be on vacation at this time of the year. I will append good comments, if they materialize. Please revisit this unit next month.

A sheet of mica near a radioactive source changes the gamma decay probability

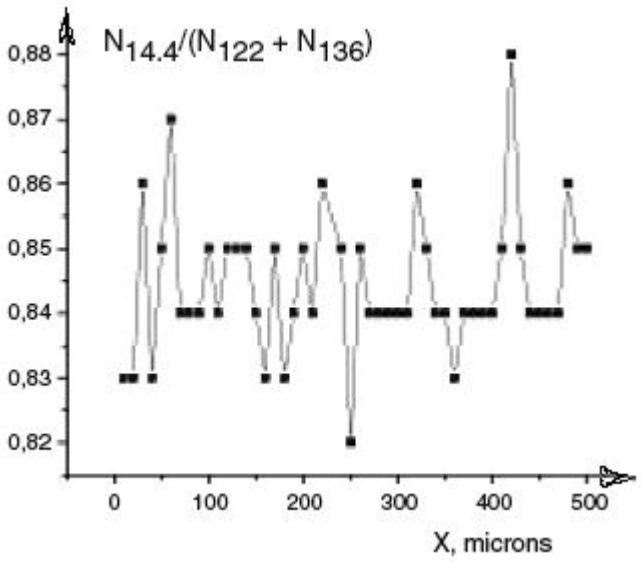
A year before announcing the microbial effect on ^{137}Cs, Vysotskii and his colleagues (from Moscow State University) made another announcement. That was at the 10th International Conference on Cold Fusion (ICCF10, August 2003). Their paper, entitled “The theory and experimental investigation of controlled spontaneous conversion nuclear decay of radioactive isotopes,” can be downloaded from the library at <www.lenr-canr.org>. Let me summarize the experimental part of that interesting paper.

A radioactive source -- ^{57}Co -- (T=257 days decaying into ^{57}Fe by K-capture) -- was placed in front of a detector. Gamma rays of energies of 136.4 keV, 122 keV and 14.4 keV, emitted from the ^{57}Fe nuclei (T=1 nsec) were recorded. There is nothing new about this; the energy diagram of the decay process is shown below.



I can easily imagine three gamma ray peaks in a multichannel analyzer. What is new and interesting is the effect thin mica sheets on relative intensities of the peaks. The authors discovered that the ratios of peak intensities can be

changed by introducing a 50-microns-thin mica sheet into the region between the source and the detector. Labeling the areas below the peaks as N14, N122 and N136 they characterized the effect of mica by the ratio R, defines as N14.4/(N122+N136). By changing the distance X, between the source and the mica sheet, they discovered that, R depends on X, as illustrated below.



Unfortunately, no bars of errors were assigned to individual data points and nothing was stated about reproducibility of results. For example, is R always equal to 0.82 when X=250 microns? And is R always equal to 0.88 when X=420 microns? I will assume that observations were reproducible and that the error bars were "too small to be shown." To give the authors all benefits of my doubt, I will also assume that control experiments were performed to show that equivalent screens made from other materials had negligible effect on the values of R at different X.

Taking these assumptions for granted I tentatively accept the main claim of the paper: "In these experiments we discovered an inhibition of the conversion channel for nuclear decay by 7–10%, and a change (increase) of the total lifetime for the radioactive $^{57}Fe^*$ isotope by 6–9%, at the optimal size *X* of the slot, in relation to spontaneous decay in free space without the thin mica crystal."

P.S.
This mica screening effect on ^{57}Fe is not as strong as the bacterial effect on ^{137}Cs. But each of these effects, if confirmed by other researchers, will show that the prevailing point of view has only a limited validity. Emission of gamma rays is a nuclear effect and ability of influencing it by screening the source with a thin sheet of mica (a mono-crystal) is not consistent with the prevailing point of view. How can a crystal, situated hundreds of microns from the atomic nuclei of the source influence what happens in the nuclei? To answer this question one should be able to understand the theoretical part of the paper. Unfortunately, i do not understand it, due to my very limited background in theoretical physics. But I would very much like to know what theoretical physicists think about the paper. By skimming the first part of the paper I notice that the explanation is based, among other things, on the concept of "zero-energy." The authors claim that experimental results confirm their theory.

Why tracers have not been used to study transmutations? (Appended on 8/8/05)
Focusing on transmutations involving radioactive isotopes has a great advantage over focusing on stable isotopes. Most people here are well aware that analytical techniques used to study stable isotopes are much less sensitive than analytical techniques used to study radioactive substances. Let me illustrate this numerically. I will arbitrarily assume that the limit of detectibiity, of cesium, by a traditional analytical method is one microgram. This is $4.5*10^{15}$ atoms. Yes, I know that the limit is different for different elements; this is probably a good representative number. Let me compare it with the limit of detectivity of ^{137}Cs, for example, in mushrooms. Suppose I am using an NaI crystal in a

situation in which a 660 keV peak can easily be identified when the corresponding counting rate is 1 per second. I will assume that the counting efficiency, including the geometry, is 1%. It means that I am able to easily recognize ^{137}Cs in a source whose activity is 100 disintegrations per second.

How many atoms are there in that source? The half-live of 30 years implies that the decay constant, lambda, is equal to $6.75*10^{-10}$ sec^{-1}. If the activity is 100 then the number of atoms is $1.48*10^{11}$. That is about 30,000 times less of the above-chosen level of detectibility by a non-nuclear analytical method. I selected cesium because bacterial transmutation of that material is being studied in Ukraine. And I have no doubt that even 10^{10} atoms of ^{137}Cs can be identified with a carefully designed high efficiency detection system.

If I were to study nuclear transmutations involving non-radioactive elements I would think about using tracing techniques. Suppose generation, or destruction, of common ^{133}Cs is suspected in the electrolyte of a Naudin's "reactor." How can this be tested? By deliberately injecting a tiny amount of radioactive ^{137}Cs, perhaps a fraction of a milligram, into the liquid before the experiment. The rest should be obvious to a nuclear scientist.

a) Take several cc of the fresh electrolyte and dry it to create a spot source. Then measure the radioactivity, A1, of that source.

b) Conduct the experiment.

c) Take several cc of the used electrolyteand dry it to create another spot source. Then measure the radioactivity, A2, of that source, under identical conditions.

If A1 and A2 turn out to be significantly different then you have an indication that the suspected transmutation might have occurred. Note that only the ratio is needed, systematic errors in A1 and A2 are likely to be identical and they should cancel each other when the ratio is calculated. That is only a general idea. Reality is likely to be less simple. Fortunately, practical difficulties can usually be resolved by anticipating various complicating factors. One should be certain, for example, that a difference between A1 and A2 is not due to the redistribution of cesium, say from the liquid to a metal, or to the surrounding air, during the experiment. Designing a convincing experiment is always a challenge.

To study transmutations involving silver the radioactive tracer could be the beta and gamma radioactive ^{110}Ag (T=253 days). To study transmutations involving zinc the tag could by ^{65}Zn (T=245 days), to study transmutations of platinum the tag could be ^{188}Pt (T=10 days), etc. Shorter half-lives are better, in principle, because they offer higher sensitivities. On the other hand, working with a rapidly decaying tracer would call for corrections based on duration of experiments. A radioactive tracer whose half-life is about ten times longer than the duration of an experiment seems to be ideal, provided its activity can easily be measured, with an available detector, at reasonably high efficiency. Yes, I know that obtaining necessary tracers can be a problem, unless one has access to an experimental nuclear reactor, or to beams of accelerated particles.

P.S.

This note has been inspired by G. Milley's ICCF10 review of transmutations. His paper is downloadable from our library at <www.lenr-canr.org>.

247) Magnetic forces and coulomb barrier penetration

Ludwik Kowalski (8/10/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

It is well known that electrically charged objects acquire magnetic poles (N and S) when they rotate. The N and S poles, situated on the axis of rotation, become stronger when the angular momentum increases. Note that I am saying "rotating" rather than "spinning" because it is not a quantum mechanical consideration. Yes, I know that laws of classical physics do not always apply at the subatomic level. The concept of magnetic poles is used because I believe in its pedagogical usefulness. Those who played with bar magnets, or with compass needles, knows that "unlike poles attract each other while like poles repel each other." That is all I need to show how rapid rotation can help charged particles to penetrate coulomb barriers.

Deuterons are positively charged. Suppose that two deuterons are rotating. Also suppose that the angular momenta are anti-parallel. By this I mean that the axes of rotation are parallel but one direction is clockwise while another is counterclockwise, when seen from the same side. In other words, if the N pole of one deuteron is up then the N pole of the other is down, and vice versa. Under such condition the particles would not only repel each other (due to positive electric charges); they would also attract each other (like two anti-parallel bar magnets). The net force between them would be reduced in comparison with what it would be without rotation. By increasing the angular momentum one would reduce the net repulsive force. The probability of fusion (at a low energy of relative motion) is thus expected to increase with angular momenta.

How large should the rotational angular momenta be to significantly increase the probability of fusion? And what kind of NAE (nuclear active environment) would produces rotating nuclei? I asked these two questions on the CMNS list. I would be happy to post the replies (anonymously), if they materialize. Please revisit this unit in a couple of days.

Appended on 8/11/05:
1) Here is one comment, sent to me in private: "In a particle physics this is called 'interaction between polarized deuterons'. I do not remember exact numbers. But I do remember that the cross section of the DD reaction does not change a lot (factor 2 maximum for some energy range) for flip and non flip states of polarized deuterons in a wide energy range of interacting deuterons." I would prefer this to be posted on the list, to see what others have to say. But private messages are welcome. I suppose that the above comment refers to free deuterons. Deuterons studied by cold fusion researches are usually not free; they are trapped in solids. Some CF researchers say that one should not extrapolate from free deuterons to deuterons in solids.

2) What I posted was inspired by a message on the CMNS list. This message is worth showing here, I think. "I agree, reproducibility is important, but it is not the main problem. The main problem is to understand the environment and mechanism that results in nuclear reactions. Without this knowledge, replication remains difficult. In addition, when replication is achieved, it is rejected because success looks like random chance rather than intention. Also, as long as replication involves measuring energy using a calorimeter, the result will be rejected simply because orthodox physics does not trust [low wattage] calorimeters. In fact, I don't trust most calorimeters. Painful experience has shown me that too many ways exist to screw up. Besides, a standard calorimeter does not exist, like a standard radiation detector. As a result, an ordinary physicist has to master each new calorimeter in order to trust the data. I suggest the only calorimeter type that is sufficiently simple for physicists to understand is the Seebeck-type, which is seldom used.

So, what is the solution? First of all, I think everyone needs to acknowledge that CANR does not occur in ordinary materials under ordinary conditions. Replication is difficult because this special material is not normally present and needs to be made before the effect can be produced. Second, any theory that is based on ordinary material, like PdD, or on special and unproven mechanisms, like ZPE extraction, must be viewed with skepticism. In fact, skeptics reject the claims simply because such theories are used to explain the observations.

If we want orthodox physics to take the field seriously and achieve reproducibility, we need to address the real world, not the limited and imaginary world proposed by many in the field. CANR has to be recognized as a normal process that is part of normal science, but one that occurs only because a special atomic lattice is available. The challenge is to understand what makes this lattice unique and what mechanisms are only initiated within this nuclear-active-environment. In addition, all of the novel observations need to be explain, not just a few that are easy for a particular model to address. After all, how many independent mechanisms and environments do you think are operating? OK, I've thrown down the challenge - what do you all think of this approach?”

Let me mention that a low wattage calorimeter was used , by Pierre Curie in 1903, to discover the unexplained heat produced in his radium source. Likewise, the theoretical discovery of neutrinos (by Pauli) was an attempt to make sense out of calorimetric data on heat from a beta radioactive source. I was under the impression that all scientists have great respect for calorimetry. But calorimetry at low wattage is far from being trivial; the person who wrote the above is one of the top experts in that field.

248) A proposed set of names

Ludwik Kowalski (8/11/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As mentioned in another unit, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. Let me share a message I just posted. It was a reply to XX, a well known scientist. Sorry for not showing names, when quoting from that list. I will append interesting replies, if they materialize. Please revisit.

On Friday, Aug 12, 2005, XX wrote:

> . . . Over time, as results come in, one's views and interests
> change. At least mine do! I have a more open mind regarding
> various "cold fusion" claims than I did years ago. That does
> not mean that I accept or even fully understand all the claims.
> Does anyone? However, I do try to listen. For example, I'm
> amazed at the results showing transmutation in deuterated
> metals -- who would have suspected this back in 1989? . . .

1) Just imagine how different would the history be if R. Gajewski, working for the DOE, did not confuse cold fusion projects of Steven Jones, already supported by the DOE, with an excess heat proposal submitted to the DOE (in 1988?) by Fleischmann and Pons. Why did Gajewski select Jones to be a reviewer of the new proposal? The essence of the P&F proposal was excess heat unexplainable by chemical reactions. Why was such proposal not sent to chemists experienced in calorimetry? If it were sent to chemists then subsequent developments would not evolve into a highly undesirable controversy.

The naming of the P&F phenomenon "cold fusion" was one of the most tragic mistakes in the history of modern science. It created a situation in which the coulomb barrier, and the absence of expected neutrons, became convincing arguments against the new field of investigation. Naming things inappropriately is undesirable, especially in science. Suggestions to stop using the term "cold fusion" inappropriately have often been made.

2) I would very much like to have a non-confusing set of names, for what we are studying, at least on this list. My message is a step in that direction. Keep in mind that it is only a proposal. Perhaps we can discuss it, modify it, if necessary, and establish a set of acceptable names.

3) The name of the entire field should be CANA (chemically assisted nuclear anomalies). The field consist of three distinct sub fields: CF (cold fusion), CT (cold transmutation) and EE (excess energy). Additional sub fields can be identified, when needs develop. Yes, I know that the name CANR would also be appropriate. But it is less easy to pronounce than cana. And the word "anomalies" is probably better than the word "reactions," at this stage. The name CMNS would certainly be appropriate if it were easier to pronounce. I suspect that speakers of many languages would pronounce CANA in nearly the same way.

4) The cold fusion sub field, CF, consists of phenomena in which fusion of hydrogen nuclei, such as D and D, takes place at ordinary temperatures. In the case of D + D the dominant output channels are n + 3He and p + 3H, as in hot fusion. Output channels would be different for the T+ D, T + H, D + H, or H + H. Several phenomena studied by Jones belong to the sub field of CF.

5) The cold transmutation sub field, CT, consists of nuclear processes in which chemical elements, heavier than hydrogen, are synthesized or decomposed, at ordinary temperatures. Transmutations produced by common neutrons, or by accelerated charged particles, are not anomalies.

6) The excess energy sub field, EE, consists of nuclear processes in which unaccounted-for energy is generated. The term "unaccounted-for'" is used to exclude energy from exothermic chemical processes. Should we add that the EE sub field deals with the CF and CT phenomena only? I keep changing my mind about this.

Please comment. Please revisit this unit; I plan to append items.

Appended on 8/15/05:

1) On Sunday, Aug 14, 2005, YY wrote:

". . . I was always convinced that calling anything ANOMALOUS is in some way contraproductive, even suicidal. . . "
Here is my reply:

If other people feel the same way then let us say that CANA stands for Chemically Assisted Nuclear Activities (not Nuclear Anomalies). But CANA is the least important part of my proposal. The CMNS name, for the entire field, is fine with me. (I preferred CANA because it is easier to pronounce.)

2) The important part of my proposal is to stop using "cold fusion" instead of CMNS. Cold fusion (CF) is only a subfield of CMNS. That is what should be recognized as troublesome. Other recognizable subfields are CT (cold transmutation) and EE (energy excess). Benefits of not referring to all CMNS phenomena as cold fusion have been recognized by many on this list, long before me.

3) OK, my attempts to initiate a discussion a discussion of the proposal failed. [YY was the only person who responded to several appeals, posted last week.] But I intuitively feel that many on this list agree that consistent terminology is desirable. Facing the unexplained resistance to discuss the "alphabet soup" of acronyms, I decided to start using new names consistently, at least for a while. Please do the same and we will see how it goes.

a) The name of the entire field is CMNS.
b) Subfield CF -- cold fusion of hydrogen nuclei -- at temperatures below 10,000 C.
c) Subfield EE -- excess energy (hopefully, not only heat).
d) Subfield CT -- cold transmutations -- excluding those due to common neutrons and accelerated particles.

4) In another thread YY wrote: "Terminology is only a part of a greater problem." That is true. But why should this be an excuse for not fixing a small part of the big problem?

To which the immediate reply was:

". . . I said that :'Terminology is only a part of a greater problem.' Because as long as we do not understand the processes, their relationships, the situation, the correlations - how do we know that the terminology has a sound basis? If you don't know that your coming child is a girl or a boy- what name can you give her/him? OK, in the US you have such gender-neutral names as Leslie- but we here have to chose- Ludwika or Ludwik, Petra or Peter."

To which I responded:

But people do refer to CF (cold fusion) as if it included the EE (excess energy) and the CT (cold transmutations). This contributed, and continues to contribute, to undesirable consequences. What harm can possibly result from our consistent use of the proposed set of names? Let us try it, at least on this list. Yes, I know that most people on this list are never confused by inappropriate use of names. That is why they do not want to waste time, I assume, on discussing the suggestion. But context dependent terms are highly undesirable, especially when we talk with others.

YY wrote:

"OK, I think this distinction is OK. Let's use it."
This turned out to be an empty promis. Less then 24 hours later, in an interesting reflection about history of the CMNS field, YY reffered to this entire field as cold fusion. He was mostly writing about EE (Patterson and Case cells, Toyota projects in France, etc.), but the term EE was not used. It is not easy to stop using terminology to which one is attached.

RR wrote:

This is a question of linguistics and language history, which I studied for many semesters 30 years ago. The answers are: this issue does not matter; we have no control over words; we should stop worrying about this; and words often do not mean what they sound like, or what they originally meant. The study of weather is called "meteorology" because people used to think that meteors had something to do with weather. "JPL" stands for Jet Propulsion Laboratory even though that laboratory has always concentrated on rocket propulsion. It was named "Jet" because when it was established rocket propulsion was somewhat disreputable, being associated with science fiction comic books. Whatever name sticks to cold fusion will stick, and no one anywhere has any say about it. Even if cold fusion turns out to be something other than fusion, if it turns out to be several different phenomena, if the name is firmly entrenched it will not change. We still talk about "dialing" a telephone number even though most people have never seen a dial, and I expect we will still refer to movies as films long after the film is replaced with digital bits recorded on hard disks.

One other linguistic note. Euphemisms never work for long. People who are embarrassed or offended by words invent euphemisms, but the stigma quickly follows and attaches to the new euphemism, so they have to invent another and another. Along the same lines, some people have suggested that we coin a new term for cold fusion because the present term -- "cold fusion" -- is associated with so much controversy. We need a fresh start. Alas, even if we could somehow get everyone to call it "LENR" instead, the controversy would follow immediately.

Referring to another message ZZ wrote:

Bill, the concept of chemistry being involved is based on the observation that a solid lattice appears to be a common feature for producing the anomalous nuclear effects associated with CANR. This environment, because it has a high concentration of electrons and a periodic nature, allows a variety of mechanisms to operate that are not present in a plasma. These features are the basis for conventional chemistry, hence allow one to observe that the nuclear reactions are assisted by chemistry. The designation CANR focuses attention on the environment while LENR focuses attention on the mechanism. The choice of which is more accurate goes to the heart of understanding, and obviously has not yet been resolved.

As for the neutron emission observed by Mizuno, we do not yet know whether this is caused by a cold fusion environment. A CF environment seems unlikely because neutrons are normally not produced by cold fusion. It is possible that several different and independent processes are operating, one producing He4, and others producing neutrons and tritium. When evaluating theory, this possibility must be kept in mind.

QQ wrote:

Regarding the definition debate PP wrote some wise lines, and I'm sure he wouldn't veto me reproducing them here: "If we say that the term 'cold fusion' is bad, it will appear that we are attempting to push away the stigma. That we cannot do, it will have to dissolve on its own accord, as a result of the scientific truth and efforts to communicate. In

terms of public relations, to divorce CMNS completely from the term CF is not appropriate and will look weak."

Ludwik Kowalski wrote:

Let me repeat it; calling the entire CMNS field cold fusion is bad. The term CF is not bad but it should be used to describe only some CMNS phenomena. Why was the term "divorce" introduced by Steven K? It was not a correct description of my proposal.

I think that referring to the entire CMNS field as CF is harmful, especially when one tries to convince scientifically educated people. Many of them associate the CF term with the coulomb barrier (Gamow factor etc.). What do they usually say when one tries to convince them that excess heat is real, in such or such experiment? The moment they hear the term CF they ask about the coulomb barrier. That is not good; I have much more confidence in reality of excess heat than in validity of existing speculations about its origin. Yes, coulomb barrier is a decisive aspect for cold fusion. But why should one think about it in discussing excess heat? It is too early to approach the excess heat subject from the theoretical side. Unfortunately, that is what often happened when I referred to excess heat as cold fusion. The discussion with scientifically educated people should focus on such things accuracy (systematic errors) and precision (random errors). And we should be open about the absence of understanding.

Confusing excess heat with cold fusion (of two hydrogen ions) was harmful in 1989 and is harmful today. How often do you hear the old argument that "if CF were real then P&F would receive deadly doses of radiation, due to neutrons." I hear this very often. We do need the term CF but it should NOT be used to describe the EE (excess energy) or CT (cold transmutation) phenomena. People will understand that what we know today is very different from what Fleischmann and Pons suspected in 1989. That what we should tell them to explain the need for the CMNS term.

249) An interesting theory of Akito Takahashi

Ludwik Kowalski (6/18/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As mentioned in another unit, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. A recently published theoretical paper of a well known Japanese researcher is now available for downloading at

http://newenergytimes.com/Library/2005TakahashiA-CondensedMatterNuclearEffects.pdf

That is what was announced on that list yesterday. After reading this paper I posted this message:

Thanks for making this paper of A. Takahashi available to all. I sense that it is an important contribution. But my background is not sufficient to understand the theory. What I would like to achieve is a simplified (intuitively appealing) description of basis assumptions and essential conclusions. I am probably not the only one who would appreciate help from somebody who already grasped the main idea. Let me try to write down what comes to my mind as I read the paper. Please correct where I am wrong.

a) The so cold "hot fusion" involves collisions between two D ions. The coulomb barrier is high because the nearest electrons are too far away to help lowering the barrier.

b) And what about two neutral D atoms forming a neutral covalent molecule? Here the average distance between positive nuclei is 0.07 nm. Thermal fluctuations around this internuclear distance do not lead to fusion because orbitals in which electrons reside are too far away. In other words, the coulomb barrier is still too high to make cold fusion observable.

c) Takahashi invents a neutral quaziparticle TSC (Tetrahedral Symmetric Condensate). It is a squeezed quazi-molecule made from two neutral molecules in tetrahedral configuration. One way to visualize this configuration is to take two identical tooth picks and imagine four positive deuterons at their four ends. Make a symmetrical cross (two sticks on top of each other) and pull one stick away from another. The distance between the sticks should be such that distances between any pair of deuterons is the same. In Figure 5 (on page 7 of A.T. paper) the four deuterons are blue sphere. Each deuteron has an electron associated with it; electrons are represented by yellow spheres.

d) I do not know what causes such system of eight charged particles to collapse. And I believe the author that orbitals in which electrons reside are such that the coulomb barrier is lowered very significantly. The main point is that fusion of four deuterons into ^{8} Be is much more probable than fusion of two deuterons into ^{4}H (from a neutral molecule). Once formed, the ^{8}Be nucleus at once breaks into two alpha particle. instability of ^{8}Be with respect to fission into two helium nuclei is a well known process.

e) Another important point is that the TSC, approaching another nucleus (such Al, Ni, Pd or U) acts as a nearly neutral particle. This happens because negative electrons reside very close to positive deuterons. (Do not ask me why.) For that reason fusion of TSC is no longer inhibited by coulomb barrier. The probability of fusion with heavier nuclei, in

this model, depends essentially on the probability of formation of TSC in condensed matter. The same is true for the probability of producing helium from TSC.

5) Is this a fair description of the main idea? Numerical conclusions are summarized in Figure 6. I see an obvious font substitution error here; what is labeled Rambda should probably be lambda. Is lambda the usual decay constant in sec^-1? I have other questions about that essential figure. But this can wait.

Please comment, please correct, please add. Please share your own attempt to understand. Thanks in advance.

That was about 24 hours ago. Nobody answered so far. Actually it is wrong; I did receive an interesting essay from Russia but I do not think it explains Takahashi's theory. Today I downloaded -- from the library at http://lenr-cmnr.org -- the paper that A. Takahashi presented at the last International Conference of Cold Fusion (ICCF11). It is also about tiny clusters of more than two hydrogen atoms. The author states that a TSC does not have to be a DDDD. In a mixture of heavy and light water a TSC can also be a DDDH, DHDH, DHHH or HHHH. Pure DDDD produces ^{8}Be that decays into ^{4}He +^{4}He liberating 47.6 Mev of nuclear energy. The DDDH, on the other hand, produces ^{7}Be which decays into ^{3}He+^{4}He liberating 29.3 MeV of energy. Likewise DHDH produced ^{6}Be which decays into ^{3}He+^{3}He. Both ^{4}He and ^{3}He are expected when an electrolyte contains a mixture of heavy and ordinary water. Instead of fissioning a TSC quaziparticle, created near the surface of a large nucleus, can fuse with that nucleus.

In other words, the variety of output reaction channels is much larger than it would be if all TSCs were DDDD. Takahashi performed an experimentally verifiable (in principle) relation between the percentage of light water in heavy water and the expected ^{4} He / ^{3}He ratios. I like when theoretical results are presented in terms of relations between measurable quantities. But I still have a bunch of questions. What leads to formation of TSC clusters? Why are these clusters so small? I hope that someone will answer such questions. I guess the answers are hidden somewhere in earlier theoretical publications of Takahashi.

Small clusters make me think about DD molecules, made from two hydrinos. They are also said to be tiny. Occasional cold fusion of two hydrinos residing in a DD molecule would produce ^{4}He while ^{3}He can be produced from fusion of hydrinos in the HD molecules. Likewise, very small DD and HD clusters, approaching heavier nuclei, would produce compound nuclei because coulomb barriers are nearly eliminated. In other words, cold fusion (CF) and cold transmutation (CT) can be explained either by hydrinos (introduced by Mills) or by larger clusters (introduced by Takahashi). What is not clear is why such clusters formed in the first place. Was their existence postulated to explain experimental data or was it derived from preexisting theories?

PLEASE REVISIT THIS UNIT; I PLAN TO APPEND REPLIES TO MY MESSAGE HERE: IF THEY MATERIALIZE.

Appended later on 8/17/05:
I was composing a reply to Kozima when the follwing message from Takahashi arrived.

Thank you for your comments to my models. I think, you are hitting the essence of my models. Could you please read my two papers and see ppt slides available at SIENA2005 of http://www.iscmns.org/ site, which treats some details, together with my paper for ASTI5 at the same site.

I have now no time to respond your questions to write detail explanation, but I hope you kindly read my older papers for ICCF9, 10, 11 and JCF4, 5, which have treated elaboration of EQPET/TSC models. For fission products distribution for A<200 nuclei, please read my paper Jpn. J. Appl. Phys., 41(2001)7031-7046.

To improve my models, I need great helps from other researchers to formulate for example TSC formation rate at some sites (we need modeling) at/near fractal surface, and for other key issues.

PS: In the last 6 days, I was busy due to the funeral of my father who died with 95 years old.

Appended later on 8/18/05:
1) The following comment was posted by Hideo Kozima, a theoretically inclined CMNS researcher.

It is necessary to understand clearly what is a theory, what is a model and what is an assumption. There are too many assumptions pretending [to be] theories. Generally speaking, following definitions will be applicable. **A theory is** based on principles commonly accepted in scientific world. **A model is** a system of assumptions based on facts but not deduced from principles trying to explain various phases of facts. **An assumption is** individual explanation of facts not forming a system of explanation for facts. We have to distinguish them especially in research of the cold fusion phenomenon. **P.S. In my opinion,** "Akito's theory" is an assumption to explain "Iwamura's data" and some others.

My reply, composed last night, was essentially "philosophy" of science not science itself. It looked childish today and I am glad it was not posted on the list. Let me replace what I wrote with what Frank Wilczek wrote recently, in Physics Today.

"A popular class of problems specifies a force and asks about the motion, or vice versa. These problems look like physics, but they are exercises in differential equations and geometry, thinly disguised. To make contact with physical reality, we have to make assertions about the forces that actually occur in the world. All kinds of assumptions get snuck in, often tacitly."

I see nothing wrong with making reasonable assumptions in attempts to match limited sets of experimental data. After being successful one can go further and make theoretical predictions. Such predictions are either confirmed of contradicted by experimental data. ..... Everybody knows how basic laws of nature were discovered. But experiments must be reproducible to rely on that kind methodology. Experimental scientists are blind without theories and theoretical scientists are paralyzed without reproducible data. That is our tragedy in CMNS.

Added on 8/19/05:
Yes assumptions must be reasonable. Some assumptions are not reasonable. Such assumptions can be called wishes . For example, I can assume that, under certain unspecified conditions, an electron can enter a duteron an remain in its center. A deuteron containing an electron (De) is not repelled by another hydrogen nucleus and fusion can take place at low temperatures. The De clusters are also not repelled by heavier nuclei. Thus they can lead to all sort of cold transmutations. Why are cold fusion (CF) and cold transmutations (CT) so rare? Because the probability of capturing an electron by a deuteron is very low. And why are CF and CT not reproducible? Because we still do not know how to control conditions under which De clusters are formed. My assumption is not reasanable; it cannot be justified in terms of what I know about nuclear forces (either strong or weak).

I suppose that Akito's assumption about neutral DDDD clusters, named TSCs, is not wishful thinking. But I do not know how it can be justified in terms of what is known about distributions of electrons in quazi-molecules. A DDDD is essentially a neutral precursor of ^{8}Be.

Last night a teoretically inclined colleague made an interesting comment about theoretical assumptions that are not reasonable. He said that an assumption should not be rejected on the basis of absence of reasonabliness. The only valid reason for rejecting an assumption should a discrepancy between logical (mathematical) consequences of using it and experimental data. The well known assumptions on Niels Bohr were that (a) electrons do not radiate electromarnetic waves due to centripetal acceleration, and (b) only certain orbits are allowed. These two ad hoc assumpions were in conflict with laws of macroscopic physics. They were certainly not based on anything known before 1912. His hypothetical theory became valid after its true predictions (facts that were not known in advance) were confirmed.

One true prediction, in Takahashi's paper presented at ICCF11, is a graph showing how the isotopic 3He/4He ratio should depend on the percentage of light water in the $D_2O + H_2O$ electrolyte. Will experimenta data confirm this graph? This remains to be seen. The unreasonable assumptions, when they lead to accepted theories are said to be beginnings of new paradigms. In the periods of normal development (between scientific revolutions) assumptions should not conflict with accepted theories. To what extent are Takahashi's assumptions reasonable and to what extent are they ad hoc?

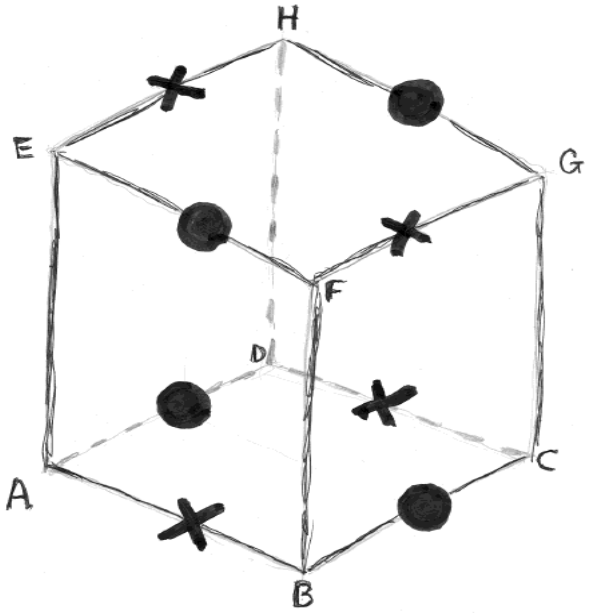
I just posted this reply :

Two deuterium atoms, separated by a distance 0.07 nm, form a covalently bound molecule. What kind of bounding keeps four deterium atoms together in a neutral TSC quazi-molecule?

Hopefully somebody familiar with quantum mechanics, and who followed the evolution of the Takahashi's model, will explain what the DDDD clusters are. Meanwhile I drew this schematic picture of a TSC.



Large black dots are atomic nuclei of four deuterium atoms while crosses represent centers of orbitals where electrons reside. If necessary, individual dots and individual crosses can be indentified by the edges at which they are located, for example, the deuteron BC. Note that only 8 edges are occupied. And I am ignoring that this TSC cluster is surrounded by other atoms. These other atoms are probably playing an important role. But this is only a guess. In my mind EFGH is one unusually small molecule and ABCD is another. They are orthogonal with respect of each other. But I have no idea why the molecules are much samller than common molecules and what keeps them together.

Added on 8/20/05:
A theoretical physicist XX posted an interesting summary of a paper that was submitted, but not accepted at a conference this year. But that was not what I expected. An hour later I received a very brief private message from Takahashi. He is going to address the issue at the ICCF12 (next International Conference on Cold Fusion, starting on November 28, 2005). Then he wrote " Please look my ppt slides for IMFP2005 (International Meeting on Frontiers of Physics), especially #58-62 slides, according to transient electron bonding for TSC." The CC of Akito's message was sent to XX.

Slides that were shown at IMFP2005 (Malaysia, July 2005) can be downloaded by going to:

http://www.iscmns.org/siena05/program.htm

and scrolling to "Saturday 14 May." The third item contains two links, one to Akito's slides and another to his talk in Siena. The slides show that the issue of formation of TSC has been addressed. One slide, for example, has this title: "Orthogonal coupling of two molecules makes a Miracle!" Another slide has long equations describing wave functions; presumably indicating where components of the "miracle" (four deuterons and four electrons in a TSC) are located. Unfortunately, my familiarity with QM is very limited; I never had a chance to go beyond what I learned about 40 years ago. For example, I accepted reality of attractive covalent forces (as between two hydrogen atoms in common H2 molecules) without studying QM machinery. What people like me need are popular versions of serious papers. Theoretically inclined physicists often overestimate their audience.

In the Siena paper I see a section about formation of TSC. Here an interesting quote: "We know surface of metal is complex and fractal with ad-atoms, dimers and corner-holes, for example, as illustrated in Fig.2. Somewhere, for instance in corner holes, incident D2 molecules are trapped by dangling bonds. Free D2 molecule has freedom of rotation and vibration. Trapped D2 would lose freedom of rotation, but can vibrate for changing distance between pairing two deuterons, and waiting for incoming D2 molecule. When incoming D2 molecule meets near to trapped D2, incoming D2 rotates with 90 degrees maximum against waiting D2 molecule to neutralize charge (minimize Coulomb repulsion energy) and form an orthogonally coupled two D2 molecules when there meets coherence in vibration modes and electron-spins are anti-parallel for counter part electrons. In this way, TSC may be formed on surface. Since the scenario is still very speculative, we need further substantiating studies."

What is missing, as far as I am concerned, is an explanation of causes of such behavior of two molecules, for example, during the electrolysis, or when hydrogen diffuses through palladium.

Appended on 8/21/05:
1) Here is the message I posted yesterday: "The slides show that the issue of formation of TSC has been addressed. One slide, for example, has this title: "Orthogonal coupling of two molecules makes a Miracle!" Another slide has long equations describing wave functions; presumably indicating where components of the "miracle" (four deuterons and four electrons) are located. Unfortunately, my familiarity with QM is very limited; I never had a chance to go beyond what I learned about 40 years ago. For example, I accepted reality of attractive covalent forces (as between two hydrogen atoms in a common H_2 molecule) without studying QM machinery. People like me need popular versions of serious papers. A set of assumptions and a set of conclusions is usually sufficient. Theoretically inclined physicists often overestimate their audience. "

2) Why am I writing all this? To dramatize situations that are probably more common than theoretically sophisticated people believe. What is the best possible way to guide experimental researchers? I do not know. Experimentalists must try to learn the vocabulary, if not the language, of those who guide them. But theoretically inclined leaders should try not to overwhelm experimentalists with details. Likewise, experimental people should not overwhelm theoreticians with practical details. What is essential for one group is not essential for another.

3) Takahashi sent me the most recent version of his slide show; it should already be downloadable from the library at <http://www.lenr-canr.org>. The beginning of formation of TSC is shown on slide 27. All four electrons, represented by crosses at my illustration above, are simultaneously pushed toward the center. The center is called site T and the process is referred to as squeezing. Squeezing forces are represented by red arrows; they originate from four Pd ions. These ions also form a tetrahedron; they are situated further away from the center than electrons. I suppose that squeezing forces are electrostatic; what else can they be? I am puzzled by directions of these forces on slide 27. Positive Pd ions should attract and not repel electrons.

4) Slide 28 introduced new notation "Quadruplet e*(4,4)." On slide 29 I see that e*(4,4) is called a single particle at site T. The size of that site (~0.01nm) is seven times smaller that the average distance between D and D in an ordinary molecule. The lifetime of that particle is calculated as 2.3 fs. Then, if I understand this correctly, it becomes TSC, whose lifetime is 60 fs. Should I assume that the TCC, in the slide title, is a typing error (it should be TSC)? Slide 31

is not clear because I do not know, for, example, what probability = 10% refers to. I also do not know the difference between dde* and dde*e*. Unfamiliar notation is the most frequent inhibitor, as far as i am concerned. Slide 32 is a reminder that the probability to penetrate a coulomb barrier depends not only on the height of the barrier but on its width as well.

5) Should I assume that 60 fs (on slide 29) is the expected time for the cold fusion to occur? If so then this time determines the outcome of competition between cold fusion (CF) and cold transmutation (CT). The probability of CT would increase if that time interval were longer.

Appended on 8/22/05:
Last night I received a private message from Dr. Takahashi; he started addressing questions and comments that were appended yesterday morning (see above). I am glad that XX, who is a theoretical physicist, also received that private message. He will certainly understand Akito's papers much better that I can. My suggestion is that he cooperates with Takahashi and that together they develop a tutorial. In my opinion a popularized version of Takahashi's model is going to help many physicists, both inside and outside the CMNS community. To trigger this potentially desirable project I am going to send this paragraph to both XX and Takahashi. I am nearly certain that XX would not object if his identity were revealed. I will do this next time, unless he prefers to remain known as XX.

2) Water at low temperatures is a crystal. At higher temperatures it becomes a liquid and than a vapor. In a liquid molecules often cluster into attached groups. Clustering is possible because water molecules are polar and because they are close to each other. Hydrogen molecules, such as DD, are not polar. Therefore the existence of a tetrahedral cluster (see the drawing above) must be explained by something else that electric attraction. Likewise, something else than electric force must explain the squeezing of a DD-DD cluster into a TSC. According to Takahashi phonon excitations are responsible for processes leading to formation of TSC. I guess I must learn something about phonons to understand this.

STAY TUNED; REPLIES WILL BE POSTED.

250) Another confirmation of nuclear anomalies

Ludwik Kowalski (8/16/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I am reading a recently published paper. It is a short note for electrochemists interested in cold transmutations (CT). I am not even a chemist; this disqualifies me from being an intermediary between scientists and laymen. But I will try, nevertheless, to share some observations. The title is: “Evidence of nuclear reactions in the Pd lattice” and the authors are Stanislaw Szpak, Pamela A Mosier Boss, Charles Young and Frank E Gordon. Submitted in May 2005 the note was published (Naturwissenschaften (2005) 00: 1–4) in July 2005.

The instrument used was an electrolytic cell with heavy water solutions of LiCl and PdCl. The anode was a platinum grid while the cathode was a gold plate coated with Pd and D. These two materials were deposited on the cathode electrolytically by using a very small current (1 mA) in 24 hours. Then the current was increased to about 40 mA (for 2-3 hours) to make sure that the distribution of deposited material is uniform. In the main experiment, lasting 48 hours, with the current was about 100 mA. During the main experiment the cell was in the electric field of a parallel plate capacitor (field of ~ 2000 V/cm). The role of the external electric field is not clear to me; the authors say it was imposed to created conditions favoring nuclear reactions. This reminded me of an experiment (D. Letts et al.) in which a laser beam was used to stimulate the cathode.

After the main experiment the electrodes were removed and examined with a scanning electron microscope. Structural changes on the cathode (localized spots which could only be formed at the above the melting point temperatures) were recognized. One of the authors told me, a telephone conversation, that highly localized flashes (indicators of high local temperatures) were observed during the electrolysis when the cathode was observed with an infrared camera. What kind of reactions were responsible for profound structural changes in the cathode and for the infrared bursts during the electrolysis?

To answer this question the authors submitted the cathode to a different kind of examination. Their scanning electron microscope was equipped with a device able to recognize chemical elements at selected spots of the surface. The name of that device is EDX (electron dispersive X-rays analysis). I never saw such device but its principle of operation is clear to me. Any selected spot can be bombarded with a beam of electrons to generate X-rays. Distinct chemical elements can be recognized by characteristic peaks when X-rays are analyzed with a high resolution spectrometer. This kind of elemental analysis was used by other researchers, for example, by Mizuno in Japan, Miley in the USA and Savvatimova in Russia. All of them reported formation of elements that were not originally present (see units #60, #85, #159 and #206, at this website).

The most prominent elements identified by Szpak et al. were: Al, Mg, Ca, Si, and Zn.
What is the origin of these elements? The authors believe that they are products of nuclear transmutations. Before reaching this tentative conclusion they consider a possibility of chemical contamination. Such conclusion, they claim, would not be consistent with known amounts of trace elements in the electrodes, and in the electrolyte. Furthermore, elements discovered in hot spots were not found in other cathode locations. Structural materials of the cell were examined before the experiment (also with the DEX device) and elements discovered later were not found on their surfaces. Such arguments against a possibility of contamination, are compelling, especially when they are presented by recognized and experienced electrochemists.

But what should I think about their tentative claim that the elements like A, Mg, Ca, etc., are products of nuclear transmutations? Similar claims have been made by other highly qualified researchers. On that basis I take a possibility of nuclear transmutation very seriously. I am puzzled, however, by the absence of radioactive CT products. Being a nuclear physicist I know that both radioactive and not radioactive isotopes are produced when transmutations are induced by accelerated particles, or by neutrons. Why are radioactive isotopes absent among the reaction products? I am certainly not the first person to ask this question. As far as I know, that question has not been answered to satisfy all researchers.

Appended on 8/18/05:
The article that I described, and another recent article published by the same team, can be downloaded from the library at <html://www.lenr-canr.org>. The second article was published in J. Electroanal. Chem., (2005. **580**: p. 284-290) and its title is "The effect of an external electric field on surface morphology of co-deposited Pd/D films."

In the second article the authors explain that the external electric field was applied to increase the capillary forces at the cathode surface. These forces are said to be responsible for some minor deformations occuring during the electrolysis. More drastic, and highly localized, deformations (hot spots), not observed in light water cells, were also observed. They are said to be indicative of local melting, presumably due to highly localized violent nuclear processes. New elements, as reported in the first paper, were observed mostly at hot spots.

One effect that should be expected, when an electrolyte is placed into a strong electrostatic field, is preferential orientation of water molecules (known to be dipoles). The number of molecules whose hydrogen sides are in contact with the cathode is probably much larger than when the electric field is off. What effect does this have on the "double layer?" The local electric field is likely to increase near the cathode surface. Is it conceivable that local electric breakdowns, in the double layer, are somehow responsible for hot spots, and for other surface abnormalities?

Appended on 8/20/05:
It is regrettable that isotopic analysis could not be performed. I am reading the 1996 paper of Miley and Patterson in which a large number of transmutation products was reported. Two methods were used to perform isotopic analysis: SIMS (secondary ions mass spectroscopy) and NAA (nuclear activation analysis). The NAA is a technique with which I am familiar; that is why I find it more convincing. Abnormal isotopic ratios are very convincing indicators that contamination was not responsible for new elements found in the Ni cathode after the electrolysis. One of the new elements was copper. The natural abundances of its two stable isotopes, ^{63}Cu and ^{65}Cu, are 69% and 31%, respectively, as reported in column 3.

251) Crack fusion

Ludwik Kowalski (8/24/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As mentioned in another unit, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. What follows is an interresting discussion of the so-called fracto-fusion. It evolved from the dabate about names of various CMNS phenomena. The sugested names, as described in unit #248, were: cold fusion (CF), cold transmutation (CT) and energy excess (EE). Somebody mentioned that fusion of two deuterium nuclei dominated by the $n+^3He$ and $p+^3H$ channels, as opposed to the ^4He channel, does not belong to CF.

Edmund Storms wrote:

Bill, the concept of chemistry being involved is based on the observation that a solid lattice appears to be a common feature for producing the anomalous nuclear effects associated with CANR. This environment, because it has a high concentration of electrons and a periodic nature, allows a variety of mechanisms to operate that are not present in a plasma. These features are the basis for conventional chemistry, hence allow one to observe that the nuclear reactions are assisted by chemistry. The designation CANR focuses attention on the environment while LENR focuses attention on the mechanism. The choice of which is more accurate goes to the heart of understanding, and obviously has not yet been resolved.

As for the neutron emission observed by Mizuno, we do not yet know whether this is caused by a cold fusion environment. A CF environment seems unlikely because neutrons are normally not produced by cold fusion. It is possible that several different and independent processes are operating, one producing ^4He, and others producing neutrons and tritium. When evaluating theory, this possibility must be kept in mind.

Ludwik Kowalski (addressing Ed) wrote:

1) According to what was reported at ICCF10 by Jones Steven (nearly two years ago) neutrons and protons are signatures of cold fusion. Does the NAE, to which you refer, have anything to do with the phenomena described by him?

2) Would you object if I characterized your current efforts to understand CMNS phenomena as, mostly, studying the EE (excess energy). I know that you were also one of the pioneers in the investigation of CF; I have the accumulation of tritium in mind.

Ed Storms wrote:

1) Personally, I do not think he [Jones] is studying "conventional" cold fusion, but I do not make a big point of this because any replication of an anomalous nuclear reaction is part of the general field and useful to obtain attention. In his case, I suggest the NAE is TiD that forms cracks where a "normal" hot fusion reaction occurs.

2) I produced tritium when at LANL. but I have no way to test for its presence in my present laboratory. This is one of

the basic problems with the field, i.e. we do not have the tools to determine just what is happening. However, I have good calorimeters and can measure heat with confidence.

Ludwik Kowalski wrote:

It seems that Ed is saying that only D + D --> ^{4}He should be called cold fusion; events leading to n+^{3}He and p + ^{3}H (tritium) channels do not belong to CMNS phenomena. If one accepts this point of view then generation of ^{4}He is just another case of transmutation and CF is no longer a subfield of CMNS. That would be ironic.

The answer to the first question is interesting. Ed thinks that electric potential differences (in microscopic cracks) accelerate deuterium ions to energies at which fusion becomes practically possible. The phrase “to obtain attention” might be an indication of something else. The following message from Stven Jones confirms this.

Steven Jones wrote:

Ed wrote: "Personally, I do not think he [Jones] is studying "conventional" cold fusion, but I do not make a big point of this because any replication of an anomalous nuclear reaction is part of the general field and **useful to obtain attention."**

Makes me feel used. My research is not just to “obtain attention” for you, Ed or for the excess-heat claims -- what an amazing, unscientific attitude you portray here.

PS – when will you return the BYU equipment I loaned to you years ago, during your visit to BYU?

The emphasis (bolding) is not mine; it was in the posted message. I was nor aware of personal conflicts within the CMNS community till last week. But that deserves a separate units.

Ed Storms wrote:

Sorry to hurt your feelings, Steve. As you well know, an understanding of CF is still in the future. While I have my opinions, these are not shared by everyone. My opinion that you are not observing what I believe to be cold fusion is not as important as the fact that you are seeing something anomalous, which I acknowledge brings attention to the field. I fail to understand why you think an acknowledgment of such attention is unscientific. Conventional physicists do pay attention to what your work, which helps the field. However, it remains to be determined how your work relates to CANR. On the other hand, should I get my feelings hurt because you don't think my published excess heat measurements are important, least of all to demonstrate CANR?

As for the power supply you loaned to me, I will return it when you want it back. It has been very useful and I'm grateful for its use when I had nothing.

Ludwik Kowalski:

It seems that Ed is saying that only D + D --> ^{4}He should be called cold fusion; events leading to n+^{3}He and p + ^{3}H (tritium) channels do not belong to CMNS phenomena. If one accepts this point of view then generation of ^{4}He is just another case of transmutation and CF is no longer a subfield of CMNS. That would be ironic.

Steven Jones:

Look, Ed, I do not think your published excess heat results are unimportant -- my personal interest remains however in the nuclear particle measurements as a better window (IMO) on what is going on sub-microscopically. I'm glad to hear the power supply has been useful; you may continue to use it for your research. Hope all is going well for you in New Mexico -- I haven't been there for a long time, but love the place! Hopefully I'll bring my wife back to Sante Fe sometime.

Ludwik Kowalski:

If I understood him correctly Ed thinks that fusion events leading to n+^{3}He and p + ^{3}H channels are due to static charges in the microscopic surface cracks. Electric fields created by these charges accelerate deuterium ions and this leads to fusion. This calls for some questions:

1) Is Ed's "fusion in cracks" an assumption or is it a fact?
2) If it is a fact then what is the experimental basis for it?
3) What evidence does Steven have to rule out a possibility of cracks fusion?

Ed Storms wrote:

You have the essence of my opinion, Ludwik. However, the effect can be initiated by additional mechanisms other than acceleration produced by static charge. This mechanism has been explored in the past and claimed to be insufficient, at least using conventional theory. The other mechanism, which has not been explored, is the effect of unbalanced charge in the surface that can produce large local voltage gradients. This mechanism has also been applied to the surface of cathodes in F-P cells. Even though the mechanism is still not understood, people who report low level neutron and energetic particle emission have conditions that would be expected to produce cracks. In addition, these emissions are at least 12 orders of magnitude smaller than the nuclear reaction rates associated with heat production and cold fusion. This large difference, along with production of n and t rather than He, suggests to me that two different mechanisms are operating.

[In other words, the effect is only assumed. How can it be assumed if it "has been explored in the past and claimed to be insufficient" to produce the observed events? What kind of theory was used? My guess is that it was the coulomb penetration formula for the highest possible differenece of potential. That is what Steven will probably write, if he decides to reply. I wish the reply from Ed was more informative. Perhaps somebody else will explains the "unbalanced charge in the surface." I also do not know the meaning of the phrase: the "mechanism has been applied to the surface of cathodes? "]

Steven Jones wrote:

Ludwik and Ed raised again the possibility of "crack" fusion to explain observations of protons, tritons, neutrons we have observed coming from deuterided metals. In the early days, this idea was referred to as "fracto-fusion." However:

1. The metal is still an excellent electrical conductor, so it is very difficult to see how the required large electric accelerating fields could be produced.

2. We actually followed up on this hypothesis several times, by grinding, bending, crushing metal-deuterides, hoping to produce "fracto-fusion" conditions. NO enhancement of particle emission was observed, at BYU or (later) at LANL in joint BYU-Los Alamos experiments.

3. The current experiments which are most successful in this area of energetic charged-particle production are those involving low-energy deuteron beams impinging on metal foils, as described briefly in my previous posts here. I do not see any connection of those experiments to fracto-fusion ideas. The explanation in terms of screening by electrons is most popular at this time, IMO, although it too seems to be insufficient to account for the large effects seen.

Ludwik Kowalski wrote:

1) I do not understand crack fusion. Ed wrote that "the Casmir effect and van der Waals forces are available to initiate nuclear reactions." Can you elaborate, please.

2) Every physics textbook tells us that metallic surfaces are equipotential. If the piece is grounded then the total charge on its surface is zero and the electric field is zero, everywhere.

3) If the piece is not grounded then a net electric charge can be introduced through its manipulation, especially if air is

dry. But that electric field is always distributed is such a way that the vector E is perpendicular to the surface, anywhere. A cavity (crack) is essentially a Faraday cage and the surface charge density in the cage is essentially zero. The only places where concentration of static charges can be high are very sharp points. Thus the term "needle fusion" would probably be more appropriate as "crack fusion" or "fracto fusion."

4) Steven Jones wrote: "We actually followed up on this hypothesis several times, by grinding, bending, crushing metal-deuterides, hoping to produce “fracto-fusion” conditions. NO enhancement of particle emission was observed . . . " . Is this not the best possible experimental proof that the postulated phenomenon does not exist? I would like to know about reproducible experiments demonstrating existence of crack fusion. Is there at least one person on this list who performed a crack fusion experiment? Please share your results.

5) Textbooks also tell us about potential differences due to dissimilar metals. For example, a particle of Zn deposited on the surface of copper can generate a difference of potential of one or two volts (I do not recall the exact number). But that is several orders of magnitude below what is needed to accelerate a deuterium ion to a kinetic energy at which the DD fusion is practically possible.

6) What is experimental evidence that rare events observed by Steven are due to crack fusion?

7) What is experimental evidence that rare events observed by Steven are due to Casimir effect?

8) What is experimental evidence that rare events observed by Steven are due to van der Waals forces?

Edmund Storms wrote:

1) Yes [in the early days, this idea was referred to as “fracto-fusion] and a large literature describing this process is available on www.LENR-CANR.org.

In addition to short lived voltage gradients [see item 1 in Steven’s message above], the Casmir effect and van der Waals forces are available to initiate nuclear reactions at low levels.

2) This [see item 2 in Steven’s message above] has been done by Russian workers. I don't have the citations just now but will find them.

3) [Referring to item 3 in Steven’s message Ed added:] Obviously something is being overlooked.

Ed Storms wrote:

1) The nuclear action occurs only as the crack forms. As it forms, unequal number of electrons and ions are separated at the two surfaces. For a brief time, this produces a charge separation, which can cause acceleration of ions from one surface to the other. This is the usual explanation. However, the crack is so small that Casmir effects can be expected. These might introduce energy into the ions from the vacuum energy. Also, the surfaces contain ions with unbalanced charge, as is the case with all surfaces, so called van de Waals forces. In this case, the surface is pure and free of absorbed ions, except deuterium. This will strongly distort the electron

charge on the D atom or D2 molecule.

2) This [equipotentiality and neutrality of a grounded metallic sphere] is only true in a gross sense. Local charge still exists.

3) Charge on a point [needle] usually exists because a gross charge is concentrated there or because electrons are being added as would be the case in an electrolytic cell or during gas discharge.

4) [Concerning "reproducible experiments demonstrating existence of crack fusion:] It is well known that if LiD crystals are hit with a hammer, neutrons will be emitted. Such work has been published.

5) Concerning Zn on Cu:] Differences in Fermi levels can create a few volts difference between metals, whether they are in contact or not. This is measured by comparing work function values.

6) "What is experimental evidence that rare events observed by Steven are due to crack fusion?" There is none. The expectation is that the very low level of emission is associated with experimental conditions used during the study that are expected to produce cracks. Also, the nuclear products are characteristic of a high energy reaction rather than the low energy reaction associated with cold fusion.

7) "What is experimental evidence that rare events observed by Steven are due to Casimir effect?" None, just a suggestion.

8) "What is experimental evidence that rare events observed by Steven are due to van der Waals forces?" None, just a suggestion.

Ludwik Kowalski wrote:
Thanks for answering all my questions, Ed. I commented: "Every physics textbook tells us that metallic surfaces are equipotential. If the piece is grounded then the total charge on its surface is zero and the electric field

is zero, everywhere.'" To which you replied: "This is only true in a gross sense. Local charge still exists." How can this (violations of Gauss law) be demonstrated?

Denns Cravens wrote:
So if I insert two positively charged D's into a metal where is the charge on the nucleus or on the metal surface?

Ludwik Kowalski wrote:
Good answer, Dennis. Gauss' law does not refer to situations in which a net charge consists of a pair of single particles. But does anybody think that a pair of duterons (or thousand such pairs) would produce observable CF (cold fusion) events? Even a million would not be sufficient to observe particles (such as n and p) generated via CF events. I was not thinking about a single pair of ions.

Suppose an insulated metallic sphere was bombarded with alpha particles. This produced a net charge of one nC. How is that charge distributed? I think that transformation of He ions into neutral atoms is practically instant. The total number of free electrons is reduced by 2*k, where k is the number of intercepted alpha particles. Is there any reason to think that the distribution of free electrons will not be uniform after the bombardment?

Ludwik Kowalski wrote:
Edmund Storms wrote: "It is well known that if LiD crystals are hit with a hammer, neutrons will be emitted. Such work has been published."

1) How well is it known? What was the reported emission rate? Who published papers describing such observations? Did someone on this list observe such remarkable CF phenomenon? My inclination is to think that neutrons were due to cold fusion, unless reality of crack fusion (or Casimir fusion, or van der Waals fusion) is independently confirmed.

2) Unless published papers are already at our lenr-canr library, I would appreciate if someone could send me a copy of the most recent paper. Write to me in private and I will send you my postal address. The phenomenon would be worth verifying, for example, by observing 3 MeV protons with CR-39. I am thinking about cracking crystals with pliers above the CR-39.

3) Steven Jones wrote: "We actually followed up on this hypothesis several times, by grinding, bending, crushing metal-deuterides, hoping to produce 'fracto-fusion' conditions. NO enhancement of particle emission was observed, at BYU or (later) at LANL in joint BYU-Los Alamos experiments." Why were no excess neutrons observed in these experiments? Who should I believe? Are the authors "hammer fusion" papers more experienced in detecting neutrons than LANL people?

4) Those with no experience with detection of neutrons, or with no access to necessary instruments, must rely on credential of researchers reporting experimental results. What else can we do?

252) A student-oriented project

Ludwik Kowalski (8/28/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
1) Suppose that an immersion heater is inserted into a beaker with water. How should thermal energy generated depend on the amount of electric energy used? The answer to this question was provided by James Joule -- one joule of heat for one joule of electric energy. In a well insulated container (to minimize losses due to convection) the temperature would rise linearly if the electric power remained constant, provided no boiling takes place.

2) And, at the boiling temperature, one would expect water to be evaporated at the rate proportional to the wattage of the heater. The latent heat of water evaporation, under normal atmospheric pressure, is 2260 J per gram. The same is expected to be true when a small amount of salt is dissolved in distilled water, to increase its electric conductivity. Salty water, by the way, is called electrolyte. Thus the maximum possible amount of water one can evaporate in 5 minutes, when the heating rate is 450 W, is 59.73 grams. In reality the amount of evaporated water would always be smaller, as illustrated in Figure 1 below, because some thermal energy is always lost via conduction, convection and radiation. That figure, was copied from a paper sent to me recently by Pierre Clauzon, a French scientist from the Laboratoire d'Electrochimie Industrielle at Conservatoire National des Arts et Métiers, Paris.

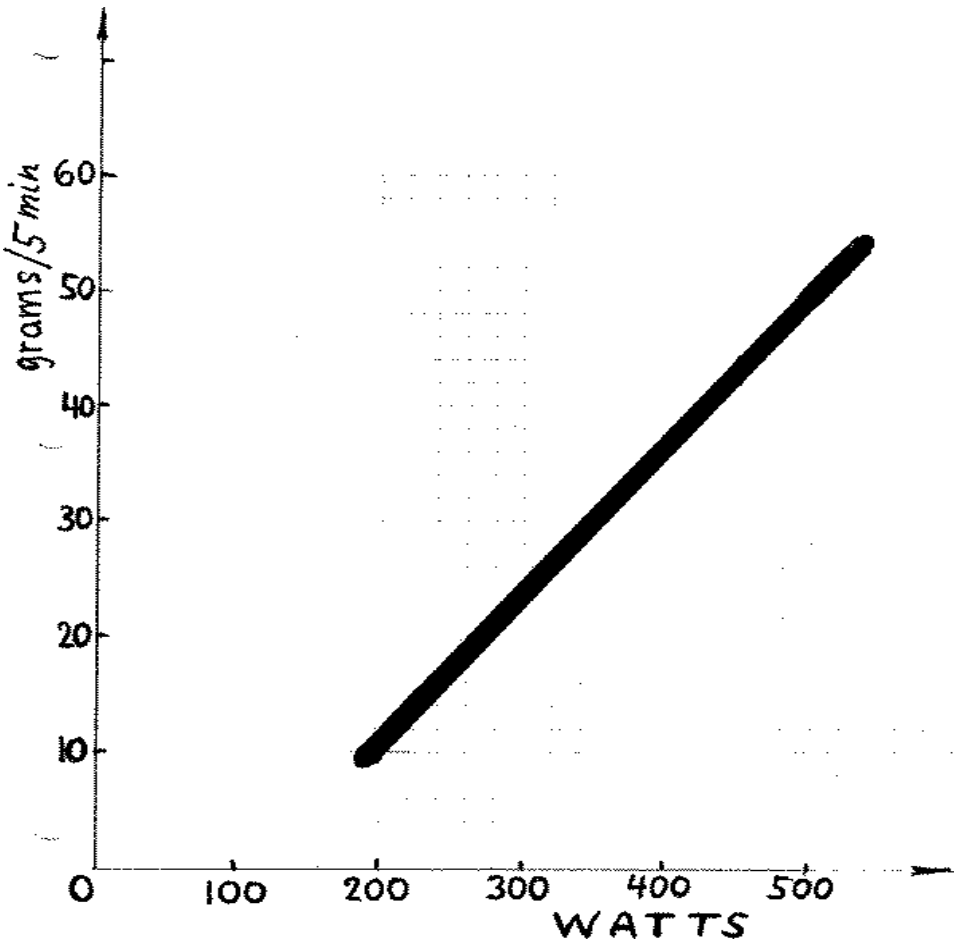

Figure 1

3) There is nothing unusual or abnormal about the black region (thick line) on that figure; it shows where a large number of experimental data points were located. The line thickness gives some idea about uncertainties of individual measurements. But the title of the paper was “Abnormal excess heat observed during Mizuno-type experiment.” Abnormalities were observed when the electrolyte was heated by a different method. Instead of passing the electric current through an ohmic heater the authors of the paper passed it through the electrolyte itself. By doing this they discovered, for example, that to evaporate 38 grams of water in 5 minutes with an ohmic resistor required the heating power of 410 W while only 300 W was required to evaporate the same amount of water in 5 minutes when the current is flowing through the electrolyte. The data point (38,300), as you can verify, is far above the black region in Figure 1. Abnormal experimental data are said to be highly reproducible.

4) How can it be? The amount of evaporated water should be the same no matter how a given amount of thermal energy is delivered to it, provided the same fraction of thermal energy is used to evaporate water. That is the dilemma. And that is why I think that attempts to replicate the experiment are worth the effort. The purpose of this note is to start a cooperative project in which several teachers would be performing essentially the same experiment at the same time. Then we can try to publish a paper that either confirms or contradicts the claimed results. If we can finish this before November 20 then I would be able to deliver this collective paper at an international conference. Schools are likely to be proud of such contributions, especially when their students are also involved.

5) Yes, I know that some might consider this suggestion ridiculous. Why bother if we already know that the claim makes no sense? Let me answer this question. By performing this experiment, preferably with a group of students, we will have a chance to practice scientific methodology. How often do we find a situation in which students can deal, in a meaningful way, with a real controversy? Here we have an opportunity to: (a) promote critical thinking, (b) focus on careful experimentation, propagation of errors, etc. and (c) possibly, if not probably, confirm a scientific discovery. The French paper has not yet been published but the authors gave me permission to write about its content, and to initiate collective students-oriented attempts to replicate the results.

6) My interpretation of such results was that some chemical reactions, taking place in the cell with the electrolyte, are producing heat in addition to electrically delivered thermal energy. In fact, I know that the tungsten rod, through which electrons enter into the solution, is partially consumed during the electrolysis. In an e-mail message to Pierre I wrote that production of heat through chemical reactions would not be an abnormal process. Here is his reply: "I know that my friends at EDF (Electricité De France) have carefully studied these problems and their answers are negative. You cannot explain the abnormal excess energy by chemical reactions with the tungsten rod. I will ask my friend Olivier to maybe elaborate more in this subject. He is a real chemist, not me !" Well, for the time being I will accept this answer; I asked for a reference to a published or unpublished report. I will insert the reference here, as soon as it arrives.

Experimental setups

7) Participants in this research will receive the French paper; do not be scare, it is in English. My anticipated setup is shown in Figure 2 below. It will be a graduated beaker (capacity close to 2 liters) containing a solution of the potassium carbonate salt, K_2CO_3, in distilled water. The concentration of the electrolyte will be 20 grams per liter (0.2 M). The electrodes (tungsten cathode and platinum anode) will have to be somehow mounted on the beaker. An ohmic heater, not shown in Figure 2, will also be mounted on the scale.

8) The first step would be to collect data with the ohmic heater. This will show where the normal data points are located (see Figure 1) for my experimental setup. Each experimental setup will probably produce a slightly different line, depending on the size of the beaker, on the lab temperature, etc. But once established, this line becomes a reference for the so-called "abnormal" results. Naturally, one has to calibrate the ohmic heater connected, for example, to a variac. Likewise one will need a high voltage power supply able to deliver up to 2 A and 600V. A sensitive scale, to support the setup, as in Figure 2, will also be needed. Note that the W cathode is placed in a glass tube; only about 1.5 cm of the cathode is below the lower end of that tube.

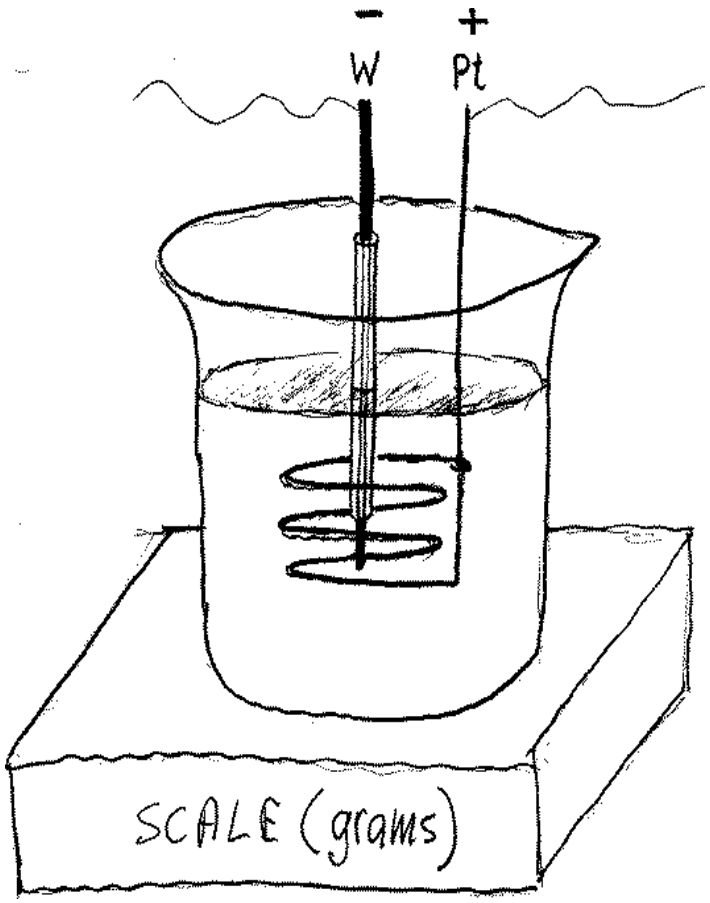

Figure 2

9) The Pt anode will be a cylinder-like spiral wire situated 4 cm from the cathode, as in French experiments. The cathode will be a commercially available tungsten rod used for welding. The water level would have to be the same at the beginning of each five-minute-long test. I do not think that replacing evaporated water during a test (from a container mounted on the scale) is worth the effort because changes in the level of the electrolyte are relatively small. On the other hand, I anticipate problems with water condensation on the walls of the beaker, and with possible splashing, abobe 200 W. Each of these two effects, if not accounted for, can contribute to an apparent excess heat.

10) I know that spectacular underwater glow discharges will be seen around the cathode. That will be associated with significant fluctuations of electric current. But the glow discharge in water is not going to be the object of this study. The purpose will be to determine the relation between the average water evaporation rate on the average electric heating power during the electrolysis. We want to either confirm or to contradict that experimental points are located above the reference line established with the ohmic heater. How will power measurements be made? I have to think about this. Rapidly fluctuating electric current, and arcing in the liquid, are likely to create problems. Please write to me, if you have some suggestions.

11) Be aware that experimenting with electric equipment, especially with a high voltage (and high power) supply, can be fatal if safety precautions are not taken. I will assume you have the necessary equipment and experience. Those who are interested should contact me in private. Let me end this invitation with a message posted by James Mackey, in another context. According to Bridgeman "[The scientist] cannot permit himself any preconception as to what sort of results he will get, nor must he allow himself to be influenced by wishful thinking or any personal bias" This seems wrong. How can one devise an experiment without having some preconceptions about the results expected. How does one decide what to measure without preconceptions about the results. The problem would arise when one allows "wishful thinking" to bias his conclusions based on the experimental results. Everyone has preconceptions about his experiments, so saying that a scientists cannot permit himself any preconception is wrong.

12) My prediction -- call it a preconception or an educated guess, if you wish -- is that the experimental data of Pierre and his colleagues will be confirmed. I also predict that the excessive heat will eventually be explained as due to well known chemical reactions. On the other hand, I remain open-minded toward other explanations. Japanese scientists, like Mizuno, whose experiments were replicated in Paris, are highly qualified chemists. They also think that excess heat released during the electrolysis is too large to be due to chemical reactions. Furthermore, they presented evidence of transmutation of chemical elements. That seems to point toward nuclear origin of excess heat. The controversy about this is not new. Do not miss an opportunity to expose students to meaningful research. They will benefit from working on this excess energy project no matter what the final verdict will be.

Appended on 8/31/05:
What I would like to do, if at least four or five teachers make tentative commitments, is to create a dedicated private discussion list. Informing each other about progress, and addressing problems, should be easier on a discussion list than via regular e-mail messages. I know that many on this list have the necessary experience but no time to perform experiments. Such people are also invited; we will need advisers. Please indicate, in a private message to me, what role do you want to play -- that of a researcher or that of an advisor?

253) Mizuno-type high voltage electrolysis

Ludwik Kowalski (9/2/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) In unit #252 I described experiments of Pierre Crauzon and his colleagues. It was based on their recent, still unpublished paper, and on my correspondence with Pierre. In this unit I want summarize what I known about other experiments of that type.

a) Experiments of Mizuno et al. (1997)
b) Experiments of Little et al. (1998)
c) Experiments of Naudin et al. (2003)

Results of Clauzon (excess energy is about 30% of the input energy) seem to be more or less consistent with what was reported in several Naudin's experiments.
Results of Little, however, indicated that the excess heat, if any, is less that about 3% of the input energy. Mizuno, on the other hand, originally reported that excess heat was 1000% of the input energy. In fact, the purpose of nine experiments undertaken by Little was to replicate Mizuno's experiments. All researchers wrote that their results were highly reproducible. That is certainly a strange situation. I also looked at the report that Mizuno presented at the 10th International Conference on Cold Fusion (ICCF10 in 2003). The main point of that paper was the discovery that the excess heat is only a fraction of excess energy; a significant part of excess energy is chemical -- production of hydrogen fuel. The amount of that fuel turned out to be much higher than what one would expect on the basis Faraday Law of electrolysis.

2) I do not have the original Mizuno paper; it was presented at the ICCF7. But his ICCF10 paper is downloadable from the library at <www.lenr-canr.org>. From that paper I see that two independent methods were used to measure excess heat: flow calorimetry and isoperibolic calorimetry. The first has already been introduced in units # 116 - 119. It is highly reliable when the cell is well isolated (no significant excess heat is lost through the surrounding wall. The second method is also quite simple; its reliability depends on stability of calibration. The calibration consists of placing an immersion heater, of known wattage, into the electrolyte and waiting till the temperature stops rising. That gives the first calibration point, for example, 50 W and 47 C. The the heating power is increased, for example to 100 W, and new stable temperature is measured. That the second calibration point. In that way a relation between the heating rate and equilibrium temperature can be established. The curve is plotted and used in subsequent electrolytic experiments.

3) In my opinion the credibility of results reported by Clauzon would go up if the flow calorimeter were used. On the other hand, I see nothing wrong in calculating the average heating rate from the average rate of evaporation. Simplicity is a great advantage, especially in educational context. Naudin also used that simple method. It is hard to believe that large discrepancies of conclusions are due to systematic errors in measuring excess heat produced at the rates higher that 50 W. Measuring rates at which electric energy is supplied to an electrolytic cell is more tricky. But I do not believe that a discrepancy of several orders of magnitude, between Mizuno and Little, is due to a systematic error in measuring electric energy.

4) So what can possibly cause the discrepancy? That is a very difficult question. As usual, one is inclined to think that

an essential success-enhancing ingredient was present in the W cathode used by Mizuno but absent in the cathode used by Little. Ed Storms call the mysterious ingredient NAE (nuclear active environment). He believes that CMNS phenomena will become reproducible everywhere after the nature of the NAE is recognized. But in the experiments #7 and #8 Little used the cathode sent to him by Mizuno. And the results were the same as in other experiments -- the average electric input power and the average thermal power were essentially identical. The controversy remains unresolved.

The only way to make progress, in my opinion, would be to bring Mizuno to the laboratory of Little (to repeat Little's experiment together) and then to bring Little to the laboratory of Mizuno (to repeat Mizuno's experiment together). Would they discover an error in at least one experiment? If not then a tentative conclusion will be that the NAE is linked to geography. But that would lead to other contradictions; many successful attempts to generate excess heat were made outside Japan, for example, in China, Russia, Ukraine, Israel, Italy, France, Canada and the USA.

Let me finish this unit by mentioning that Naudin's experiments were reproduced by other researchers, as illustrated at <http://jlnlabs.online.fr/cfr/>. They are not very different from the experiment of Clauzon and his colleagues. What is remarkable is that no expensive platinum was used in many of his devices. Very large amounts of excess heat were reported with cells whose both electrodes were identical, for example both tungsten or both stainless steel. In other words, two knives or two spoons can be used. Two tungsten rods for arc welding, he told me last fall, are excellent electrodes. It is not difficult to find suppliers of such rods by googling. Let us hope that a massive assault (many teachers, students and other qualified people working on the same kind of experiment at the same time) will help to solve the puzzle.

254) An interesting theoretical paper

Ludwik Kowalski (9/4/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As mentioned in another unit, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. In unit #249 I wrote about one interesting theoretical interpretation of CMNS phenomena. Here I would like to mention another theoretical interpretation. A link to the following webpage was shared, this afternoon, by one of the contributors.

http://arxiv.org/abs/cond-mat/0505026

It points to an interesting paper, dated Mat 5, 2005, of A. Windom and L. Larsen. I am not a theoretical physicist but I have an urge to share what I think can be understood in terms of elementary nuclear physics concepts. Let me begin by mentioning the familiar form of radioactive decay in which an orbital atomic electron is captured by a nucleus producing a transformation of a proton into a neutron. A well know example of such process is the decay of ^{51}Cr into ^{51}V (T=27.8 days). Can a hydrogen ion be transformed into a neutron by capturing an electron? That question is answered positively by Windom and Larsen.

First they remind us that transformation of protons into neutrons has been observed when negative particles captured are negative muons rather electrons. The mass of a muon is sufficiently large to overcome the mass excess of a neutron over a proton. That makes the reaction energetically possible. Transformation of protons into neutrons, by capturing electrons, is energetically impossible; the mass of a free electron is much smaller than the mass difference between neutrons and protons. But it would be energetically possible if the mass of an electron were 2.53 times larger. The authors observe that “the electron mass in condensed matter can be modified by local electromagnetic field fluctuation” on metallic hydride surfaces.

The paper addresses details of this issue in terms of concepts with which I am not familiar. That is why I would very much like to know what quantum electrodynamicists think about the paper of Windom and Larsen. For the time being I will tentatively assume that anticipated mass enhancements of electrons are realistic and that heavy electrons do produce neutrons, occasionally in metals, such as palladium, loaded with hydrogen. The author anticipate that neutrons produced from protons will have very low energies. At those energies capture cross sections are very large. For that reason, they speculate, only a very small fraction of neutrons should be experimentally observable.

One can argue with this. Most neutrons would indeed be absorbed (via nuclear reactions) if they were generated in a thick metallic sheet. But that expectation does not seem to be consistent with the idea that most neutrons are produced at metallic surfaces. The explanation of helium production, via equations (26), makes sense to me but production of ^{6}Li, via equations (28), is much less likely. This has to do with the extremely short half-life ($2*10^{-21}$ s) of ^{5}He. That nucleus will emit a neutron long before it is hit by a second neutrons produced from a proton. And I do not know how to consolidate the suggested mechanism with frequently reported absence of gamma rays. Pd isotopes, for example, absorbing neutrons, would produce several gamma radioactive isotopes of silver. Likewise ^{181}Ta and ^{58}Ni would produce gamma radioactive ^{181}W and ^{58}Cu, respectively.

254) Excess energy; progress report

Ludwik Kowalski (9/6/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) In this unit I plan to write about reports, comments and reflections related to the project described in the unit #252. Two discussion lists were used to announce the initiative: PHYS-L (~200 subscribers, mostly physics teachers) and CMNS (~ 150 subscribers, members of the International Society of Condensed Matter Nuclear Science). Most members of that society either conduct or conducted research in three areas of CMNS: cold fusion (CF), cold transmutations (CT) and excess energy (EE). Except for myself (LK), I will refer to authors of comments as either T (teachers), S (students) or R (CMNS researchers).

2) Here is the first message on PHYS-L; it was posted by me yesterday.
Dear colleagues: Please read what has just been posted at my website as:

http://csam.montclair.edu/~kowalski/cf/252clauzon.html

It is an invitation to participate in a collective student-oriented project. The idea of turning what I wanted to do into a collective Internet project was prompted by the ongoing debate about scientific methodologies. Give your students a chance to participate in a research project they can easily understand.

3) Here is the first message on CMNS; it was also posted by me yesterday.
The following has just been posted on a discussion list for science teachers (PHYS-L): . . . [see item 2 above]. I would also like to reach people who are not on the PHYS-L list. Some of you might know teachers who are qualified to participate in this research project. If so then share the above URL, and my e-mail address, with them. By the way, it would be great if you could assist them. Please comment on the idea of organizing easy-to-set-up Internet-based CMNS projects.

4) So far I had only one person commitment. A physics professor T1 wrote:
"We would like to participate. One or more students from my experimental physics class (senior physics majors) will set up and perform the experiment. Thanks for the opportunity."

5) Several interesting comments were made on the CMNS list. Here are extracts from their messages:

R1: ". . . I do not think experiments of this nature will produce definitive evidence, and I doubt it will change the minds of any of the professional skeptics. I expect this work will be like the experiments conducted by high school students working with John Dash: interesting, worthwhile, thought-provoking, but not fully convincing. The students are smart cookies and they deserve an A for effort. The experiments are excellent publicity for cold fusion. They attract young people, which the field desperately needs. But most researchers I have spoken with feel that the instruments are too crude to be convincing. .....I hope that some of the leading researchers in the field, such as McKubre, Storms, Dash and Mizuno, will lend a hand and offer advice directly to the participants."

R2: (who was not able to confirm excess heat in similar experiments): " .....I applaud the idea of making the

experiments public via the Internet. I think it will go a long way towards getting to the bottom of this particular phenomenon. As you can see from our 'Experiments" pages [several links were provided] .....we have tried a variety of closely-related experiments and never observed the excess heat reported by other investigators. ..... Since the heat output is relatively easy to measure in these experiments (especially in the Clauzon embodiment), this means there is a high probability that the other investigators are either getting real excess heat or mis-measuring the electrical input power. Due to the highly erratic nature of the current flowing in this experiment, the latter is a very real possibility.

I therefore urge all participants in this experiment to focus on the accuracy of their electrical input power measurement. In lieu of purchasing an expensive power analyzer (such as our Clarke-Hess 2330), experimenters should consider using an ordinary residential watt-hour meter (readily available on Ebay for ~$25). The smaller of these meters have low Kh values (watt-hours per revolution of the dial) and finely graduated dials so they can be used to measure pretty low energy values accurately. For example, half a revolution on a Kh=1.8 meter, would be 0.9 watt-hours or 3240 joules, which is the energy delivered by a 324 watt source in 10 seconds -- this is well within the range of interest in this experiment.

I look forward to seeing the results of these experiments. Because of our history with this experiment we will wait and see how things turn out....for now. If several groups obtain positive excess heat results and double-check their electrical measurements, naturally we will drop everything and join the party immediately."

R3: ". The discrepancy between Mizuno's results and Little's are a mystery. I do not think progress toward resolving this mystery will be made until Little and Mizuno spend several weeks working together, perhaps using some of both sets of instruments. Mizuno reportedly has a great deal more space these days in his new lab, so it should be easier to work with him. "

R4:" LK asked: 'Can a chemist tell me how much thermal energy is released when one gram of tungsten is totally oxidized. A sentence or two explaining the calculation would also be appreciated. Quick and dirty reply, W has an atomic mass of about 184 so 1 gram is 1/184 moles or about 0.0054 moles. Assuming it goes to WO2 with O2 that is about 140 Kcals /mole. That is about 0.76Kcals."

LK: "Thanks. That translates into 3181 joules. Dividing this by 300 s (for a 5 min. test) one gets only a 10 W contribution to excess power. According to Clauzon, experimentally measured excess powers are often higher than 100 W. To explain 100 W one would have to assume that 10 grams of tungsten "fuel" is consumed in 5 minutes. That is about 0.5 cc. I do not know by how much the mass of the cathode was reduced in experiments in which excess power was 100 W. I suspect it is no more than 2 or 3 grams; but that is only a guess based on what I know."

R4: "If I understand correctly, tungsten is the cathode where hydrogen is produced, not oxygen. Therefore, the tungsten can not oxidize. Loss of material from the cathode is caused by other reactions including vaporization when a plasma is used."

R3: "Yes, but LK asked about one gram of tungsten being totally oxidized. It may or may not be in an electrolytic system. The W may or may not be a cathode since some of these are run with AC. "

R4: "True, but this is an important fact anyway. In addition, if W is run as the anode, it quickly oxidizes and disappears. Use of AC gives some protection because the oxygen activity at the anode does not get as high as would when using DC."

LK: "R4 makes a good point that oxidation of tungsten is probably not the main cause of its gradual consumption. I was thinking about the worst possible scenario. Even with that scenario the reported excess power is too high to be due to chemistry..... "

R2: " . . . The formation of tungstic acid is exothermic and yields 270.5 kilocalories/mole...BUT, the dissociation of 4 moles of H2O into the H2 and O2 needed for the formation of H2WO4 is endothermic and requires 4 x 68.3 = 273 kilocalories.... an almost perfect cancellation."

R4: “T2, I suggest the H2WO4 was not made by electrolysis but by hot W reacting with steam in the bubbles. Of course, this would produce energy and extra hydrogen, but not from the electrolytic process. The electrolytic process is too reducing at the cathode for H2WO4 to form - a small point that might help clarify thinking about the process.”

R2: “I don't see the "produce energy" part. It looks like a slightly endothermic reaction to me 270.5 kC/mole for the formation of H2WO4 but it costs 273.2 kC to get the 4H2O dissociated into H2 and O2. Net heat of formation under these circumstances: -2.8 kC/mole (here the minus sign signifies the reaction consumes this energy. not releases this energy. Yes, I know that's contrary to conventional heat of formation sign conventions but I'm a physicist not a chemist.).”

R4: “I don't have the numbers handy, R2, but this reaction would only go above about 1000° C. Are your heat values for this temperature. Such a temperature would be expected to occur for brief times on the surface of the tungsten in contact with the plasma. In any case, such a reaction would not go unless it is exothermic.”

6) I see three very distinct aspects in this project. First is to ether confirm or contradict experimental facts reported in the French paper. Is it true that less electric power is used to evaporate a given amount of water in five minutes via high voltage electrolysis than via ohmic heating? In other words, is it true that the experimental data points (rate evaporation versus electric power, as in Figure 1) from high voltage electrolysis can be located above the data points from ohmic heating? The second aspect is to interpret experimental results, after they are recognized as valid. Can the difference between the two sets of experimental data be explained in terms of well known chemical processes or not?

The first task is relatively simple; both physicists and chemists are trained to deal with it. The second task seems to be much more complicated because it calls for the expertise in analytical chemistry. All major chemical reactions, taking place during the high voltage electrolysis, must be recognized and their thermal outputs must be calculated from enthalpy tables. If the existence of excess energy is confirmed, and if that energy cannot be attributed to known chemical reactions, then the situation is really abnormal and worth of additional investigations. The third task would consist of numerous projects designed to identify the abnormal phenomenon, to explain it in terms what is known, and to explore possibilities of practical applications. One particular “abnormal” phenomenon comes to my mind -- I am thinking about the first transformer. An electric current was discovered (Faraday, 1830’s) in a circuit not connected to a battery.

Appended on 9/1/05:

7) This is my reply, posted on the CMNS list, to what R2 wrote yesterday, about kWh measurements. “Commercial kWh meters are probably designed to operate when volts and amps change sinusoidally. The high voltage electrolysis cell is an arcing and sparking load. Therefore the instrument must be calibrated; otherwise honest skeptics will have good reason not to take the reported excess heat seriously. Please comment on the following way of calibration (or suggest a better way).

A small cell with a cold electrolyte is immersed into a high school calorimeter (a double-wall aluminum cup) and the high voltage is applied to electrodes. The electric energy, taken from the a.c. 110 V outlet, flows through the kWh meter to the HV power supply and then to the cell. That is the anticipated setup. At time zero the switch is turned on to start arcing and sparking. The switch is turned off when the temperature of the electrolyte becomes, for example, 60 C, as monitored with a thermister. Then the kWh are recorded. The amount of heat received by the calorimeter is calculated (from the change of its temperature, the amount of water in it, etc.) The kWh meter can probably be trusted to measure the energy needed to operate the power supply when the load is disconnected.

Suppose that the electric energy needed in two minutes, when the load is disconnected, is 1 kJ. Also suppose that during two minutes of arcing and sparking the measured electric energy was 36 kJ (10 kWh). That would indicate the net electric energy of 35 kWh. Suppose that the calorimeter shows that ~35 kJ of thermal energy was delivered to the cell at the same time. That would mean that the kWh recorded by the electric instrument are reliable. On the other hand, suppose that the thermal energy delivered to the calorimeter was found to be 20 kJ. That would indicate a correction factor of 35/20=1.75. That factor would have to be used to convert the kWh read by the electric instrument into true input energy. The accuracy of measuring thermal energy with a high school calorimeter is not great (~5%) if

one is careful. But such instruments are probably sufficient to avoid larger calibration errors."
P.S.
As I read my own message, thinking critically, I see need to specify that electrodes used to calibrate the kWh meter should be nonmetallic, for example, carbon rods. Why is this important? Because a metallic cathode, especially Pd, is believed to promote releases of thermal energy from nuclear reactions. My anticipated method of calibration is based on the assumption that thermal energy and electric energy are equal (during a given time interval). Is this an acceptable assumption when carbon electrodes are used? If not then a better way of calibration is needed. Do you agree that the recalibration of a commercial energy-meter is essential when the load is an arc or glow discharge?

P.P.S.
This is not the whole story, unless the cell was sealed (to be totally immersed inside the calorimeter), and contained a recombiner of hydrogen and oxygen. Without the recombiner chemical energy produced (formation of hydrogen and oxygen from water during the electrolysis), would have to be added to the reading of the calorimeter. Like heat, chemical energy, produced during the calibration, comes from electric energy.

How much chemical energy is produced in 5 minutes when the electric current is 2 A? The total charge is 2*5*60=600 C. According to Faraday Law 96500 C will produce one mole of atomic hydrogen. This in turn becomes 1/2 mole of molecular hydrogen (one gram of H_2). The heat of combustion of hydrogen is 143 kJ/gram. In other words, production 1 gram of H2 fuel, via electrolysis, will use the electric charge of 96500 C to store 143,000 J of energy. This translates into 1.48 joules of excess energy per coulomb. Mizuno called it "heat of formation." For I=2 A and t=5 min the charge is 2*5*60=600 C. The corresponding chemical energy is 1.48*600=889 J, or nearly 0.9kJ. This is about 1% of the excess energy reported by Clauzon and his colleagues. In other words, excess heat would not increase significantly if production of chemical energy was taken under consideration. But the total immersion of the calibration cell, in the high school calorimeter, is important, as in bomb calorimeters used to rate bread, butter, sugar, potatoes, etc.

R2: "I suggest we use a residential watt-hour meter for one of the instruments and a pair of DMM's for the other instrument. One DMM [digital multi meter] can measure the voltage across the cell and the other, perhaps with some filtering, can register the average current through the cell. Since the average cell current often changes significantly throughout a run (due to erosion of the cathode), the experimentalist will have to discipline themselves to record voltage and current at regular intervals throughout the run and then add up the total energy delivered. BTW, residential watt-hour meters can handle significantly non-sinusoidal waveforms. They must do so in order to accurately meter the electrical energy consumed by motors, light dimmers, etc.

R4: "Carbon is not good, LK, because CO is made at the anode and CH4 is formed at the cathode, thereby contributing extra chemical energy. Clean Pt is the best material for both electrodes."

LK: "Pt is in the same group as Ni and Pd. But I will take your advice, R4. By the way, those who are very skeptical about CMNS phenomena will not object to the calibration on the basis that "nuclear energy might possibly be released on the metallic surface." They think that this is impossible. To convince myself (that calibration is correct) is much more difficult. I agree with R2 that the level of confidence will go up when several methods of calibration give nearly the same result.....Something has to be trusted as one goes from what is known to what in not known."

256) On measuring electric energy

Ludwik Kowalski (9/15/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) What can be more simple than measuring electric energy delivered to a resistor at constant current? Measure the current, measure the voltage, multiply amps by volts (to get power in watts) and multiply by time in seconds. This gives energy in joules. The same is true of common alternating current, for example, at 60 Hz. Most voltmeters and ammeters show so-called effective values and that is what is needed to calculate the power in joules correctly. Electric power meters, calibrated in watts, can also be used in d.c. and a.c. circuits. Furthermore, electric energy meters can be used. Nearly every house has an energy meter; cost of electricity is usually calculated on the basis of such instruments. (They display energy in kWh; 1 kWh=3.600.00 J).

2) But what about a case in which an electric current is highly irregular? I am referring to an experiment described in unit #252. Two days ago I received a message from a German engineer, XX, who read that unit. He suspects that at least some researchers did not measure electric energy properly. He wrote: “

“. . . Some comments in #254 shows that I'm not the only one which sees the measurement of electrical energy consumption as one of the keys to this experiment. On the other side there seems to be some believe that if one take two multimeters and take the average I and U one could easily measure the electrical power of the experiment. At that point I want to stress that doing so could easily generate errors of nearly any magnitude. I will give you and example. Take the case of a pulsed waveform. Let us assume a pulse width of 1/10s and a pulse voltage of 1V. The current which is forced by the pulse of 1V should be 1A . The pulse should be repeated every second. So how can I calculate the energy used in 100s? It is really simple. Is it?

Method ONE (I'm sure the correct one): The energy of one pulse is 1A*1V*1/10s = 1/10Ws. In 100 second we have 100 pulses so we have a consumption of 100*1/10Ws=10Ws= 10J.

Method TWO (I'm sure the erroneous one): Let us calculate the energy taking the values of our two multimeters. The voltmeter in our case shows us a value of 1/10V and the ampere meter shows us and value of 1/10A. If we now calculate the energy simply by using U*I*t we get 1/10V*1/10A*100s = 1Ws= 1J. We have on error of factor 10 (exactly the inverse of the 1/10 duty factor of our case).

Now you can think what's the point of this discussion? The point is that I have found some experiments I assume exact this kind of error has happened. One of them is in an experiment from Kanarev you mentioned in #172. Here is the link to the description http://www.newpowers.org/heat_generator_test.html. At the end of the paper the calculation of consumed energy is discussed and Kanarev insist on the calculation like method two. Because duty factor in that experiment is small he get huge excess power. Also some people from SITIS (?? obviously some guys he cooperate with) made him aware of the wrong calculations he argued that his method is correct. I have to admit that I'm a little bit surprised at this. Everybody can make errors but a professor should realize such an error at least after he was point the error. The other one I found was on the homepage of Naudin you mentioned also in 172 and 174 (I want to note that I like his homepage) in his experiments with MAHG. There I assume the same error happens. He calculates the energy consumption of his pulsed system with values reading from his two RMS multimeters. At the least he should have been skeptical after looking on his own results http://jlnlabs.imars.com/mahg/tests/maghwr.htm. The COP factor

scales nicely with the inverse of the duty factor. It is exactly the error one get if using method TWO.

I write this message not to accuse somebody to spread false claims or do a bad job I do not even totally exclude the chance that my thoughts in this email are based on an error of myself also I strongly belief that I'm right. I write this long message only to make interested people aware of the fact that using the values of two multimeters (even if they are true RMS multimeters) to calculate the energy consumption of an experiment could result in huge errors. The size of this error depends strongly on the waveform used during the experiments. Please do not hesitate to comment my email even if the comments should be critical.

Replying to the above I wrote that arcing and sparking produces highly irregular current. This makes energy measurement even more difficult that for the pulsed waveforms described by XX. Fortunately a simple calorimetric method can often be used to calibrate the system. Here is an illustration. Produce an irregular current by inserting a vibrating contact (like in a Tesla coil, or in a door bell) into a circuit containing your resistive heater. Immerse this heater into a calorimeter and turn the power on, for example, for 300 seconds. Suppose the heat capacity of your calorimeter (including the cup and the heater) is 500 cal/C = 2093 J/C. Suppose the temperature goes up by 30 C in 5 minutes. Then the average power (rate of heating) is 2093*30/300 = 209.3 J/s. Your electric power meter is reliable if the average power is close to 209.3 W. The calorimeter tells us that 209.3*300 = 62,790 J of thermal energy was delivered and that should agree with what is measured electrically.

257) Questioning a statistical protocol

Ludwik Kowalski (9/13/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Units 240 and 241 were devoted to a paper of Robert Bass. Two days ago he sent me a new version of that paper; that version will appear in the ICCF10 proceedings. I see that the second author, Michael McKubre, was added. I also see my name mentioned at the end; I am glad than my critical comments were useful. That encourages me to revisit the long-forgotten topic and to comment on the new version. Here is the message sent last night to Robert Bass:

= =

1) Thanks for sending me Your ICCF10 paper, and for mentioning my name. I read the protocol and the description was clear to me. In the example of 5 data points (plus blank that is always 0,0) you found that rho was between 1/3 and 1/2. The 95.4% level of confidence was assigned to this experiment (to this set of 5 data points) on that basis.

I am familiar with the concept of level of confidence when samples of limited size are drawn from large populations. For example, suppose that heights of 100 of randomly selected students, in a large university, were measured and the average was 167 cm. A statistician might say that, at the level of 68% confidence, the true average height, for the entire population, is between 163 and 171 cm. Or she might say that, at the level of 95% confidence, the true average height is between 159 and 175 cm. To validate the protocol I could, at least in principle, collect 1000 random samples (from the same population) and count how many samples are consistent with a prediction. For the 68% prediction to be valid, about 680 random samples must yield means between 163 and 171 cm. The protocol (or the assumed randomness of selections) would be shown to be wrong, for example, if only 250 mean values were in the predicted range.

But your 95.4% level of confidence applies to the statement that "the relation is linear." It does not apply to a number that is confined to a specified range. Suppose the experiment is repeated 1000 times (producing 1000 sets of five slightly different data points). What should happen to confirm your statement? What should happen to contradict it? In other words, what does the 95.4% level of confidence refer to?

P.S.
You can DEFINE a rectangle whose sides are 2 cm and 3 cm. Then you can say that the area is 6 cm^2, with 100% confidence. Or, after MEASURING two sides, you can say that the area does not differ from 6 cm^2 by more that 1%, at the level of 90% confidence. But saying that the MEASURED area is 6 cm^2, at the 90% confidence, for example, is meaningless. Why is it so? Because it can not be verified by performing a finite number of experiments. Suppose the mean value, after 1000 measurements, becomes 6.09. That would contradict the 1% range. But the range was not specified in the last statement. Therefore results like 6.09 or 5.9999 neither confirm nor contradict it. As you know, statements that are not falsifiable are not acceptable in experimental science. That is why, I am questioning the statement about linearity, in your modified ICCF10 paper.

= =

2) The reply will be appended here, after it arrives. For the time being I will assume a range of values about which the confidence level was 95.4% will be specified. This will offer me a possibility to test the protocol by simulating

experimental data with a Monte Carlo code.

= =

3) Bass and McKubre wrote:
"It is universally accepted, even by nonscientists, that if the measured output from a physical system is double, triple, or quadruple that obtained when the measured stimulus/input is doubled, tripled, or quadrupled then there is a "cause and effect relationship" between the input and output (e.g. total energy input versus excess energy [or nuclear ash] output in a cold fusion experiment)."

Deciding what is stimulus/input for a given output is not always easy. Two quantities measured in a given experiment my be proportional to each other without being part of a "cause and effect relation." Suppose that temperature and pressure of atmospheric air are measured for several hours. A correlation, between p and T, even linear, is discovered. Which variable is the input and which variable is the output? It is not at all obvious that one variable affects the other; both might be influenced by something else. The same is true in the case of burning fuel. Is the energy released caused by ash or is accumulated ash caused by released energy? Both are byproducts of a complex process. The same can be said about the weight and height of a growing child. I think that the reference to the "cause and effect" is totally unnecessary; the main purpose of the paper is to offer a tool for testing linearity between two experimentally measure quantities.

4) The simplest, well known, approach consists of plotting the data points with error bars. Then one can see how a straight line fits the data. Also well known is the linear regression analysis of a scatter plot. It offers the "best possible" straight line and the correlation coefficient. That coefficient gives a general idea about how the actual data points are scattered on both sides of the best line. The authors of the paper, however, want to go beyond this. They want the "level of confidence." I already wrote that this is not possible unless a region in which the straight line is expected to be located is also specified. Without this their rho parameter is just another useful indicator of the "goodness of fit."

5) But can experimental data in the area of CMNS be processed in the same way as in an area in which experimental data are reproducible? In my opinion the CMNS field is not ready for the "level of confidence" analysis. But I will ignore this fact and try to evaluate the protocol presented by Bass and McKubre. That protocol is straight forward. Given N-1 data points, and an additional (0,0) point, called "blank," one calculates a single parameter, rho (Greek symbol in the paper) and uses it to determine the level of confidence. More specifically, the level of confidence is 68.3%, 95.4% and 99.7% when rho is less than 1, less than 1/2 and less than 1/3, respectively. It would be useful to have a table in which the range of levels of confidence were broader (for example, 50% to 100%) and steps in rho were smaller (for example 0.05). What surprizes me is that the outcome does not depend on the error bars assigned to individual data points. To test the protocol I will use the following set of six data points:

(0,0), (1,3), (2,4), (3.6), (4,11.9) and (5,13.8).

For these points, according to Figure 1, rho is between 1/3 and 1/2 and the level of confidence is supposed to be 95.4%. I will take this statement for granted and use the Monte Carlo method to determine its validity. In doing this I will assume that the first variable, in each pair, has a negligible random error. The second variable, however, in each data point, will be assigned an error bar, as explained below. The confidence level of 95.4% implies that in 10000 Monte Carlo trials (based on the above data points) at least nearly 9540 should produce regression lines confined to the specified region. Agreements with expectations will be labeled as YES. For example, if YES is 3500 then only 35% of experiments produce regression lines in the specified region.

. . . . How many YES out of 10,000 ?
Case 1: vertical error bars (sigma = 0.5%) ....>
Case 2: vertical error bars (sigma = 5%) ....>
Case 3: vertical error bars (sigma = 10%..................... >
Case 4: vertical error bars (sigma = 20%..................... >

Added on 9/17/05:

6) My Monte Carlo code is ready but Robert did not reply. Perhaps he is away, perhaps his computer is not working. I hope he is not sick. I suspect the value of rho is linked, somehow, with the "width" of the straight line; smaller values of rho refer to wider lines. I can not test his protocol without knowing how to distinguish YES from NO. But I can do the following (just to illustrate the working of my code). Let me arbitrarily assume that the calculated rho defines the width of the region as 5% of the mean expected value. The expected values are those found from linear regression fits. If the regression line, based on a set of six simulated data points is confined to the expected region then YES is incremented. Otherwise it is not incremented.

With such artificial choice the results were as follows:

. . . . . How many YES out of 10,000 ?
Case 1: vertical error bars (sigma = 0.5%) .....> 10,000
Case 2: vertical error bars (sigma = 5%) .....> 2,958
Case 3: vertical error bars (sigma = 10%..... > 335
Case 4: vertical error bars (sigma = 20%..... > 28

The fact that the vertical error bar has a decisive influence on the number of YESes is not surprising. This is likely to happen no matter what criterium is used to identify YESes. Validity of the protocol will always depend on vertical "width" of the regression lines (region of confinement) and on the vertical error bars, as intuitively expected. The weakness of the protocol is that it does not take into account bars of error and that it does not define what is and what is not a linear relation between two experimentally measured quantities.

258) Sampling errors are not likely to occur

Ludwik Kowalski (9/20/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

An interesting discussion developed between people planning to replicate the experiment described in unit #252. The voltage applied to the cell, v(t), will be essentially constant but the current, i(t), will be highly irregular. They are interested in measuring electric energy delivered to the cell during a test of a known duration. Consecutive values of i(t) will be determined by an instrument performing digital sampling. That energy will be calculated as a sum of consecutive dE = i(t)*v(t)*dt, where dt is the time interval between samplings. The frequency distribution of i(t) is likely to be very wide. Suppose that the sampling frequency is much lower than some frequencies contributing to the shape of the waveform. Can this lead to a systematic error in an attempt to determine the electric energy delivered to the cell? That question is answered below.

Consider a current waveform shown in Figure 1. It has been generated by using random numbers (from a uniform distribution between 0 and 2). The time intervals between consecutive current changes were 0.1 ms, as indicated. It is clear that the spectral composition of that waveform contains frequencies higher than 10 kHz. The mean current, over a long period of time, is 1 A, by design.

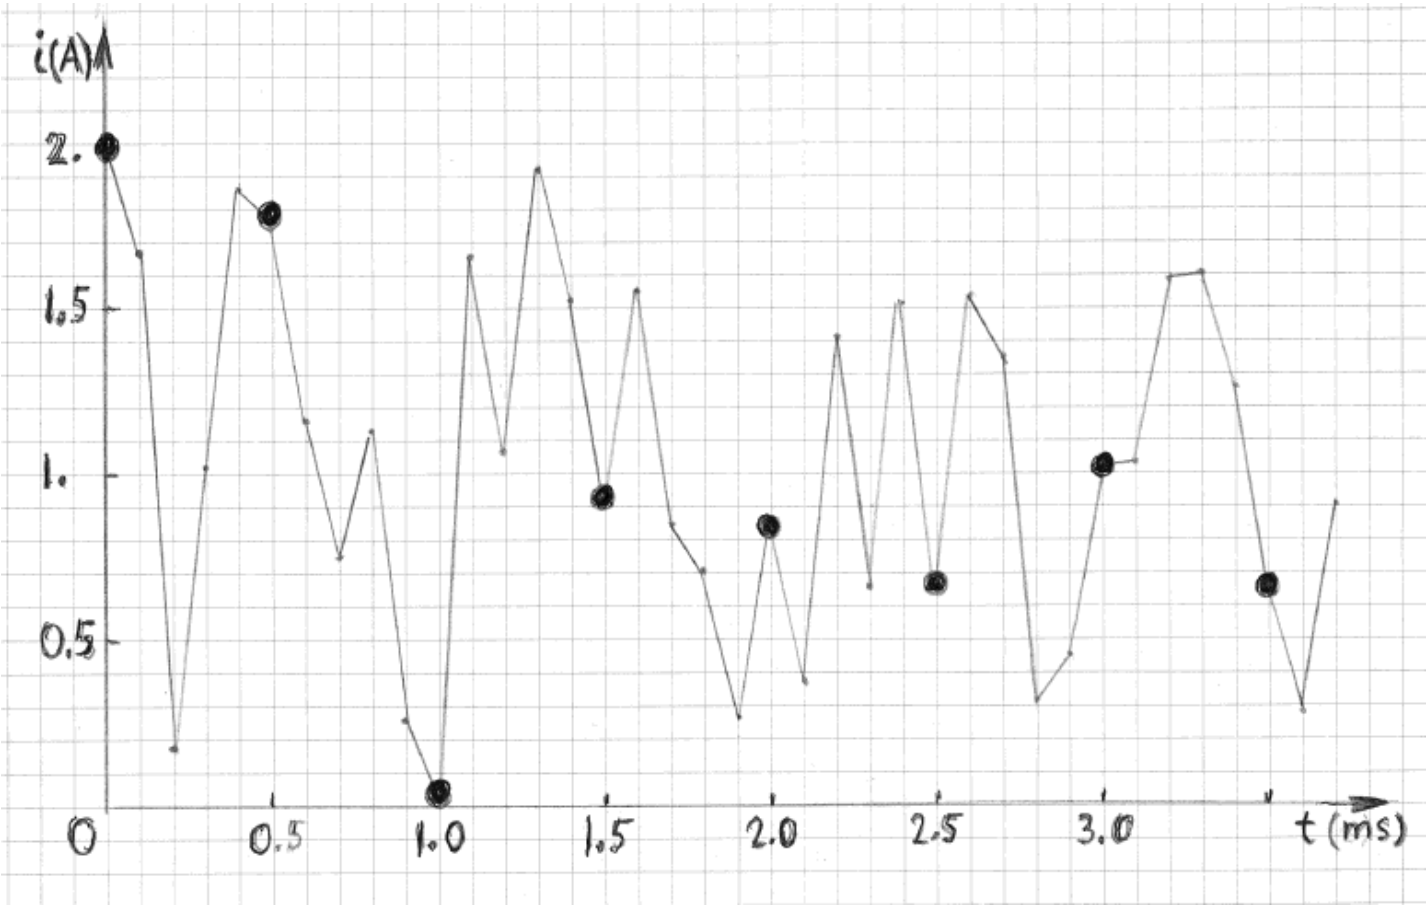

FIGURE 1

Suppose that the shape of this waveform must be determined by sampling. The rate of sampling would have to be considerably higher than 10 kHz , for example, at least two or three measurements during every 0.1 ms. The dark circles show the waveform one would obtain if the rate of sampling were only 2 kHz. This is certainly not a correct representation of the real shape of the

waveform. But the situation becomes dramatically different when the purpose of sampling is to determine the mean current over a long time interval, for example between 0 an 20 seconds. In that case the mean value from the true waveform and the mean value from the circled waveform would be practically identical. This fact was numerically verified by using a computer code. The six mean currents, obtained by executing the code six times were: 1.000, 0.999, 0.993, 1.001, 0.992 and 1.004 A.

In other words, the sampling frequency necessary to determine the mean current can be much lower than what would be necessary to determine the shape of the signal. The only requirement, to obtain a reliable mean value, is to gather a sufficiently large number of samples during the experiment. This conclusion is intuitively obvious for any random waveform. The situation, however, can be different for a periodic waveform, as illustrated in Figure 2. In that example the sampling interval -- 1 ms -- is the same as the period of repetition. The apparent mean current would thus be 0.2 A; that is several times smaller than the true mean current.

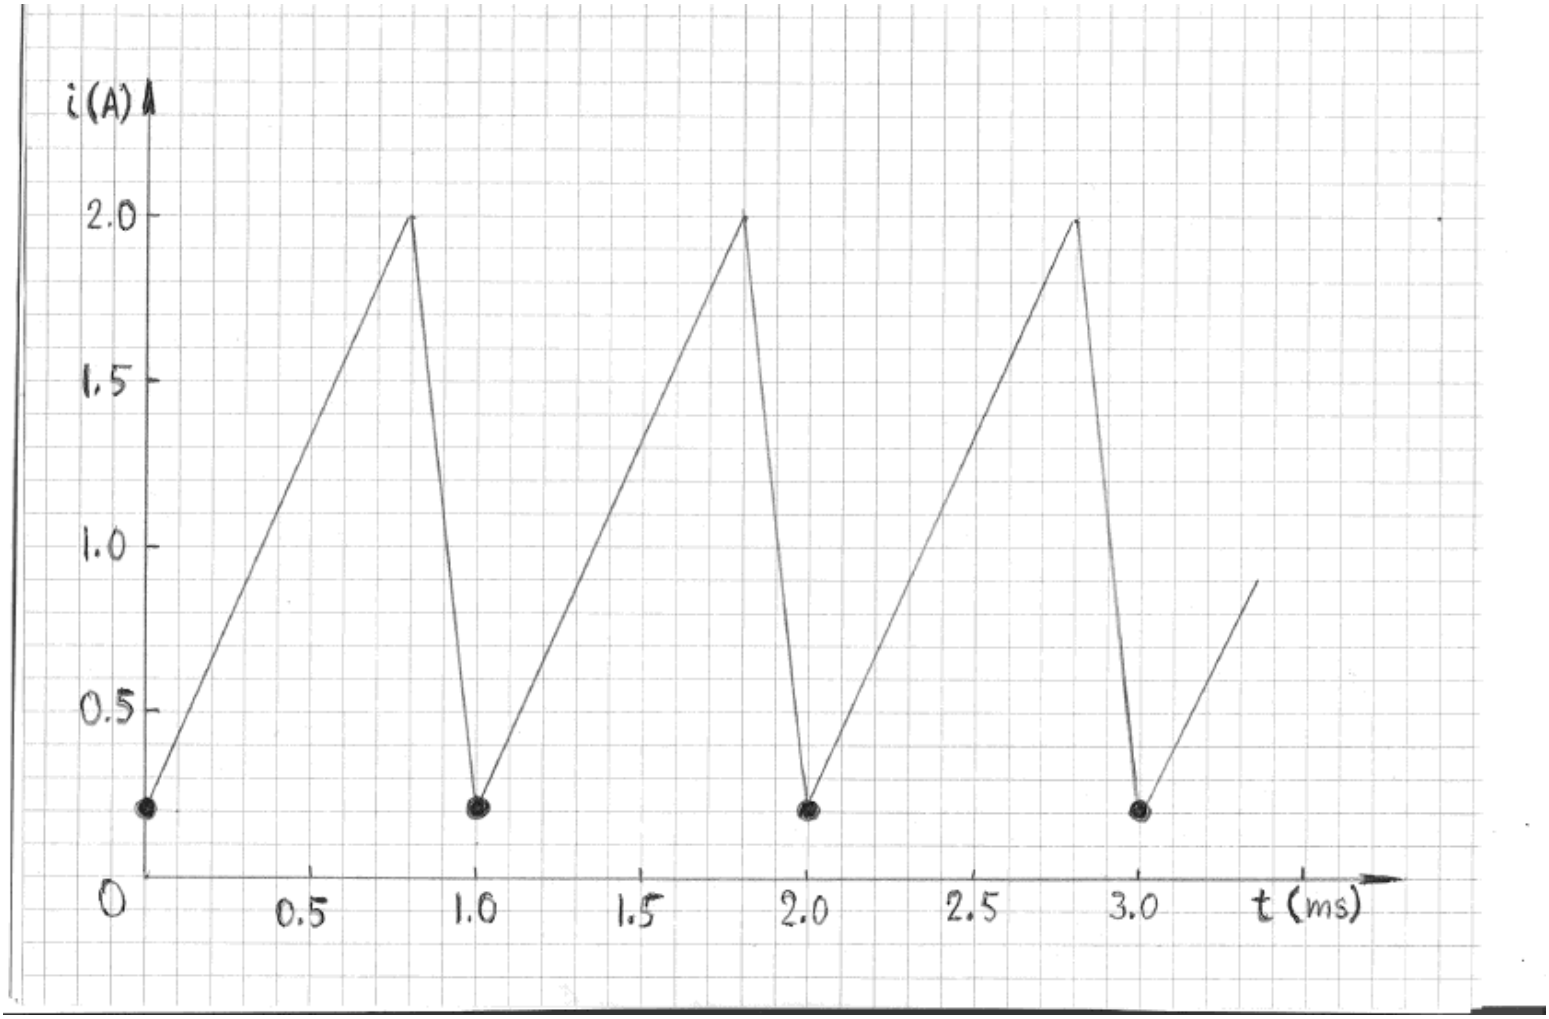

FIGURE 2

Note that the apparent mean current of 0.2 A would occur only at sampling frequencies of 1 kHz, 0.5 kHz, 0.25 kHz, 0.125 kHz, etc. At all other sampling frequencies the apparent and the true means would be nearly identical, provided the sampling interval is negligibly small in comparison with the duration of the waveform. In other words, an error due to a poor choice of sampling frequency, for a periodic waveform, is possible but not very likely. To eliminate possible systematic errors periodic waveforms must be sampled at randomly distributed intervals (rather than at equal intervals, as in Figure 2). using consecutive sampling at two different frequencies, such as 13 kHz and 17 kHz, and showing that the means are nearly identical, would be a good indication that a sampling error did not occur. Another way to gain confidence would be to connect two ammeters (sampling at different frequencies) in series. Nearly identical readings would indicate that an error due to sampling did not occur.

259) What is this experiment about?

Ludwik Kowalski (9/22/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Next week I will be working with Scott Little and Gregory Luce an ETI (Earth Tech International, Inc.) in Austin. The purpose will be to replicate the experiment described in unit #252. In the past Scott tried to confirm excess heat in similar experiments (performed by Mizuno and then by Naudin) but all results were negative. He thinks that this attempt to observe excess heat will also be negative. On the other hand, in a message sent two days ago, he wrote: "If we confirm the excess heat effect, Ludwik, I guarantee you we will try EVERYTHING to see what makes it tick. ..!!!! " At the end he added: "Let vision of fame and glory not be the enemy of accurate measurements." I like this kind of attitude. Each of us would be happy to confirm excess energy but we want to be objective.

To describe our experiment to a person familiar with high school physics I would begin by asking a question. What is the maximum possible amount of water that can boil out of a beaker in 5 minutes when an electric heater of 400 W is immersed in it? Then we would calculate the electric energy received by water, E=400*5*60=120000 joules. Dividing this by 2260 the answer would be 53.1 grams. That is because 2260 J/g is the well known latent heat of evaporation. In reality less water would be evaporated, perhaps only 40 grams, because not all heat is lost via evaporation; some of it is lost via conduction, convection and radiation.

Suppose that somebody performed the described experiment and reported that the amount of water evaporated was actually 70 grams. "What would you think about such report?" I would ask. Then we would discuss two possibilities: a hidden experimental error and a hidden source of thermal energy. The third alternative, that the law of conservation of energy is not valid, would not even be discussed in our context. Such topic should be discussed at much higher levels.

An experimental error, either on electrical or on thermal side of the procedure, would certainly be the first thing to suspect in an experiment performed by a student. But in this case the anomaly (more water evaporated than allowed by the law of observation of energy) is reported by top scientists. P. Clauzon is a retired nuclear physicist who worked on the French breeder reactor for at least two decades, J.F. Fauvarque is a recognized international authority in the area of electrochemistry. We are trying to replicate experiments they described in a paper to be published. Furthermore, Fauvarque et al. were not the first to report the anomaly. Similar reports, from a large number of similar experiments, were published on Naudin website. And Naudin was only confirming the claim made by Japanese researchers, such as T. Mizuno and T. Ohmori. It is not likely that scientists of such caliber, working in different laboratories, could make large experimental errors.

That is why my inclination is to suspect a hidden source of energy. Is it possible that chemical reactions are responsible for excess energy? That was a question I sent to Fauvarque. His reply was a categorical no. The only possible source would be oxidation of tungsten. But the maximum possible amount of chemical energy from tungsten, he wrote, is much smaller than what is needed to evaporate the reported amount of water. I have to take such statements for granted because I am not a chemist. For the time being the only option I have is to replicate the experiment as carefully as possible. That is exactly what we will do next week.

So what has to be measured in each test? Electric energy deposited in water, EL, the mass of the evaporated water, MS, and the amount of non-evaporative thermal losses, TH. Ignoring a hidden source of energy we expect

EL = MS*L + TH.....(1)

where L=2260 J/g, is the well known latent heat of evaporation. What can be more simple than to verify that the left side of the equation is approximately equal to the right side? We want to measure excess heat, EH, defined as:

EH = MS*L + TH - EL..... (2)

According to Fauvaque et al., that quantity can exceed 30 kJ in five minutes (100 W). If this is true then the determination of MS, TH and EL should not be too difficult. Our methods of measuring these quantities are going to be theirs. The MS will be measured from the readings of the digital scale supporting the entire setup. The precision of measurements is expected to be better than 0.1%. To determine TH we will multiply the rates of non evaporative cooling, at 100 C, by the test duration, such as 300 seconds. The rates of cooling, in joules per second (watt), will be measured at several temperatures between 90 and 98 C. The rate of cooling at 100 C will then be obtained through the linear extrapolation. The expected uncertainty in the value of TH, approximately 2%, will be due mostly to fluctuations in room temperature.

The expected uncertainty in the third quantity, EL, will also be close to 2%. Potential sources of error have already been discussed in unit #256. I think that our method of measuring the average current should be calibrated by using a simple high school calorimeter. That method has been described in unit #255 (in the piece appended on 9/1/05). Scott knows, on the basis of previous experience, that working at voltages exceeding 300 V might introduce difficulties not encountered at lower voltages. From what Scott wrote I inferred that problems he encountered might be due to the effect of emitted HF on the data gathering component. If this is true than grounding the anode, which forms a cylindrical screen around the cathode, might be helpful. he has some other “tricks” to deal with that issue.

And in the worse possible case we can stop collecting data with the computer. Fauvarque et al., reported 49 kJ of excess, in 5 minutes, at 350 V. That is 41% of EL, on the average. And it corresponds to the production rate of unexplained energy equal to 164 W. Even very crude voltmeters and ammeters could be used to detect such rates of production. The strategy , however, should be to do as much as possible at 250 V and at 300 V there the rates of production of EH was reported as 8% and 15%, respectively. Splashing of the electrolyte will probaly also be more intense at high voltages. Than can lead to an overestimation of MS, and consequently to an underestimation of EH. Condensation of vapor on the wall of the beaker, and return of water dropps to the electrolyte, can have the opposite effect of EH. I suspect that these will be our most serious difficulties.

My last comment has to do with L. How do we know that L does not becomes samller than 2260 J/g when vapors are formed in the presence of intensive arcing and sparking? Using an inflated value of L would certainly generate an illusion of excess heat, as one can see from the last equation above. How can one distinguish a true excess heat from an apparent excess heat (due to unaccounted lowering of L)? By using a method of measurement of EH that does not depend on L. How can all thermal energy generated in 5 minutes be measured? What comes to my mind is a closed steel container with very strong walls and some space above the electrolyte. That space would contan the vapor while temperature and pressure are going up rise during a test. Then

EH = (FC + TH) - EL

where FC is the energy removed by the flow calorimeter and TH, as before, is the heat lost by conduction, convection and radiation. TH can be minimized by surrounding the cell with a thick layer of styrofoam, as Scott did in trying to replicate Mizuno’s experiments. TH depends only on the cell’s geometry; it can thus be determined, at various temperatures, from the cooling curve for the empty container. To avoid excessive temperatures and pressures the volume available to vapor should be sufficiently large.

P.S. HERE IS A MESSAGE I POSTED TODAY ABOUT L ON THE CMNS LIST.

“Naudin, and others, confirmed large excess heat in Mizuno Ohmori type experiments. The most recent confirmation is described in the paper of Fauvarque et al. That paper is now downloadable from the library at <www.lenr-canr.org> . It shows that excess power increases with applied voltage (from nearly nothing below 200 V to ~35% at 350 V. The first author is an electrochemist and I asked him about a possibility that excess heat might come from chemical

reactions. He does not think so. The only possible fuel, he wrote, would be tungsten and not enough of it was consumed to account for the measured excess heat.

So what is the source of excess heat? The name of the device is CFR (where R stands for the reactor). That indicates one possibility. But to confirm nuclear origin of excess heat one must show that reaction products accumulate (in a high voltage cell) at a reasonable rate. I am thinking about another interpretation of experimental results. The underlying assumption is that intense electric arcing, the cause of evaporation, has no effect on the latent heat of evaporation, L. But what evidence do we have for the validity of that assumption? The value of L was actually measured by Fauvorque et al. and the result came out to be very close to the known value, 2260 J/g. That shows that no significant errors were made by performing thermal and electrical measurements. But the expected L was found by using an ohmic resistor.

Let me speculate by assuming that L decreases (perhaps by ~35%) when the cell voltage changes from 200 V to 350 V. Not being aware of this, and using 2260 J/g, one would underestimate the expected amount of water to be evaporated. Expecting 40 grams, for example, and observing 50 grams, would then be interpreted as excess heat. But that would be an apparent excess heat, not real excess heat. Was this possibility discussed at some conferences?

Latent heat of evaporation depends on binding energy of water molecules (surface tension, if you prefer). I am speculating that presence of a strong electric field might enhance evaporation. What is wrong with this speculation? “

Appended on 9/23/05:
XX wrote:
“I believe that Conservation of Energy tells us that your speculation cannot possibly be correct, Ludwik. Assume for the moment that we already have a strong electric field in existence (between capacitor plates, for example). Now bring some water into this field. I think we can do this for free (energy-wise) provided the water is already at the correct potential. We just "slide" the water in between the capacitor plates crossing all the E field lines orthogonally at the correct potential point. Now assume for a moment that your speculation is correct. With the water in the strong E field we can evaporate it using less than the usual amount of energy. Now we convey the water vapor back out of the field along the same path and condense it in a low field region, recovering the usual heat of vaporization. The result: free energy. ..just from playing games with ordinary water. My conclusion: Conservation of Energy tells us that the heat of vaporization of water will not be dependent upon the ambient electrical field strength.”

My reply was as follows:
I recognize this "reductio ad absurdum" rebuttal. The absurdum is a possibility, at least in principle, of constructing a perpetual motion engine. This kind of criticism is very powerful and convincing. Let me rephrase the speculation; perhaps this will make it less vulnerable to the rebuttal.

Suppose there are two ways of turning water into a vapor (not two ways of decomposing it, as mentioned by Dennis Letts). The first is direct, requiring 2260 J/g, and the second is indirect, requiring only 1000 J/g. The products, ejected from the liquid, are not the same in these two processes. The first process creates water molecules in air and these are able to recombine and generate 2260 J of heat per gram of water. The second process creates something that can not recombine, unless an additional 1260 J/g is used OUTSIDE THE CELL, to turn them into common H2O molecules. Do not ask me what the intermediate products are, or through what kind of oxidation are they transformed into H2O outside the cell. This is only an abstract speculation invented to avoid Scott's rebuttal. Can a perpetum mobile be constructed on the basis of these two processes? I do not think so.

How can these two processes be used to explain the excess heat reported by Fauvarque et al.? Suppose that the second process does not take place unless the applied voltage is higher than 200 V. Above that threshold the second process becomes more and more probable when the voltage is increased. At 350 V the second process is responsible for 50% of the lost liquid. Thus one half of the liquid water is lost at the cost of 2260 J/g while another half is being lost at the cost of 1000 J/g. The effective L is considerably less than 2260 J/g and this is responsible for the apparent excess heat. The only thing I did was to postulate that the effective L might be voltage-dependent. What right do we have to assume that any process through which liquid water can be removed from the cell must have the same energy cost?

Yes, I know that all this will remain highly speculative, until the second process is identified and experimentally confirmed. But this observation is also applicable to other kinds of speculation, including the idea of nuclear reactions, hydrinos, Casimire effect, monopoles, bacteria, etc. etc. The Mizuno Ohmori effect seems to be real and we must understand it..... The whole point of this discussion is to consider a possibility that not all liquid water is lost at the same energy cost of 2260 J/g. Can water lost via splashing be treated as if it were lost via evaporation? I do not think so. How to avoid splashing (or how to account for it)? According to Pierre Clauzon (private communication) splashing becomes more and more pronounced as the wattage goes up at higher voltages. Practical advice on that point would be highly appreciated.

P.P.S.
Large bubbles seen in boiling grow from tiny bubbles spontaneously formed in water at any temperature. Boiling occurs when vapor pressure inside tiny bubbles exceeds the outside pressure (at t=100 C, when the outside P=1 atm). Under such conditions bubbles formed in the liquid do not collapse; they grow and rise to the surface. This is not the same kind of evaporation as at lower temperatures, when vapors are formed at the surface. It turns out, however, that the values of L, measured at the boiling temperature (2260 J/g) are nearly the same as the value of L measured below the boiling point. So much for normal boiling and evaporation.

Is the glowing volume of plasma, surrounding the cathode inside the electrolyte, made of ionized water vapor? If so then one might think that plasma is an electrically formed vapor made of ions. Why should the energy needed to form one gram of ionized vapor be the same as to form one gram of neutral vapor?

Appended on 9/24/05:
YY wrote: "The correct answer to Ludwik's question is that L (change in enthalpy for vaporization) is a STATE function, hence it can only depend on the initial and final states-it is independent of path. Thus, the change from D_2O(liq) to D_2O(vap) at standard conditions will always yield 45.401 kJ/mol or 2266.9 J/g. The cell voltage used cannot change this value. If this were not true, you could construct a cyclic process that returns the system to the initial state and produces energy, i.e. a perpetual motion machine in violation of the First Law of Thermodynamics."

And here is my reply: "Thanks for your comment, YY. XX made a similar rebuttal last night. That forced me to modify the speculation. In the subsequent message I introduced two kinds of vaporization and two kinds of products being ejected from the liquid. Do you think that the subsequent speculation is also in conflict with the first law? In other word. IS MY SPECULATION, INVENTED TO EXPLAIN EXPERIMENTAL DATA OF THOSE WHO CONFIRMED EXCESS HEAT IN HIGH VOLTAGE ELECTROLYSIS, IN CONFLICT WITH THE FIRST LAW?

In the normal evaporation (path #1) neutral molecules are ejected from the liquid electrolyte at the cost of 2267 J/g. In the competitive process (path #2) what is ejected, at the cost of 1000 J/g is not an already made water molecule. It is something that would need an additional 1267 J/g, outside the cell, if it had to become a water molecule. That additional energy would have to be taken from somewhere (for example, a chemical reaction) outside the cell. In the context of the experiment I want to interpret the only factor that counts is the mass lost during each 5-min test. We do not care what happens to the lost mass outside the cell. Is this position acceptable? It is an alternative hypothesis; the other hypothesis is to postulate that an exothermic nuclear process takes place in the cell and that only path #1 is responsible for the lost liquid."

260) Facts versus interpretations

Ludwik Kowalski (9/25/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
As mentioned before, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. In units #252 I wrote about an anticipated experiment. The setup has already been assembled at ETI in Austin (by Scott Little and George Luce); I am going to join them tomorrow. Various aspects of that experiment were discussed in units #253, #255, #256, #258 and #259. What I want to show here is the continuation of the discussion that was described in unit #259.

Voices from the CMNS list:
1) Responding to ZZ, YY wrote:
"Yes, I agree that the energy needed for vaporization is the same. However the source of that energy could be other than purely heat applied. Some of that energy could be derived from dielectric insertion. It is also an energy source. There is energy released by insertion of a dielectric into a constant potential capacitor. That is: the 2267J/g can come in part from heat and part from other sources. The thing that must be kept in mind is that even if you created water vapor between capacitor plates, and find that it takes lest heat than you expect to vaporize it in the region between charged capacitor plates, it would take an addition amount of energy to remove it from that region."

2) Responding to my message (shown at the end of unit #259) YY wrote:
"I think that you are focused on Fauvarque's recent work. The problem, is that he is assuming that the loss of weight is due to water being removed by evaporation. Could it just be that some water is leaving by droplets in the gas flow? The water surface of these things is very active and they did see droplets outside the beaker. I would want more care on that point before I would spend too much time on the possibilities that you are asking about altering the latent heat of vaporization. The same with Mizuno's gas levels of 80 times Faraday numbers - could some of it be CO2 from the electrolyte?"

3) My reply was:
"The first thing Fauvarque et al. did was to measure the latent heat of evaporation with the immersion heater (see Figure 2 in their paper). They measured L at several wattages, up to 600 W. In all cases the measured value was essentially 2260 J/g. Boiling is quite intense at 600 W; if droplets were ejected the value of L would be significantly smaller than the accepted value. This shows that both thermal and electric measurements were accurate. One may argue that droplets are more likely to be ejected when the current flows through an electrolyte, that when it flows through a wire. Oxygen and hydrogen bubbles might carry some invisible droplets, especially when the current is large. I do not know if ohmic heating at 600 W generates more invisible droplets than electrolytic heating at 250 W (at which significant excess heat was reported). What kind of control experiment would you (or others on the list) suggest to demonstrate absence of droplets? Rita permitting, I might be involved in another attempt to replicate the Mizuno-type experiment (next week in Texas). We would be happy to add control experiments designed to make conclusions more acceptable."

4) YY responded:
"I would suggest that you consider the reflux calorimeter method (see my ICCF4 paper in the proceedings). Basically

you put a condenser on top of the cell, and do flow calorimetry on the water flow of the cooling condenser with everything well insulated. You also can put a recombiner at the top of the condenser. The surface of an electrolytic system at several hundred watts can be very "frothy" and very fine droplets can be produced when the bubbles pop. Hydrogen gas in the bubbles "lift" more than just water vapor. I would be very cautious using water loss as a measure of heat. You might could check things by measuring the carbonates remaining in the solution. I would think that the droplets would remove some of the carbonates but evaporation would not. I have not proceeded that way, but it might be a good check."

5) A message from WW (who did observe droplets):
"In the past I did a lot of experiments using a plasma electrolysis system (send to me by E. Mallove) with a condenser which was built on top of the electrolysis cell.(about 1-1.5 meter high). The condensate was collected in a flask. I used a W cathode and a platinum anode during the electrolysis of K2CO3.(in the beginning to carbon electrodes). The main purpose of this experiment was to look for changes in T 1/2 of radioactive elements. First I used radioactive Thallium 201. I put about 5 MBq of 201 Tl into the solution and started electrolysis with a low current. After a few hours the Thallium was adsorbed on the W electrode. I measured the gamma emission with a solid state detector. Then I increased the voltage to 70-80 V and plasma electrolysis started . Then the voltage was increased until 220V. During the experiment I could clearly see a drop in gamma emission from the solution. After electrolysis I noticed that a lot of the radioactivity could be found on the bottom of the reaction vessel, mainly in (WO2?) particles. I concluded that the change in geometry of the distribution of radioactivity caused the decrease in gamma counts. I did not persue further analysis of the particles. Further it was remarkable that about 10- 20% of the radioactivity was found in the condenser solution. I concluded then that droplets with radioactive solution went through the condenser into the condensate. My conclusion was that during my experiment about 10-20% of the solution was not evaporated but was transported as small droplets. This has to be taken into account if one wants to calculate the power balance of the cell. It is possible that during more intense plasma electrolysis at higher voltages,higher percentages of non evaporated solution can be expected."

6) My comment on what YY wrote:
"a) While reading YY's paper I realized that he was also addressing the issue of the path #2 (ejection of liquid water from the electrolyte at the energy cost of less than 2267 J/g). The only difference between his version and my version is the mechanism of the second path. I had no idea what the mechanism might be; Dennis associated it with invisible droplets in the streams of bubbles of hydrogen and oxygen. Each of us is saying that excess heat in high voltage electrolysis, or at least part of that heat, might turn out to be apparent. As far as I know that potential source of error was not discussed by those who published reports on excess heat in Mizuno type cells. Is this a correct assessment? How can this be explained?

b) The way to eliminate the suggested source of error is worth taking seriously. It is probably too late to try D2's old approach in our next-week experiment. But it is something to consider, if the excess heat is observed.

c) The idea of paying attention to the concentration of the K2SO3 in the electrolyte is also attractive. The initial concentration is 20 grams per liter. After only two 5-min tests one is expected to loose about 100 cc of liquid water. Let me tentatively assume that 50% of that is removed in the form of droplets (producing a lot of apparent excess heat) . That would take away 1 gram of the salt. The concentration of the remaining electrolyte, in Fauvarque's experiment, would then change to 19 grams per liter. Such change is probably not very difficult to measure. Here is a suggestion for our next-week experiment. A sample of the initial electrolyte should be preserved in a bottle. The used electrolyte, for example after ten or twenty tests, should also be preserved. A comparison of concentrations seems to be worth making. Why was this not done before? Thanks for the suggestion, D2.
P.S.
d) VV's contribution is extremely valuable. It shows how radioactive tracers can be used to perform very accurate measurements of the relative contribution of the path #2 identified by Dennis. The probability of the path #2 should increase with the voltage because the current (and the associated rates of generation of O2 and H2 bubbles) becomes larger. If that is true then the excess heat should also go up with volts, as reported by Fauvarque et al. But that would be an apparent excess heat."

7) Responding to droplets mentioned by YY, VV wrote:

“(a) I do not know how he confirmed this. Ohmori confirmed it by placing paper towels around the cell, and weighing them after the run.
(b) No. The gas goes through a condenser and then a sample is sent through a mass spectrometer to measure composition.
See: <http://www.lenr-canr.org/acrobat/MizunoThydrogenev.pdf>.”

8) YY responded:
Thank you; I had not seen that paper. I am quite taken by his figure 10. This is quit comforting. The jump in output between 70 and 75 is about what I had noticed in many other CF type systems. In fact I now (since 95) run most all my "good" CF cells above 72 C and many right at boiling. I would say that although Mizuno runs similar electrodes (W,W/Th. ...). I normally run with sulfamic acid (yes, that is sulfamic not sulfuric) at higher current densities.

As an aside- mine glow blue instead of yellow/orange. See picture on my home page <http://www.netmdc.com/~physics/>.

My work right now is going after the hydrogen stream. I am also trying to see if I can get some additional photo-dissociation within the cells. (Compare to work of using Rh ions to mimic photosynthesis and creating the ions in situ from the electrolysis by adding rare earth ions to the electrolyte). As I said in an earlier thread, recovering H for part of the "excess" energy makes the engineering breakeven easier since you only get about 30% of the heat back (for an electrical input loop)-if you are very good- because of Carnot, but you can get 60 to 90% back in the H stream via a fuel cell to use for input electrical energy. I hope to get some funding to be able to burn it "in" a Stirling engine. I have a small one right (about 1 Watt)now but it is hard to match to the high power levels. I have not yet been able to scale down these sparkly cells to levels below about 70 or so watts. It is much easier to get them to "work" at higher levels. You need the high current densities and if you scale it down you have to use a point and those just erode very quickly. Thanks for the info.

9)My message:
According to the 2005 paper of Mizuno et al., <http://www.lenr-canr.org/acrobat/MizunoThydrogenev.pdf> the temperature and pressure in the plasma region are extremely high (up to 9000K and 4000 atm. respectively). I am inclined to think that a sizable fraction of the liquid water lost during each test is vaporized near the cathode. And it is reasonable to thing that the fraction increases with the voltage. (Foe example from ~0% at 200 V to ~36% at 350 V.) That fraction would be "the abnormal" evaporation.

In the Sears and Zemansky's "University Physics" I see this statement : "as we approach the critical point [along the vaporization curve in the pT phase diagram] the differences in physical properties between the liquid and vapor phases become smaller and smaller..... THE HEAT OF VAPORIZATION ALSO BECOMES SMALLER AND SMALLER AS WE APPROACH THE CRITICAL POINT, AND IT TOO BECOMES ZERO AT THE CRITICAL POINT." I suppose that this statement was more than a speculation; it was probably based on some experimental evidence.

Thus associating abnormal evaporation with the lower than usual heat of vaporization is not at all silly. The implied assumption (made not only by Fauvarque et al.) -- that the average latent heat of vaporization is 2267 J/g -- might be not valid. Accepting this point of view one would conclude that the reported excess heat might be apparent. Thus we can list five competing qualitative explanations of experimental data:

a) Excess heat is real; it is due to nuclear reactions.
b) Excess heat is apparent, due to ejection of tiny droplets (experimentally observed by Peter van Noorden).
c) Excess heat is apparent, due to the lowering of the average heat of evaporation.
d) Excess heat is real but its origin remains to be identified.
e) Excess heat is apparent for a reason not connected with (b) and (c).

I would like to know how rapidly L decreases when T is going up. Unfortunately, the water vapor table I consulted does not have a column for L.”

9) I expected to hear from more of those who reported on reality of excess heat on the basis of the amount of water

evaporated. Their contributions to the debate, if any, will be appended here. Please revisit.

9) XX responded:
"I don't think 'c' can be an explanation for the apparent excess heat results. I agree that the heat of vaporization does go to zero as you reach the critical point (where there is no distinction between liquid and gas, hence no such thing as vaporization anymore). But, as Miles told us, 'L (change in enthalpy for vaporization) is a STATE function, hence it can only depend on the initial and final states-it is independent of path.' Thus, the following two processes will require exactly the same energy input:

a) Evaporating 1 gram of water at 100C and 1 atm pressure (i.e. ordinary boiling).

b) Taking 1 gram of water at 100C and 1 atm pressure up to the critical point, evaporating it there for 'free', and then bringing the resulting vapor back down to 100C and 1 atm.

In our experiment, water at 100C and atmospheric pressure moves towards the cathode where it is somehow converted into vapor. The vapor bubbles rise up through the water and burst at the surface releasing water vapor that is essentially at 100C and atmospheric pressure. From an energetic viewpoint, I think we can therefore ignore the details of the vaporization process at the cathode."

10) YY responded:
"You may also want to look at the fugacity of the water at the cathode. But it too is a state function. Just having done this types of items, I would first design the experiment to check b) first."

11) My reply (not posted):
I agree with this, if what "evaporates" at much higher p and T consists of common H_2O molecules. But the first law does not seem to be violated if the substance escaping from the liquid does not consist of H_2O. The escaping matter might become H_2.O, outside of the cell, at the expense of energy of some chemical reactions. I should have phrased the explanation (c) more carefully, as I did before. In any case; we are not discussing water as a fluid in a cyclically operating, and reversible, engine.

12) I expected to hear from more of those who reported on reality of excess heat on the basis of the amount of water evaporated. Their contributions to the debate, if any, will be appended here. Please revisit.

261) Energy in high voltage electrolysis

Ludwik Kowalski (10/6/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

An experiment to be performed was described in unit #252. Results from our work, still in progress, will be presented at the next international conference on cold fusion (ICCF12) in Japan. Facing the deadline I submitted the following abstract.

Searching for excess heat in Mizuno-type plasma electrolysis

Ludwik Kowalski (a), Scott Little (b), and George Luce (b)

(a) MSU (Montclair State University), Montclair, New Jersey, USA.
(b) ETI (Earth Technology Institute), Austin, Texas, USA.

Excess heat generated in the glow discharge plasma electrolysis, first reported by Mizuno and Ohmori (1), has been studied by several researchers, both in Japan (2, 3, 4) and in other countries (5, 6, 7, 8). Most reports, but not all, confirmed generation of excess heat. Facing this situation we decided to replicate the most recent experiment in which excess heat was found to increase with voltage (8). The planning for the design of this project was described in (9). Considerable progress has been made toward the building and testing of a cell able to operate at high power levels. This work, still in progress, should either confirm or contradict the results reported in (8).

WHAT FOLLOWS IS AN ATTEMPT TO DESCRIBE OUR WORK. THIS IS A DRAFT;
IT WILL GROW IN COMING WEEKS. PLEASE REVISIT. PLEASE COMMENT.
kowalskil@mail.montclair.edu

Introduction:
Suppose that a common immersion heater is inserted into a beaker with water. How should thermal energy released in the container depend on the amount of electric energy supplied? The answer is in the law of conservation energy. In a steady state the amount of electric energy, E, supplied during a time interval, t, must be equal to the amount of thermal energy released, Q, during the same interval.

$E = Q_v + Q_c$ ..... (1)

where Q_v is thermal energy released by vaporization and Q_c is thermal energy released by conduction, convection and radiation. But in the setup described in (8) the sum of the two terms (on the right side of the above equation) was reported to be significantly larger than the electric energy on the left side. The authors believe that some hidden energy, presumably nuclear, is released during the electrolysis. That is the essence of the excess energy claim. To verify it we constructed a similar setup and measured E, Q_v and Q_c. The work is in progress; the results will be added, probably in three weeks or so. The purpose of this unit is to describe the methodology and to share some observations. The electric energy on the left side is the integral of $dE = i(t)*v(t)*dt$, over a test duration.

$E = \text{integral}(dE)$ .....(2)

where i(t) and v(t) are the instantaneous current and voltage between the electrodes, respectively. Instruments used to measure E are described in the appendix. To measure Q_v one must determine the amount of water evaporated, M_p, during the plasma test

$Q_v = M_p*L$..... (3)

(4) where L is the latent heat of evaporation. Two measurements of the evaporated mass were performed, one when the current was flowing through the electrolyte, giving us M_p, and another, when the current was flowing through the ohmic heater immersed in the electrolyte, giving us M_o. The value of Q_c can be calculated as

$Q_c = L*(M_t-M_o)$ .....(4)

where $L*M_t$ is the amount of thermal energy that would be lost if evaporation were the only way of loosing heat. In other words M_t*L is nothing else but E measured at the same time as M_0. One does not have to measure M_t to calculate Q_v. Additional nuances involved in experimental determinations of Q_v and Q_c will be addressed in the next section. The equation (1) is certainly satisfied when an ohmic resistor is used to sustain boiling. But will it also be

satisfied when boiling takes place during the high voltage electrolysis? That is the question we want to answer.

Experimental setup

According to the sketch, shown in unit #252, the setup is conceptually simple. But gathering reproducible data turned out to be difficult. Two differences between the initial sketch and the actually used setup had to be made to match (8) as close as possible. Instead of a spiral Pt anode we used a cylinder made from the platinized titanium mesh. The height of that cylinder was 5 cm and its diameter was 6.3 cm. The anode was a welding tungsten rod containing 2% of thorium. The electrolyte, as in (8), was a 0.2 M solution of K_2CO_3 in distilled water. To keep the volume of the boiling electrolyte constant the evaporated water was continuously replaced by fresh water coming from an auxiliary reservoir. As shown in Figure 1, that reservoir was mounted on the same support as the scale.

The temperature of water in the reservoir, T, typically 25 C, was constantly monitored. If that temperature were 100 C then the value of L, to be used in formulas (3) and (4), would be 2260 J/g. At a lower T, however, the effective latent heat of evaporation is 2260+4.186*(100-T). Thus the effective L is 2594 J/g at 20 C and 2553 at 30 C. Two thermistors were used, one to monitor the temperature of the electrolyte and another to measure T of water. A simple open beaker, turned out to unsuitable above 250 volts, due to splashing of the electrolyte. The beaker was thus replaced by a taller cylindrical vessel made from polycarbonate. The depth and the inner diameter of that vessel were 32.0 cm and 11 cm, respectively. A set of ani-splashing baffles was mounted near the top of the vessel, as illustrated below.

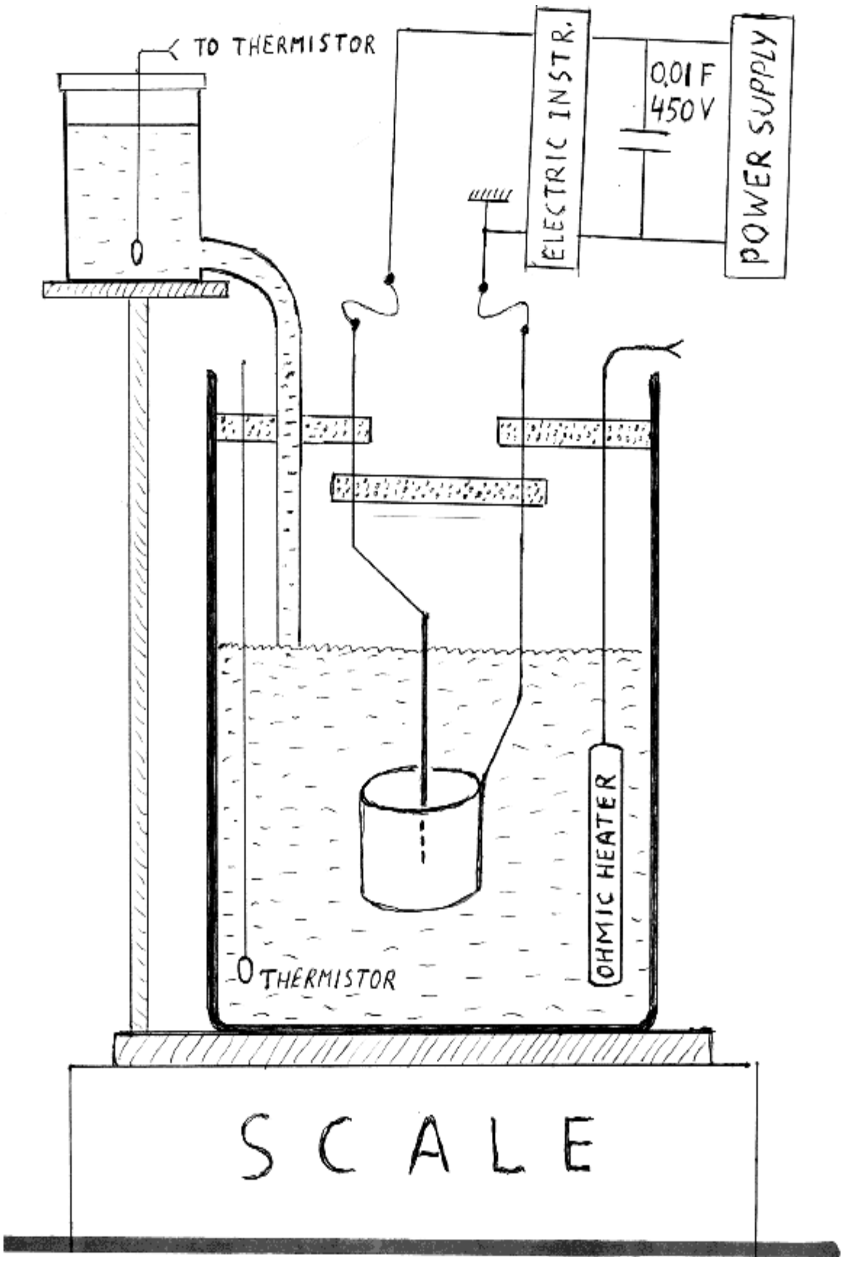

FIGURE 1
Schematic diagram of our first setup. The volume of the electrolyte was 650 cubic centimeters. The dotted baffles, in the upper section of the cell, offer an escape path to the vapor but not to the splashing electrolyte. Vertical rods supporting the electrodes are mounted on these baffles. The "electrical instruments" box, at the upper right corner, stands for the Clark-Hess meter (model 3200). It is essentially a set of three digital instruments: an ammeter, a voltmeter and a wattmeter.
= =

Masses of water evaporated in consecutive tests (M_p and M_o were determined from the readings of the scale. Light flexible filaments were used to connect electrical components inside the vessel with outside circuits. That arrangement did not prevent us from measuring mass differences (typically 40 grams) with a sufficient accuracy (at least 0.5%). The entire vessel was wrapped in a layer of polyethylene foam. The purpose of that thermal isolation was to keep the walls temperature as high as possible in order to minimize condensation of vapors on the inner surface. Condensed water dripping back into the electrolyte would reduce values of m_1 and M_o . Splashing, on the other hand, would make M_p and M_o larger than what were evaporated.

Note that the intensity of splashing, if not mechanically reduced, would increase with the applied voltage. This could

possibly create an illusion of a voltage-dependent excess heat. The same kind of illusion could occur if the "invisible splashing" was significant. Ideally only water vapor (plus some hydrogen and oxygen) should escape from the electrolyte. Suspecting that tiny droplets of electrolyte might also be escaping from the cell we compared concentrations of the electrolyte before and after some tests. These two concentrations should be the same because evaporated water is replaced by fresh water. But replacing droplets of the electrolyte with water would make the second concentration smaller than the first. A reduction of the concentration was noticeable but not significant to create an illusion of excess heat. Another possibility of a systematic error, could possibly occur if the rising temperature of water in the reservoir were not taken under consideration. The flow of steam escaping from the vessel increases with voltage and affects the temperature in the reservoir. This, in turn, changes the value of L used in formulas 3 and 4. Using L=2595 (correct at 20 C) when in reality it is 2427 (at 40 C), for example, would create an illusion that Q_V and Q_C are 7% higher.

The ohmic heater was used to preheat the electrolyte to the boiling temperature and to measure M_o. After that the ohmic heater was turned off and boiling was maintained by the current flowing through the electrolyte. The evaporated masses m1 were measured after the ohmic heater was turned off and after desired voltages were applied between the anode and the cathode. The Figure 2 shows time dependencies of our two most essential parameters. The line labeled "masses" refers to evaporated water (M_p or M_o in grams along the left-vertical axis). Likewise, the line labeled "energies" refers integrated electric energy (E in kJ along the right-vertical axis). Other measured, or computer-calculated, parameters were also monitored during the experiments but their time dependencies are not shown in the figure below. The mass lost was essentially zero until the boiling temperature was reached. After that the amount of water evaporated started increasing. The segment AB of the mass curve was used to determine M_o. The segments CD and EF of that curve were used to determine M_p at two different voltages. The corresponding segments of the energy curve, A'B', C'D' and E'F' were used to determine the values of the energy received in the matching time intervals.

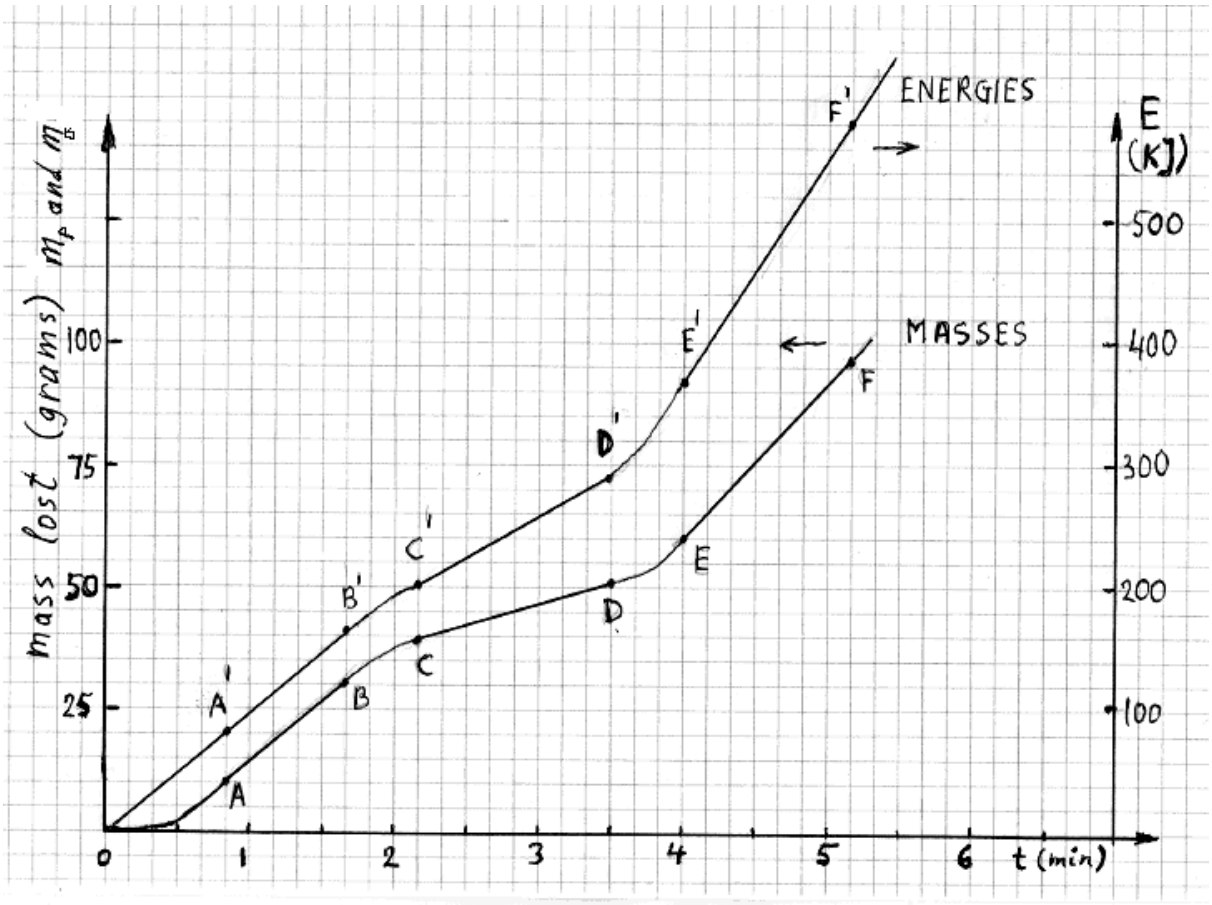

FIGURE 2
Typical time dependencies of M_p (or M_o) and of E for three short tests. Boiling point was reached at t=0.5 min but the first test started (in this hypothetical illustration) at t=0.833 min.

= =

Due to micro explosions in the electrolyte, especially in tests above 300 volts, the mass curves often displayed wiggles (not shown in figure 2). Wiggles, representing dynamic effects on the scale, did not interfere with determinations of masses of the evaporated water because only initial and final readings were needed. We were always able to stop cell shaking by lowering the voltage for three to five seconds.

Results

Figure 3 shows how the rates of non evaporative losses (measured with the ohmic heater) depended on the electric power. The values of electric power, in watts, are shown along the horizontal axis while the vertical axis shows rates of non evaporative losses (also in watts). The rate of loosing heat by conduction and convection increases with electric power. This is an expected result; the rising column of steam acts as an air pump which drives convection currents more strongly than when generation of steam is less intense. Furthermore, more rapid boiling is equivalent to more intensive mixing of the electrolyte. This too is likely to increase the rate of cooling by conduction and convection.

The values of E, Q_V and Q_O, at different voltages, are shown in the table below. Most cells of this table contains two numbers; the mean value and the standard deviation. For example, a cell at the intersection of the row labeled 300 V and the column labeled E, shows that the . . .

Single numbers, in the last column, labeled COP, are coefficient of productivity at different voltages. By definition:

$COP = (Q_v + Q_c) / E$

The numerical values of COP were calculated from the mean values of Q_V, Q_C and E, at corresponding voltages. The data show that . . .

Please revisit this unit in November to see the results.

APPENDIX 1
Measuring electric energy

The electric energy E, delivered to a cell, is the integral (over a test duration) of dE = i(t)*v(t)*dt. The instrument we used, Clark-Hess model 2330 power analyzer, sampled the v(t) and i(t) about 2000 times per second. As expected, the voltage between the cell electrodes, v(t), was essentially constant but the current i(t) was highly irregular. Digitized samples of v(t) and i(t) were recorded by the computer and the cumulative E was displayed during the data acquisition, as shown in Figure 2. A highly irregular nature of the i(t) waveform guarantees random sampling and the average energy, over a time longer than several seconds, is highly reliable. To verify this we also used an a.c. watt meter at the input of our d.c. power supply. The a.c. energy, E', measured with that instrument was only slightly larger than the d.c. energy, E. The difference, (E'-E), was consistent with what is necessary to operate the power supply when it is not loaded. A high quality digital multimeter, Fluke 87, was also used to measure the mean current. The result was identical with the mean current measured by the Clark-Hess instrument.

APPENDIX 2
Measuring electric energy
A polycarbonate cell whose height and internal diameter were . . . cm and......cm, respectively, replaced the taller cell used in the previous set of experiments. The new cell (see Figure 4) has a lid made from the linen-based phenolic plastic. The lid is firmly attached to the cell with four nylon-tipped screws. The electrodes, the water reservoir, the ohmic heater, and the thermistor are now mounted on the lid. A PVC exhaust pipe, whose inner diameter is 2.54 cm, is also mounted on the lid. Its purpose is to conduct steam escaping into air. A plastic baffle, placed 2 cm below the pipe’s input (inside the cell), is an effective shield against consequences of splashing the electrolyte.

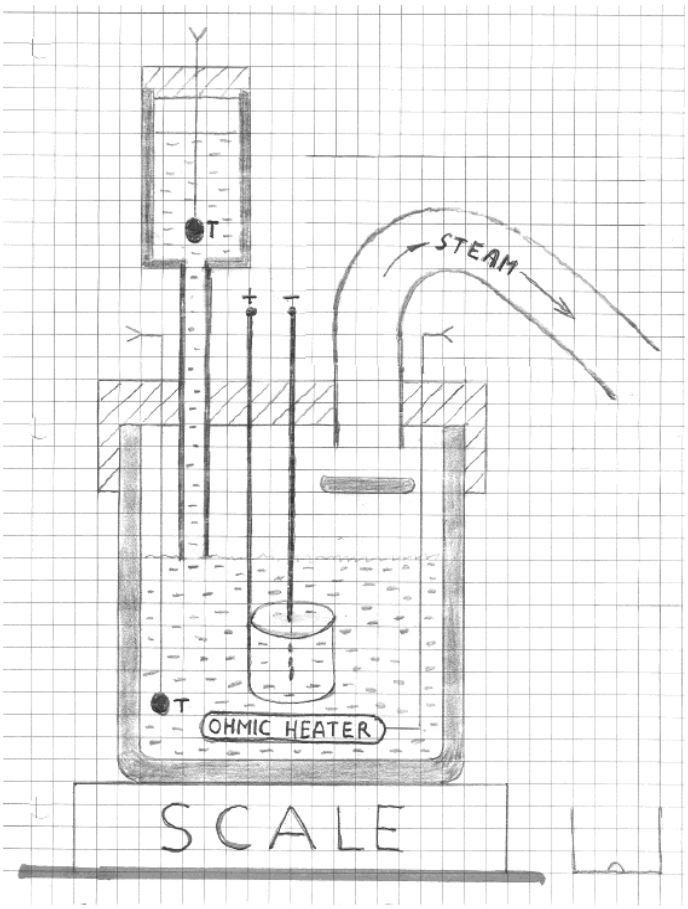

FIGURE 4
Schematic diagram of our second setup.

Some condensation is expected to occur on the inner surface of the exhaust pipe, mostly in the outermost section where the temperature is the lowest. That section was directed downward so that drops of water could drip down to be collected. Note that in a vertical pipe condensed water would return to the electrolyte. Also note that steam ejected from the cell is kept away from the water reservoir and from electrical connections above the lid.

The Pt-coated Ti mesh anode, same as before,is now supported by two titanium rods (instead of one) to minimize shaking. As before, the exposed end of the tungsten cathode (about 1 cm) was located at the center of the cylindrical anode. One of the problems encountered with the previously used cell was arcing between the electrodes in the space above the electrolyte. All metallic components in the new cell are covered with insulation. Hopefully this will reduce the probability of arcing.

NOT TO FORGET:
1) Recognizing that the idea of measuring the concentration of salt in the electrolyte (before versus after a test, in order to investigate a possibility of ejection of tiny droplets) was suggested to us by Dennis Cravens. Also his critical comments on measuring E.
2) Electroplating as a method of calibrating our C-H ammeter, if necessary.
3) Recognizing Clauzon's help in providing details about their setup.
4) Try to understand presence of tungsten in the water reservoir (discovered with the X-ray fluorescence instrument)
5) Recognizing Puthoff's (ETI?) hospitality, contribution and encouragements.

262) H_2O versus D_2O

Ludwik Kowalski (10/5/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As mentioned before, I belong to the International Society of Condense Matter Nuclear Science (ISCMNS). That society has a restricted discussion list, called CMNS, for its members. The purpose of this unit is to record what I learned from recent messages posted on this list. The topic is as old as cold fusion itself. Fleicshmann and Pons announcement was based on experiments with palladium in heavy water. Similar experiments with common water, if I recall correctly, produced negative results, as far as cold fusion was concerned. Later, however, cold fusion phenomena were observed by using other metals and common water. In what follows authors of messages are identified as researchers, R1, R2, R3, etc.

Voices from the CMNS list:

1) R1:
CMNC group - as you may know, I have been asked to discuss "CMN Effects in Light-Water and Hydrogen Systems" at the ICCF-12 short course. I would welcome any suggestions of recent work/results that you think should be included in this discussion. I anticipate positive results, but if you have arguments against this aspect of CMN, I would want to know those also.

2) R2:
To my knowledge, no real test has ever been performed with "pure" light water, which means that it is not possible to rule out the possibility that the residual (.02%) component of heavy water might be causing the Excess Heat. For this reason, I would suggest the term "normal water" be used in the future, not "light water."

3) R3 wrote:
I agree. The term light water should only be used for water with no D or T. To my knowledge no one has used light water. Also, most of the normal water- nickel, normal water- W, Mo, Zr systems I have used always appeared to work better with some D2O added.

4) R4:
I suggest when the argument that the deuterium in normal water is the source of heat in light water experiments, you should take into account that electrolysis concentrates light hydrogen in the cathode. If the electrolyte contains 0.02% D, the cathode will contain only about 0.001% D. This seems like too small a concentration to have much effect.

5) R3:
Yes the concentration will be small at the cathode. However, I still think the term light water should only refer to water devoid of any D or T. If not, we will have a problem later when someone does a true light water experiment.

6) R5:
My colleague and I, have effected some tests with the cell of Mizuno in which we have introduced some quantities of D2O. The amount of anomalies of energy did not change.

7) L.K. (addressing R2):
On the other hand, according to Fauvarque et al. "In any case, the device presented in this paper is a very simple device which can be used to rapidly verify hypotheses without sophisticated means. For example, we have verified that this phenomenon does not seem related with the heavy water which is found at one part in 7,000 in natural water. We increased the concentration of heavy water by a factor of 100 in our electrolyte, i.e. to 1 part in 70. We did not see any perceptible change in our results." This seems to be a good experimental proof that the role of deuterium is not dominant in Mizuno-type generation of excess heat.

8) R4:
I agree with D2 that we should make a distinction between normal water and pure light water. However, it has always concerned me that a little H2O in D2O will kill a heavy-water cell, but it is claimed that a little D2O in H2O will add to the excess energy. Why should it be so?

9) R2:
But if the effect is tied to crystal size (and considerable evidence exists that smaller, nanoscale structures are helpful) and/or magnetic effects, ideas associated with "how much" D in the cathode might not be relevant.

10) R3:
I have not made a study of it directly. However, it always seemed to me that the important part was the D2O purity on initial loading. Once it is loaded it was less sensitive to H2O. There have been a few times when I ran out of D2O and had to add H2O to an existing cell. They seemed to continue for some time even with 10 to 20 % H2O added if they were first loaded in good D2O and still running. - Now the counter to that is that if I had made a mistake in measurements, those errors just were continuing with the H2O addition. I know that X made several runs with H2O added to D2O runs and got reasonable results. In the Old CETI days, most of the "good" runs were those that where first run in D2O. If you added H2O they would continue about 2 or 3 days then "die out". R4- have you done some study at the replacement rate in a loaded cathode if the current is never removed after first loading with D?

11) R6:
If the claims are correct, the result is a function of the cathode material. With Pd, H2O kills the reaction. With Ni, ordinary water works, but increasing the deuterium content enhances the reaction. Apparently, with W glow discharge, the deuterium content makes no difference. This is a summary of what some people have reported. I do not think that these claims have been rigorously tested, except the first: H2O poisons the Pd heat producing reaction. What it does to the reactions that generate tritium and other nuclear effects I cannot say.

12) R4:
I think we need to consider two main points. If the nuclear reaction is simple fusion, the reaction rate will be proportional to the D concentration squared. If clusters are required, such as D4, then the rate will be proportional to the fourth power. This is presumably why the D concentration needs to be so high. Dilution with H would reduce the D concentration even though the total hydrogen concentration would remain high. The second point is that if, as we all believe, the effect occurs in the surface region, exchange with H will be very rapid because the electrolytic process consists of D dissolving in the Pd, diffusing to the nearest crack, and leaving the metal as D2. In other words, a steady flux of D(H) passes through the surface region. The only way D would not be rapidly replaced by H would be for the D to be trapped in a very stable lattice site, presumably by formation of a compound more stable than beta PdD. This is one of the reasons I have been suggesting that the NAE is PdD2 rather than PdD.

13) R7:
R1, you may want to talk about our work with CR39 detector plastic, showing alpha tracks after exposure to electrolysis using ordinary tap water and Li2SO4. The relevant papers can be found in the proceeds of ICCF-11.

14) R8:
If I were to take a long view of this, as Peter Gluck often does so well, I would say that the current body of knowledge and understanding of this field is only a mere fraction of what it will eventually be ... and that the semantics may not be so important.

15) R9:
Hi R4, would you please explain to the group (including me) how you arrived at the numbers above?

16) R2 (responding to R4):
This is one scenario. But there can be (and probably are) many scenario's. In band-like states, comparing concentrations of H vs D is like comparing apples and oranges because the statistics, possible modes of occupation, and forms of interaction are entirely different. In this kind of scenario, the concentration is of band state H's (protons) or band state D's (deuterons, d's). These concentrations can transient and/or (potentially) virtual (i.e., not long-lived). Within this scenario, many possibilities occur. Interfacial effects, however, will be important.

17) R4 (referring to R9's question):
If you look at Fig. 1 in "The Effect of Hydriding on the Physical Structure of Palladium and on the Release of Contained Tritium" you will see how H is substituted for D in Pd at high concentrations of D. In this region the substitution factor is about 2 with a tendency to larger factors as the H/D ratio in the electrolyte increases. My suggestion of 20 for normal water is largely a guess which I suggest to get people thinking about this effect. Obviously, this measurement needs to be made more accurately if a model is based on the amount of D in Pd after electrolyzing in normal water.

18) R4 (addressinging R2):
It does not matter what changes the concentration of D, whether it be dilution by H or distribution between different states. It is the concentration of D in which ever state that allows the nuclear reaction to occur that matters. As long as several D nuclei must be in the same place at the same time for a reaction to occur, the concentration will influence this probability. The greater the number of D that are required too form the final product, the more the reaction rate is increased by increases by the concentration in the active state or environment, i.e. by concentration raised to increased power. Granted, the active state or environment may not have the composition obtained from measurement. If I understand your suggestion, you are proposing that the active state has a composition that is relatively independent of the measured composition and that no matter how much D is present in the electrolyte, the active state is always saturated. If this were so, heat production from the cold fusion should never be sensitive to the amount of H in the heavy water, which is clearly not the case

19) R2 (replying to R4):
Implicit in my comments are subtle points associated with band states and the fact that only a very small band state occupation is required and the fact that in a many situations, assuming such a picture is valid, when the band state occupation becomes to large, the reaction will turn off. Implicit in my comments is also the notion that in a true, many-body situation, many charges are involved, and this can drastically alter the situation in such a way that basic notions about being "localized" at the same place can be replaced by a counter-intuitive notion: being at "same" place simultaneously at many different locations. Below, I am providing specific answers to your questions.

It does not matter what changes the concentration of D, whether it be dilution by H or distribution between different states. It is the concentration of D in which ever state that allows the nuclear reaction to occur that matters.

Not true if some of the deuterons are in in band states and some are not.

As long as several D nuclei must be in the same place at the same time for a reaction to occur, the concentration will influence this probability.

Not true when the deuterons interact with many charges coherently; in this case the d's need not "be" in the same place in order to react. Waves are not localized.

The greater the number of D that are required too form the final product, the more the reaction rate is increased by increases by the concentration in the active state or environment, i.e. by concentration raised to increased power.

Not true when only a small amount of d are required and when the reaction turns off if too many are involved, which is the case when "ion band states" (or even ion band state fluctuations) are involved.

Granted, the active state or environment may not have the composition obtained from measurement.

There need not be a single "active state." In fact, Quantum Mechanics requires that "all" accessible states be included.

If I understand your suggestion, you are proposing that the active state has a composition that is relatively independent of the measured composition and that no matter how much D is present in the electrolyte, the active state is always saturated.

This is partly true. The solid can (and probably does) filter out potentially reactive d's

If this were so, heat production from the cold fusion should never be sensitive to the amount of H in the heavy water, which is clearly not the case

This pre-supposes saturation is required. The key point is that the electronic structure dictates what goes on. The electronic structure dictates the chemical potential, and this determines if the d's (and/or protons) can occupy band states. The point is that the solid (which can have characteristic dimensions as small as 10's of nanometers) plays a key role.

20) R4 (replying to R2):

a) I wrote:
It does not matter what changes the concentration of D, whether it be dilution by H or distribution between different states. It is the concentration of D in which ever state that allows the nuclear reaction to occur that matters.
You replied:
Not true if some of the deuterons are in in band states and some are not.

I see that we are talking past each other. I will try to make my point clearer. You point out that some of the deuterons are in band states and some are not. Those that are not in an suitable band state can not enter into a nuclear reaction, hence are irrelevant to the discussion. This is point I was making. We must only concentrate on those D that are in a state that allows the nuclear reaction to occur. This means that the total measured D concentration is not the main variable we must discuss.

b) I wrote:
As long as several D nuclei must be in the same place at the same time for a reaction to occur, the concentration will influence this probability.
You replied:
Not true when the deuterons interact with many charges coherently; in this case the d's need not "be" in the same place in order to react. Waves are not localized.

Granted, the waves are not localized so that my description does not apply. Nevertheless, a probability exists that describes the interaction of waves. Would not this probability be sensitive to the number of waves present in the active state?

c) I wrote:
The greater the number of D that are required too form the final product, the more the reaction rate is increased by increases by the concentration in the active state or environment, i.e. by concentration raised to increased power.
You replied:
Not true when only a small amount of d are required and when the reaction turns off if too many are involved, which is the case when "ion band states" (or even ion band state fluctuations) are involved.

I do not understand this argument. You seem to be adding additional variables that allow anything to be explained, i.e. the model can never be tested because its failure to predict behavior can be explained by too much D or too little, neither of which can be measured.

d) I wrote:
Granted, the active state or environment may not have the composition obtained from measurement.
You replied:
There need not be a single "active state." In fact, Quantum Mechanics requires that "all" accessible states be included.

Are all accessible states active in initiating nuclear reactions? My point is that only those states that are active are important.

e) I wrote:
If I understand your suggestion, you are proposing that the active state has a composition that is relatively independent of the measured composition and that no matter how much D is present in the electrolyte, the active state is always saturated.
You replied:
This is partly true. The solid can (and probably does) filter out potentially reactive d's

What do you mean by "filter out"? All d are identical until one converts to a wave by being in a band state. Presumably a mechanism exists that converts one d to a wave while another d that is dissolved in Pd does not convert. What determines how many d form waves?

f) I wrote:
If this were so, heat production from the cold fusion should never be sensitive to the amount of H in the heavy water, which is clearly not the case.
You replied:
This pre-supposes saturation is required.

No, this only presupposes that the number of d waves available for interaction determine the reaction rate. If the number of d waves is reduced by the presence of H, the nuclear reaction rate will be reduced.

g) You wrote:
The key point is that the electronic structure dictates what goes on. The electronic structure dictates the chemical potential, and this determines if the d's (and/or protons) can occupy band states. The point is that the solid (which can have characteristic dimensions as small as 10's of nanometers) plays a key role.

This is all true, but does not address the issue.

= =

21) LK (myself):
OK, I will stop recording this thread. It turned out to be a good sample of interactions between CMNS researchers. It does not seem to differ from interactions between scientists in other areas. So why do people continue to think that the field is pseudoscientific? Why are reports from investigations in that field rejected by mainstream journals? Why do their research proposals not supported by the DOE or NSF grants? Who benefits from this highly abnormal situation?

By the way, as I type this I recall a recent conversation with a mathematician in Austin. He said that the situation cold fusion finds itself in is not unique. Something similar is taking place in astronomy. A group of highly qualified people, rejecting the "big bang" idea and proposing another interpretation of experimental data, is practically excommunicated from the community of astronomers. Their publications, he said, are rejected by mainstream journals and they find it difficult to get access to large telescopes. That is interesting. My impression was that only the CMNS field is treated in that way.

263) Fraud or not fraud?

Ludwik Kowalski (10/7/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

In 1812 Charles Redheffer traveled through Philadelphia and New York, charging a dollar admission (a dollar was a lot of money in these days) to see his perpetual motion machine made up of wheels, gears and pulleys which kept moving continually with no apparent source of energy. He did very well until someone discovered a little man in a back room turning a crank. <www.answers.com/topic/charles-redheffer>

I am probably not the only one who receives many fraudulent proposals over the Internet. Below is one of them; it has nothing to do with cold fusion. But it made me think about a company called iesi (Innovative Energy Solutions, Inc.). So I went to the website of that company <www. iesiusa.com> hoping to find some new information. But I was disappointed; nothing new was added there since my units, #216 and #226, were posted. That was about four months ago. Why is it so? It is also strange that not a single message about Dr. Yang's research has been posted on the CMNS discussion list. Peter Hagelstein, who saw the demonstration five months ago (see unit #237), suggested that I suspend judgment and wait. How long should I wait? According to Dr. Arrison (see the insertion at the end of my unit #229), the impressive prototype was already working in 2004 and "the second plasma device is expected in early 2005." So why didn't a single company scientist come to the 2004 conference in Marseilles to tell us about the impressive cold fusion device? How is it built? How was the 100% reproducibility achieved?

According to <http://peswiki.com/energy/PowerPedia:Cold_fusion> the company is already in the process of commercializing "cold fusion as an energy source." I am a cold fusion researcher trying to keep up with new developments. It puzzles me that the iesiusa website is totally silent. Are they also planning to declare bankruptcy (as Mr. E.B Fasheyiky, see below) after collecting millions from poorly informed investors? That would hurt the reputations of many honest cold fusion researchers, including my own. So far I have not seen any convincing evidence that what the company does is a cold fusion application.

But that is not the view of the editor of Cold Fusion Times. In volume 12, No 12 of this magazine (page 23) I see a report entitled "iESi Technology." The author was probably among those invited, about five months ago, to see the demonstration in Edmonton, Canada. The report states that "the level of power generation was several kW for about 15 minutes" and that the energy gain was "in excess of 5." Assuming that "several kW" stands for 3 kW, the energy generated would be 9 MJ. The gain of 5 implies that 80% of that was due to cold fusion. About 200 grams gasoline would have to be burned to generate the same amount of heat. But what evidence do they have that excess heat comes from cold fusion? How do we know, for example, that it was not due to a chemical fuel, such as alcohol, released into circulating water?

P.S.
Nothing has to be released into the circulating oil because that fluid itself can be used as fuel.

= =

From:Mr.E.B Fasheyiky <fasheyiky1@tiscali.cz> London, U.K

Greetings to you: I am Mr.E.B Fasheyiky and though I reside in the U.K, I am actually a citizen of U.A.E. I am the heir apparent to a family business with its "roots" in Dubai, U.A.E. The importance of my position in my family mandated that I be sent to study for a degree in the U.K. At the conclusion of my degree programme, my family decided to open the first European branch of the company in the U.K and I was put in-charge to run it. This was of course a good beginning for me. At present, we are at the end of another trading year and our auditors have once again brought it to our attention, that the tax rates applicable to our company due to the fact that we the owners are not british is gradually "killing" our business. Unlike the last time I was alerted, I have this time, taken a critical overview of the records from "day one" and the auditors seem very correct. This situation when related to my father has really been disturbing. After much "brain storming", my father has decided to close the UK branch. He has directed that we salvage what is left of our investment and concentrate our efforts on Dubai in the United Arab Emirates.

Now, you must wonder why I have contacted you! I am contacting you now because there is an arangement that I have personally mapped out to ensure that what ever cash remaining in the Company account be transferred to whoever is willing to assist me in this regards. All you will be required to do is to draft an agreement from your end that you will be supplying Medical and Agricultural Equipment to the tune of $18,500,000 (Eighteen Million, Five Hundred Thousand United States Dollars) in my Company's favour. Once this agreement is set up, I will need to see the contents and have a copy submitted to my bankers here so they can immediately begin the transfer processes of the stipulated amount in favour of goods to be supplied (Supposedly) by you.

After the agreement between you and I has been submitted to my bankers, I will file for bankruptcy while the agreement still stands with my bankers. This way, I will be able to leave the U.K back to my Country without having to pay so much taxes on the funds remaining and I will not be loosing much money at the same time. You must understand that I personally have something in it for myself because what I declare to the company in Dubai, is what will be stated and accepted. If you are willing to assist, please respond to this message and bear in mind that your confidentiality is required because if this arrangement fails, I will probably loose everything I own in the U.K. For your assistance, there is a reward. This will be discussed as soon as I get a response from you. Feel free to reach me by email. I will be awaiting your response anxiously. Thank you in view of your anticipated urgent cooperation. Yours Faithfully, Mr.E.B Fasheyiky

Cold fusion researchers I worked with are certainly honest. But are all researchers honest? Probably not. A possibility of honest errors, or self-deception, should also not be ignored. A claim made by an honest researcher is not always valid. Extraordinary scientific claims become valid when other qualified researchers confirm them. Complete openness is essential in science. An invitation to qualified engineers, not associated with the company, to inspect the device, would certainly be desirable at this point.

Inserted on 7/15/07

Scientific people behind the iESiUSA technology are A.I. Koldomasov (from Russia) and H. Yang (from Korea). A set of essays, including my own, about their work can be found at:

264) Measuring electric input

Ludwik Kowalski (10/14/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The topic of possible systematic errors, in measuring electric energy supplied to a cold fusion cell, is often discussed on the CMNS list. The purpose of this item is to show interesting extracts from recent messages, to comment on them, and to ask additional questions. Note that item #258, and the appendix in unit #261, were also devoted to this topic. As usual, authors of messages from which I quote are not identified. I refer to them as researchers: R1, R2, R3, etc. I will be happy to substitute these Rs by real names, if requested. Likewise, I will remove a quote if the author asks for this. Please let me know. This issue, by the way, was raised by two young journalists on the CMNS list. They feel that quoting without permission is not consistent with journalistic ethics. I am not a journalist but I understand their concern. Therefore, from now on, items of that kind will not be posted before showing the draft to the list members, and waiting a day of two for possible requests.

Inserted on (10/16/05):
The above paragraph triggered an interesting discussion about privacy. It jad nothing to do with this unit; it had everything to do with ethics. Many old-timers feel that quoting them, even anonymously, is not appropriate. Before showing anything that was posted on the CMNS list to outsiders one must have a permission. I will start followong this rule. But this unit was composed befor the topic of privacy was discussed. That is why I decided to post it. Only one quote was removed because I now know that the author is against anonymous quoting without permission.

R1:
. . . The biggest concern in my view is when folks are simply measuring a voltage and current points and multiplying them, and assuming this represents accurate AC wattage. This is another source of potential systematic error in cold fusion experiments which I've seen time and again. Any good engineer who knows AC power issues will look at the results of that experiment, see the simplistic approach used, and discount the results.

My comment:
In a standard a.c. setup, i.e. when the waveforms are sinusoidal and when the phase factor, cos(phi) is known, the power is I*V*cos(phi), where I and V are effective values read from two instrument. The phase factor can be measured by using an oscilloscope. What R1 has probably in mind is a situation when v(t) and i(t) are not sinusoidal, or when cos(phi) is time dependent. In unit #261 I was addressing a situation in which v(t) remains constant and only i(t) is highly irregular. In that case the approach we used seems to be reliable.

R2 (referring to the approach described in item #261**):**
Note: R2 did not want to be quoted. The essence of the message was that the v(t) and i(t) waveforms contain frequencies excedding the limit of the instrument, 82 MHz. The sample rates must thus be higher than 100 Mhz. He worned us about possible errors associated with the assumption that v(t) was cinstant.

L.K.:
My reply was that we were cautious; voltages were sampled at the rate of 2000 per second and mean values were calculated (and recorded) five times per second. That was like using an oscilloscope. The near constancy of v(t), when i(t) is highly irregular, was possible because a capacitor of 0.01 F was used, as illustrated in Figure 1.The issue of the

sampling rate was discussed in length in item #258. My conclusion was that the frequency of sampling can be as low as one wants, provided the number of random samples is sufficiently high.

R3:
I think all this talk about the difficulty of measuring power only applies to people who are working on a shoestring and do not have enough money to buy a top-of-the-line power meter. I do not think there is any difficulty measuring power when you use professional instruments costing thousands of dollars. With regard to glow discharge experiments, it should be noted that Mizuno measured power with both the Yokogawa and with an ordinary computer-based meter. The results agreed to within 1 percent, and the excess heat was considerably larger than this. The Yokogawa PZ4000 specifications are here: <http://www.yokogawa.com/tm/pdf/bu/pz4000/pz4000spec.pdf>

R4:
It is important when trying to measure power deliver to a varying load that the source impedance of the supply be much lower than the load. The power industry never has to worry about this as their line impedance is zero compared to what we have connected. If not we blow the breaker. We can be fooled by top of the line watt meter if there is not a correct match between the source and the load. If the match is incorrect the watt meter is measuring power that is dissipated in the source and in the load.

In the Mizuno Experiment the load impedance is low and changing rapidly. The impedance of the source must be significantly less than the changing load impedances. If it is not then getting correct power measurement is much more difficult because the impedance of the source must be added to the equations.

R4 (in an earlier message)
I've been interesting in CF since 1989 when fellow engineers at Eberline (Radiation Detection Equipment) in Santa Fe. NM tried to duplicate the P&F experiment without success. Advanced Energy is a manufacture of precision power supplies for the semiconductor industry. These supplies are ideal suited for testing the Mizuno plasma excess heat experiment. The supplies are fully programmable with voltage, current and power regulation. The supplies can deliver 20KW at voltage to 800V. They can also measure Joules delivered to the target at 1% accuracy, sample rates on the order of 1ms. The supply can be programed to run many different types of waveforms. It is also able to suppress arcing within the plasma. I'm setting up an experiment here in either Fort Collins or Boulder any one in the Denver area that is interested in helping is welcomed. I'm basing the experiment on the one done by Fauvarque and Clauzon. This is the web site for the Pinnacle power supply spec.

<http://www.advanced-energy.com/products/ProductDetail.asp?PID={4D7A014D-32FF-4653-AADC-0B9FEB0C9279}&cat=Cat&subcat=Power%20Systems>

R6:
We are making good progress. I agree, many NAE exist. However, I suggest a common mechanism operates in all of them. Based on your model, part of the common mechanism would be the creation of band states that cause wave formation. Other conditions would include an environment that can dissolve sufficient D and an environment that can properly host the resulting He wave. When all of the many required conditions are combined, very few chemical systems would appear to qualify. The BIG questions is, how does a person identify such a system in advance based on your model?

LK:
I am commenting on information posted by R4. Ability to suppress electric arc, for example, in a Mizuno-type cell described in item #261, might be very important. Uncontrollable arcing was the main cause of our difficulties. Let me speculate about one possible consequence of being able to eliminate arcing. The cell receives a measured amount of electric energy, E, and a measured amount of thermal energy, Q, is produces. The coefficient of productivity, COP, is defined as Q/E.

Many different processes occur in the cell, such as dissociation of water molecules, glow discharge, arcing, etc. We do not know which process creates NAE (nuclear active environment) mentioned in the message above. But we can imagine that

E=E1+E2+E3+ . . ., Q=Q1+Q2+Q3+ . . . and COP=COP1+COP2+COP3+ . . .

where 1, 2, 3, etc. refer to individual processes. Suppose that only process #1 (glow discharge) creates NAE whem E1=50 kJ and Q1=200kJ. This would make COP1=4. Also suppose that the second process, arcing, does not generate any excess heat; for that process E2=5000 kJ and Q2=5000 kJ. To shorten this speculation I will ignore other processes. Not able to measure E1, E2, Q1 and Q2 we measure E=E1+E2=50+5000=5050 kJ and Q=Q1+Q=200+5000=5200 kJ. Then we conclude that CPU=5200/5050=1.03. This shows how much would be gained, in this hypothetical situation, if arcing could be suppresses. It should be much easier to argue that the COP=4 is real than to argue that CPU=1.03 is real. Furthermore, assuming the test lasts 5 minutes, the power without the arc would be 167 W while the power with the arc would be 16,833 W. Designing a cell for 5 minutes of electrolysis with arcing is certainly much more difficult than designing a cell in which the arc is suppressed.

R1:
I've read the posts regarding measurement of "watts in" in complex AC/DC high-voltage systems. ..... R5 and I spent many months investigating this issue and found that it is somewhat of a black hole. We're of the opinion that such measurements cannot ever be accurate or dependable, regardless of the sampling rate. The problem is that in high-voltage, high-frequency systems, the power factor of the AC current is quite unpredictable. Voltage and current are NOT the only variables that lead to wattage. Power factor and phase are a major issue, and they are extraordinarily complex. > . .

Another problem is that conversion efficiency of the power supply. ..... Sometimes the power supply is 60% efficient, sometimes 50% efficient, and you cannot predict that efficiency at any moment. Our solution was to abandon the entire concept of "measuring" AC power as a product of voltage and current. We simply don't try to do it. We adopted a simpler and we think more accurate approach. We have designed our systems so that the power input to the system is always low-voltage DC (6 to 40 volts) -- this can be be accurately and reliably measured as a power input.

Then we convert that DC to high-voltage AC within our apparatus, and the converting electronics are enclosed in a separate and unique calorimeter. This allows us to precisely measure the energy loss of the electronics. By the way, this is also the method that the vendors of wattmeters use to calibrate and test their wattmeters. Ultimately, measurement of heat output via calorimetry is the most "true" form of watt meter. So why not just use that method to start? The above method has proven to be very simple, reliable, and robust for us. But, your mileage may vary.

L.K.:
I know that R4 and R5 work with a gas glow discharge cell. Could their approach be used in working with Mizuno-type electrolytic plasma cells? I do not think so. Here is my reply to the above message. Suppose you begin with a d.c power supply whose voltage is very stable, for example, 60 V. The voltmeter shows volts and ammeter shows current feeding the next step. It the current is 5 A then P1=300 W. The next box is a high voltage power supply. It receives electric energy at the rate of 300 W and uses it to generate, for example, 500 V. You apply this to your gas glow discharge cell. Right?

At what rate is the cell receiving electric energy? The rate is P2=P1-X, where X is part of P1 that is converted into heat in your high voltage supply. You must know X to calculate P2. That is why your entire high voltage power supply is located in a calorimeter. That box has only four wires connected to it, two at the input and two at the output. Input receives electric energy at the rate P1 and the output delivers it to the cell at the rate P2. After waiting many hours the temperature of the calorimeter stops rising and you calculate X. Suppose it is 50 W. You know that P1=300 W because your d.c. is 5 A. Therefore, you know that P2=250 W.

That is a good method when the glow discharge is very stable. But suppose it is not stable because things change inside your cell. You are aware of changes because the d.c. is going down or going up. Your ammeter reacts to all changes at once but your calorimeter takes hours to react. Suppose that the d.c current changed from 5 A to 10 A. Thus P1 becomes 600 W, for exactly 10 minutes. Then the current becomes 7 A and P1 becomes 420 W. Your experiment ends 30 minutes later. How many joules of electric energy was supplied to your cell during the last 60 minutes? I do not think that the answer would be correct if you used the same X at all P1. That is a limitation of your method. I

suppose it is highly reliable when P1 remains constant during the entire experiment. To conduct an experiment at a different cell voltage you would have to wait many hours to find the new value of X. Do you agree?

265) A paper of Antonella, Antonio, Antonietta, Emilio and Guiliano

Ludwik Kowalski (10/20/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

How can cold fusion be explained? The answer to this question can be found in the appendix of a paper of Antonella De Ninno et al. “Experimental evidence of 4He production in a cold fusion experiment.” The pdf file containing this paper was sent to me (October 2005) by Jed Rothwell. Thanks, Jed. Imagine molecules of air through which sound is propagating. They oscillate with amplitude which increases with loudness. Layers of compression and layers of rarefaction follow each other as water crests in a wave propagating along the surface of a pond or pool. Oscillations of sound, however, are in the direction of propagation, not perpendicular to it, as in familiar water waves.

Looking on two nearby molecules, oscillating along the direction of sound propagation, one would see that the distance between them tends to increase and decrease periodically. Something similar might occur in palladium loaded with deuterons. The average distance between the two nearby ^{2}D ions is too large to allow fusion but the nuclei can occasionally fuse when distances are close to the minimum. But this is only part of the story. The other part has to do with answering a different question: “why are cold fusion products,are different from the hot fusion products? Most CMNS products are ^{4}H while most CF products are n, p, ^{3He} and radioactive ^{3}T.”

The authors say that, according to QED (Quantum ElectroDynamics), sudden change is expected to occur in Pd when atomic concentration of dissolved ^{2}D ions exceeds 0.7. Deuterium ions start oscillating “inside shallow potential waves . . . [and] “the Coulomb barrier turns out to be smaller than in vacuo, because of the high concentration of the negative” electrons. That is the answer to the first question “why does cold fusion happen?” Addressing the second question the authors describe cold fusion as a three step process:

a) Two ^{2}D ions fuse forming the excited compound nucleus ^{4}He. The well known excitation energy is 23.8 MeV.
b) Rapid “cooling” -- decay of the excited nucleus to the ground state
c) Transfer of the released energy to the Pd crystal.

The step (a) must occur in any kind of fusion (in gas-like plasma and in condensed matter). But steps (b) and (c) are very different in these two kinds of fusion. In plasma deexcitation , most often, takes place by by fragmentation of the compound nucleus. It breaks into either $n+^{3}He$ or $p+^{3}H$. Deexcitation by emission of gamma rays is also possible but it is much less probably. In condensed matter, on the other hand, fragmentation is prevented by close proximity of charged particles, negative electrons and positive ions. The released energy goes to charged particles, mostly to surrounding ions. Metallic grains in which fusion occurs become very hot, momentarily, and loose heat by well known mechanisms (radiation, convection and conduction). Helium gas is most often released from very hot “micro furnaces.” The appendix end with this sentence: “From our ‘prejudice’ that almost all fusion occurring in the Pd lattice should produce ^{4}He, we derive that the easiest way to evaluate the energy output is to count ^{4}He atoms in the cell gasses.” And that what the main part of the paper is about.

= = = = = = = = =

LET ME APPEND A MESSAGE I RECEIVED TODAY FROM ONE OF THE READERS.

Dear Dr. Kowalski-

The more I examine the information about cold fusion, the more it appears to me that the most probable explanation of the phenomenon is the Palladium catalyzed conversion of D:D to He4 along with an overlooked concurrent Pd catalyzed conversion of H:H to Deuterium atoms. It is very possible that the electrical field is not necessary and the electrolytic cell is serving only to furnish D:D for conversion.

It is possible that Hydrogen gas forced through a thin sheet of Palladium would show Deuterium enrichment on the other side and a temperature rise of the Palladium barrier. Similarly, if Hydrogen gas heavily enriched with Deuterium were forced through a Palladium barrier, it would not be surprising to see heat, Tritium, He3 and He4 produced. In so far as I can tell, no one has considered the molecule to "atomic isomer" transformations as a possible explanation of the phenomenon.

If one looks at the published data re size and mass of the electron and the proton one finds an interesting situation. We usually think of the proton as being large and massive and the electron small and light. However, if the electron were scaled up to a 1 cm. water balloon, the proton would be more like a 100 meter soap bubble! You're undoubtedly a better mathematician than I , so you probably can work out a better comparison than that. The point is that the mass and charge density of the electron is many times that of the proton, indeed, the disparity is so great that there seems no reason at all that electrons cannot pass freely through protons. Similarly, two protons would have to approach to about the diameter of an electron to experience the same repulsive forces as two electrons colliding. In other words, there is a fair chance that a Hydrogen Molecule spends at least some time in the same configuration as a Deuterium atom, but does not stabilize to that form because of the vibrational energy content...,.(This could be considered as essentially the same reason that absolutely pure gaseous water will not condense to liquid droplets .....) The same kind of analysis applies to the D:D, He4 system and the H:D to Tritium possible conversion....Best Wishes, Dean L. Sinclair, BA, MS, PhD

From previous correspondence with Dean, whose life circumstances are not favorable to conduct research, I know that he would be happy to receive comments. Here is his email address: <deanlsinclair@gmail.com>

266) First scared then reassured.

Ludwik Kowalski (11/1/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The experiment described in item #261 is still in progress; without my participation. In about ten days I will be participating in another version of that experiment. The advantage of the second version will be Pinnacle, a very unique power supply. It will allow us to nearly instantly (several microseconds) suppress arcing, if it develops. Several days ago my collaborator sent me a message with a question about the latent heat of vaporization, L. “Do you know what L values were used by Clauzon in their
paper?” Replying to this question I wrote that L was 2260 J/g plus a small correction needed to raise the temperature of 20 C water to the boiling point. The correction was necessary because 20 C water was constantly added to replace the evaporated water.

After answering I started to think about a possible interpretational errors in the determination of excess heat from the amount of water evaporated. Latent heat is determined by attractive molecular forces between the escaping molecules and remaining liquid. In other words, L is determined by the surface tension. Suppose that water is not pure and that a thin layer of "something" is present on its surface. Is it not reasonable to assume that the presence of that "something" might change the effective value of L significantly? Suppose that the presence of that "something" lowers the L by 50% but a researcher is not aware of this. Instead of multiplying the mass of the lost water by 1130 he multiplies it by 2260 and concludes (wrongly) that the amount of released thermal energy is much larger than the amount of received electric energy. That would be an illusion of excess heat.

Is the above scenario possible? Can the surface tension of water be lowered significantly by "something?" What can that "something" be? Can it come from the salt used to make the electrolyte? Can it come from the body of the cell, etc.? Can it come from products of reactions taking place near the cathode? These questions were actually posted on the CMNS discussion list. Fortunately, about 24 hours later, somebody responded by emphasizing that vaporization, at the boiling temperature, takes place deep below the surface. The lowering of the surface tension by an additive would be expected but this should have no effect on the L that must be used to calculate excess heat. I also learned that ionic compounds tend to increase the surface tension of water while organic compounds added to water tend to lower it very significantly.

Responding to this reassuring comment I wrote: “I agree with you. Bobbles are indeed formed below the surface, as one can see, and surface tension should not play a role. This, however, is not true when evaporation takes place below the boiling point. At 40 C, for example, one cannot see bubbles coming from the bottom. Therefore I expect L to depend on the surface purity at temperatures below boiling. Fortunately, this has nothing to do with measuring of the COP (Coefficient Of Performance) in Mizuno-type experiments. Thanks for restoring my confidence in the validity of methodology described by Fauvarque et al.” But a day later I started worrying again. Here is my next posting on the CMNS list.

“Evaporation of water (below the boiling temperature) is a surface phenomenon. Boiling, as emphasized by X, consists of bubbling that takes place in the entire volume. Is it just a coincidence that the latent heat of evaporation and the latent heat of boiling are identical? Slow evaporation seems to be reversible, fast boiling is not reversible. (I have never seen bubbles forming at the surface and going down to condense near the bottom.)

By the way, a large fraction of bubbles is produced near the very hot cathode. Some bubbles are probably born as

chunks of supercritical water (neither liquid nor vapor). Is it possible that supercritical evaporation, if not accounted for, might lead to the lowering of the effective L? Recall that L approaches zero when the critical point is approached in the P,T diagram. Lowering of the effective L could possibly create an illusion of excess heat. Evidence of extremely high temperature (sufficient to melt tungsten) was clearly visible when our cathode was examined under the microscope."

The answer, if any, will be paraphrased below; unless I decide to ask for permission to quote the reply. The responsibility of addressing such issues -- the so called burden of proof -- should be an obligation of those who make a discovery. A month from today I will be presenting results of an ongoing study at a conference in Japan. The issue of the "effective L" seems to be central when the amount of excess heat is deduced from the amount of lost water. Was that issue addressed by those whose conclusions we are trying to either confirm or refute? I do not think so.

267) Searching for excess heat in Mizuno-type plasma electrolysis

Ludwik Kowalski (a), Scott Little (b), and George Luce (b)

(a) MSU (Montclair State University), Montclair, New Jersey, USA.
(b) ETI (EarthTech International, Inc.), Austin, Texas, USA.

Abstract:
Excess heat generated in the glow discharge plasma electrolysis, first reported by Mizuno and Ohmori (1), has been studied by several researchers, both in Japan (2, 3, 4) and in other countries (5, 6, 7, 8). Most reports, but not all, confirmed generation of excess heat. Facing this situation we decided to replicate the most recent experiment (8) in which excess heat was reported to increase with voltage. Our results do not confirm reality of escess heat. An additional experiment confirming this conclusion will be described in unit #270.

Introduction:
Suppose that a common immersion heater is inserted into a beaker with water. How should thermal energy released in the container depend on the amount of electric energy supplied? The answer is in the law of conservation energy. The amount of electric energy, E, supplied to the cell must be equal to the amount of thermal energy released, Q.

$E = Q$. ..... (1)

But in the setup described in (8) the right side of the above equation was reported to be significantly larger than the electric energy on the left side. The authors believe that some hidden energy, presumably nuclear, is released during the plasma electrolysis. That is the essence of the excess energy claim. Another way of expressing the claim is to say that the coefficient of performance (COP), defined as Q/E, is larger than unity. According to (8), the COP at 350 V is between 1.31 and 1.41.

In this experiment, where the electrolyte is always boiling, part of the heat energy produced goes into vaporizing water (at the rate of 2260 joules/gram) and the remainder is lost from the cell through conduction and radiation. To determine the heat output in this experiment we measure the amount of water evaporated, multiply by the heat of vaporization (i.e. 2260 joules/gm) and then add on a correction to compensate for the nonevaporative loses of heat. Expressing this in terms of power (i.e. the rate at which energy is delivered and released):

$P_{out} = dm/dt * 2260 + P_{loss}$ .....(2)

where P_{out} is the total heat power produced in the cell, dm/dt is the rate at which mass is lost by the cell due to vaporization, and P_{loss} is the heat power lost through conduction and radiation.

To determine P_{loss}, we conducted a series of tests in which the electrolyte was boiled with an ohmic heater at various power levels. Comparing the actual mass loss to the electrical energy input revealed that, as in (8), the heat loss through conduction, and radiation is reasonably constant and independent of the electrical input power. That stands to

reason because the cell is always operating at ~100C and always has approximately the same level of electrolyte in it. As detailed below we observed a P_{loss} value of 94 +/- 10 watts from our cell.

The COP can also be expressed in terms of power as follows:

$COP = P_{out}/Pin.$ .....(3)

where Pin is the electrical input power.

Experimental setup

As described in (9), this experiment was prompted by desire to either confirm or refute reality of excess heat as reported in (8). That is why our setup was very similar to that used by Fauvarque et al. Approximately 725 cm^3 of the K_2CO_3 electrolyte (0.2 M) was placed into a polycarbonate vessel whose depth and the inner diameter were 32.0 cm and 11 cm, respectively. The initially anticipated setup, shown in (9), had to be modified to match (8) as closely as possible. Instead of a spiral Pt anode we used a cylinder made from the platinized niobium mesh. The height of that cylinder was 5 cm and its diameter was 6.3 cm. The anode was a 2.38 mm diameter tungsten welding electrode containing 2% of thorium. Both electrodes, and the steam-escape PVC pipe, were mounted on the lid of the main container. The entire setup was supported by a sensitive scale, as shown in Figure 1. "The fresh water reservoir, also mounted on the lid, provided periodic refilling of the vessel. In our case, as described later, the refilling would not proceed as anticipated. A plastic baffle, near the steam exit, was used to shield the pipe from occasional splashes of the electrolyte foam and liquid.

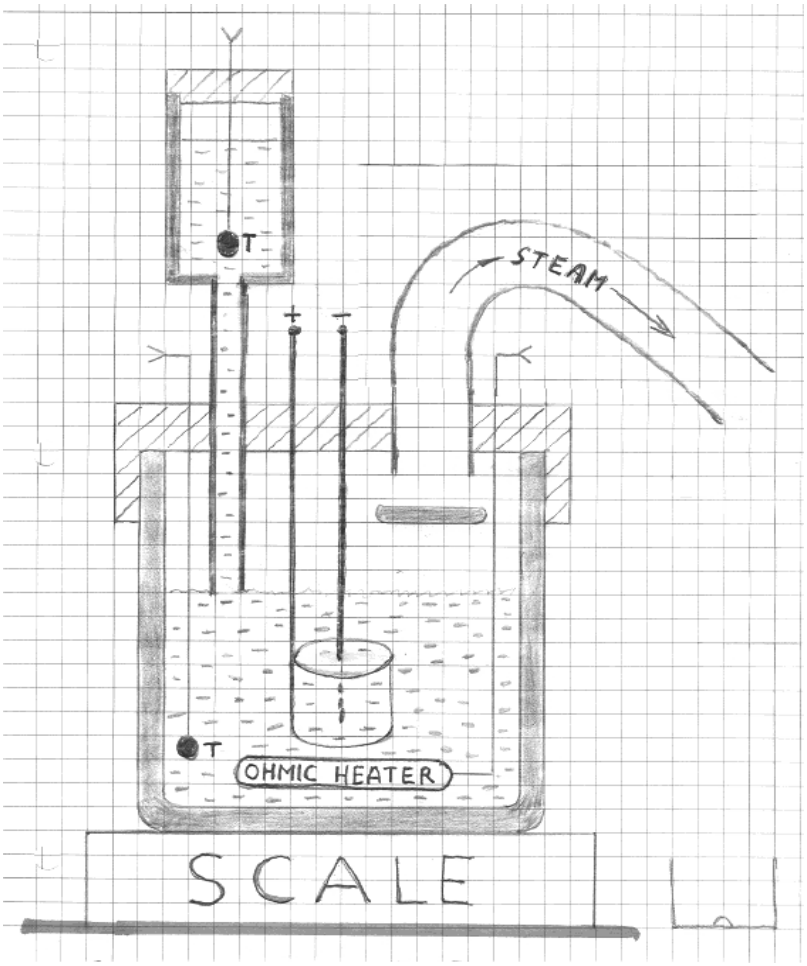

Figure 1
Schematic diagram of our setup. Some condensation is expected to occur on the inner surface of the escape pipe, mostly at the section where the temperature is the lowest. Drops of condensed water could occasionally be seen

dripping into a collector. Temperatures were monitored with two thermistors, T.

The intensity of splashing during the high voltage electrolysis, had a tendency to increase with the potential difference between the electrodes. Unless mechanically reduced, such splashing could possibly create an illusion of a voltage-dependent excess heat. The same kind of illusion could also occur if invisible droplets of foam, mixed with steam, were ejected. Ideally only water vapor (plus some hydrogen and oxygen) should escape from the boiling liquid. The photographs of the entire setup are shown in Figure 2 and 3. Potasium carbonate, used in common detergents, decreases the surface tension of water and causes foaming (10). Foaming interfered with constant replacements of evaporated water, used in (8). The head space in our well-closed cell contained almost nothing but hot water vapor mixed with foam. When bubbles would start up the refill tube so as to permit water from the reservoir to be displaced into the vessel, the bubbles would rapidly collapse and disappear completely upon entering the cooler water in the refill tube. However, when we turned off the power to the cell briefly cooler water vapor would successfully enter the reservoir and allow the refilling to occur. For that reason replacements of evaporated water (typically 30 grams) were preformed manually before the tests. The electrolyte was then brought to the boiling point by using the ohmic heater. Masses of water evaporated in consecutive tests were electronically determined (once every second) from the readings of the scale. Flexible conductive filaments were used to connect electrical components mounted on the lid with outside circuits. This did not interfere with precise measurements of masses (better than 0.5%).

Figure 2
The photo of the setup showing the foam above the electrolyte. The dark cushion below the vessel helped to prevent bouncing of the scale. The inner diameter of the white PVC pipe was about 22 mm.

= =

Figure 3
Electrodes and other components mounted on the lid. The ring below the anode is the ohmic heater, the vertical glass tube on the right contains the thermistor. The transparent antisplashing buffle can be seen below the lid. The side screws were used to mount the lid rigidly on our polycarbonate cell (note the deep groove on the lower surface of the lid). The tip of the tungsten cathode is shown in Figure 4 below.
= =

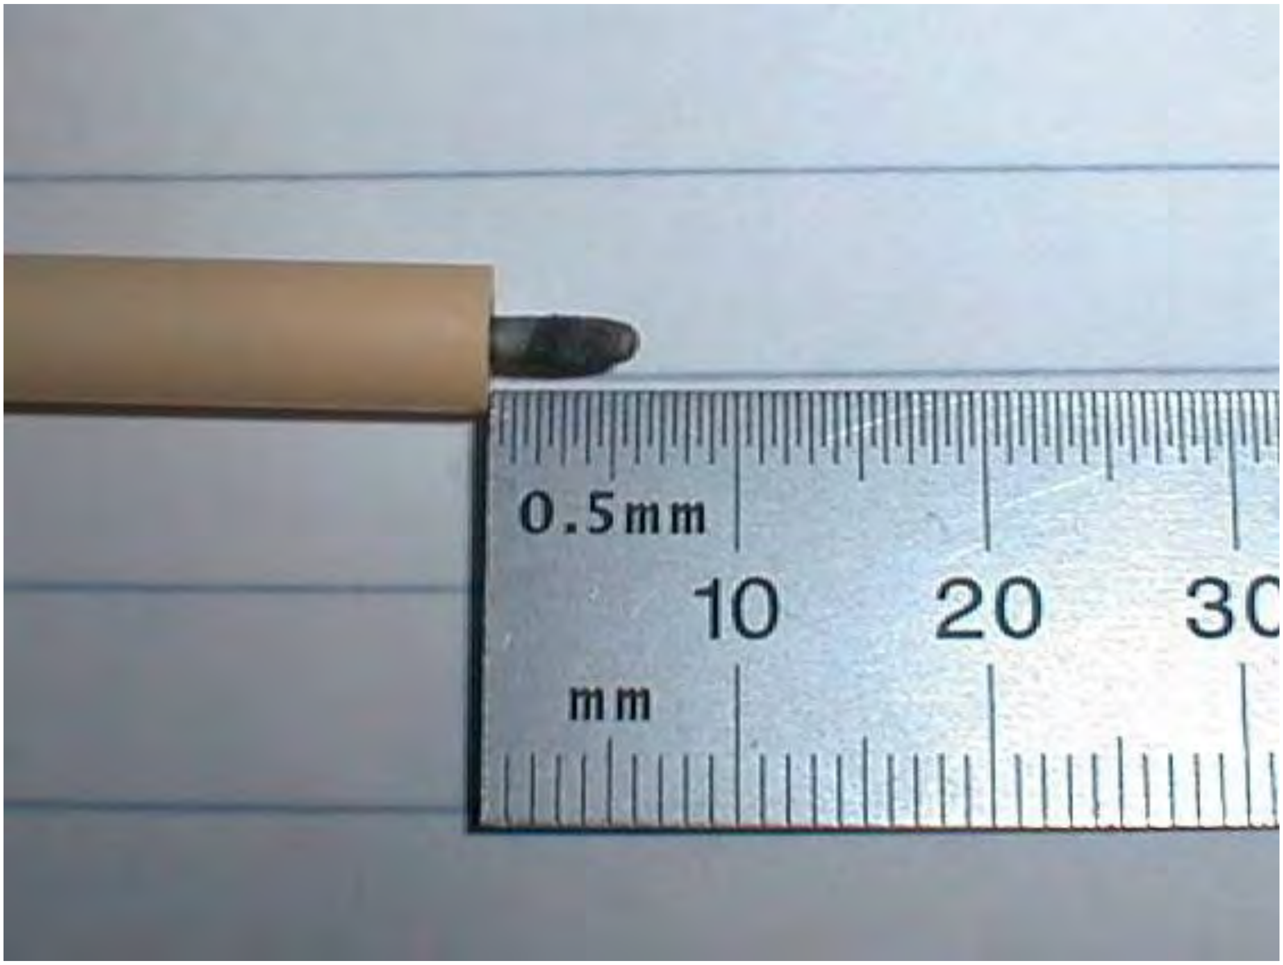

Figure 4
Appearance of the cathode, originally extending 13 mm beyond the ceramic sheath, after a 350 V plasma test (see below) lasting 3 minutes. Typical current densities were in the range from about 3 to 10 A/cm^2.
= =

The ohmic heater was used to measure the P_{loss}, and to preheat the electrolyte before plasma experiments. A computer-based data acquisition system was recording average electric currents, i(t), average potential differences, v(t), and the remainng mass m(t) once every second. The Clarke-Hess 2330 Power Analyzer measured power delivered to the cell by simultaneously sampling v and i at about 2000 Hz, multiplying the pairs of readings together, and averaging the results over several seconds. The data acquisition system interrogated the Clarke-Hess once per second to obtain the lastest values for rms I, rms V, and power. The electrical setup is shown in Appendix 1.

Ohmic heater results
The d.c. power supply of our ohmic heater was similar to that used during the plasma electrolysis. Time dependencies of E and m, at constant electrical power, are shown in Figure 5.

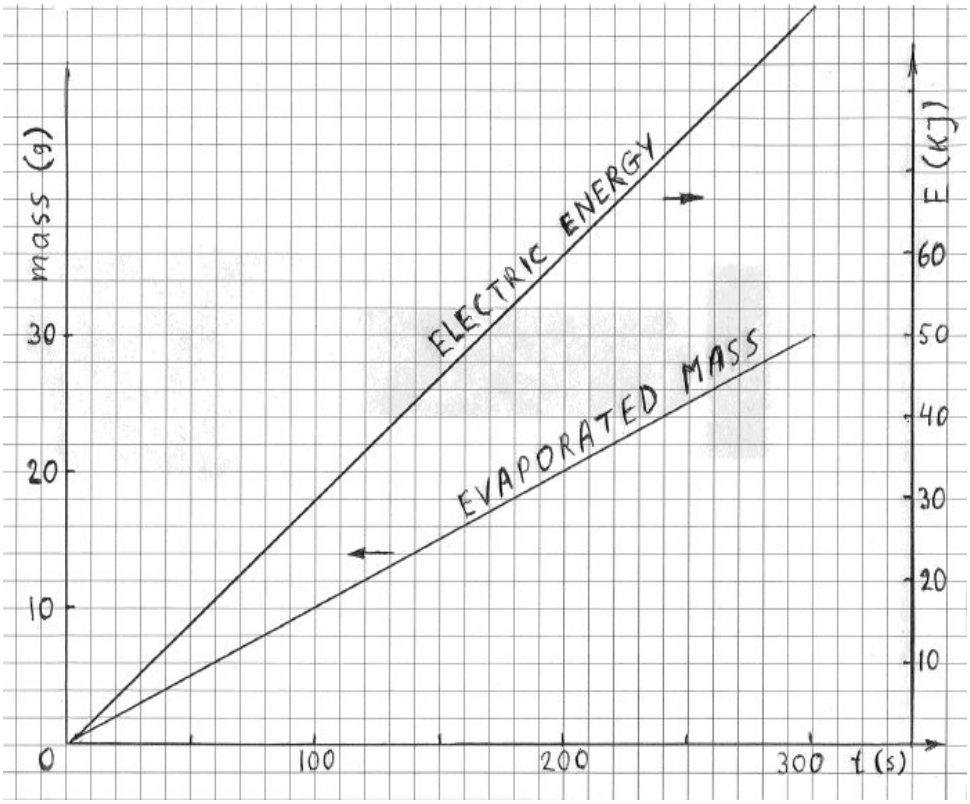

FIGURE 5
Time dependence of the energy received (P_{in}*t) and of the evaporated mass, m(t), at P=300 W using the ohmic heater.

The rate of evaporation, dm/dt, was also constant, as illustrated. The values of P_{in}, P_{out} and P_{loss}, extracted from this figure are shown in the line 4 of table below.

Table 1 (Ohmic heater results)

Pin	Pout	Ploss	Pout+Ploss	COP*
201	107.3	93.7	201.7	1.00
230	131.9	98.1	226.3	0.98
262	184.9	77.1	279.3	1.07
300	208.1	91.9	302.5	1.01
364	280.2	83.8	374.6	1.03
479	377.1	101.9	471.5	0.98
486	380.5	105.5	474.9	0.98
565	461.6	103.4	556.0	0.98

* The last column shows what the COP's would be if they were calculated by using the mean value of Ploss, 94.4 W, instead of numbers from column 3.

That table summarizes results of eight measurements; powers in lines 1 to 3 and 5 to 8 were calculated from the time dependencies similar to those in Figure 5. Note that the third column displays differences between the numbers in column one and two. These are values of nonevaporative powers, P_{loss}. As in (8), we found that the values of P_{loss}, are essentially identical for all P_{in}. This is illustrated in Figure 6. The mean value and standard deviation of P_{loss} turned out to be 94.4 W and 9.9 W, respectively. The last column shows that the COP fluctuations match experimental uncertainties in the third column. Note that the variations in COP using the ohmic heater are essentially the same as they are with the plasma going (last column in Table 2 below).

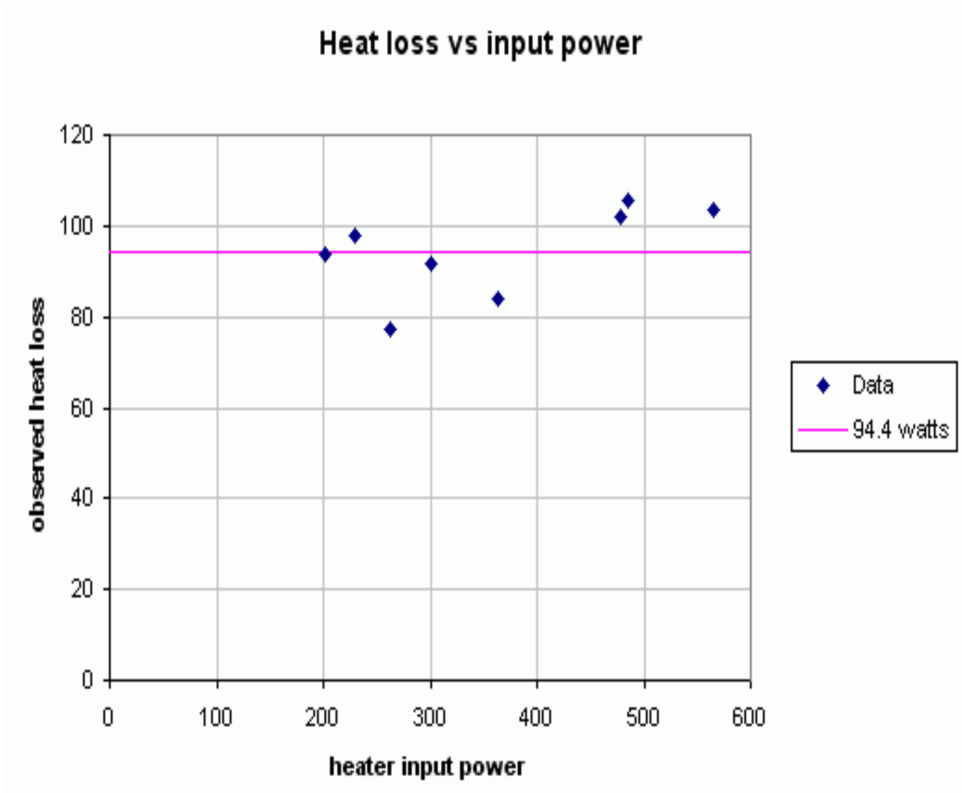

Figure 6
Dependence of P_{loss} (conduction and radiation) on the electric power, P_{in}.
=======================================

In performing these experiments we discovered that the potassium carbonate electrolyte tends to creates foam above the boiling surface. This is illustrated in Figure 2. At first we though that the foam was due to chemical interactions between the electrolyte and cell materials (walls, partially coated electrodes, the lid or the PVC pipe). But foaming was also observed when the electrolyte was boiled in a clean pyrex beaker. Foaming seemed to be less intense during high voltage electrolysis. Occasional accumulation of the foam resulted in its sudden ejections. Fortunately, a setup in which all measurements are recorded once a second can identify ejections as sudden mass changes. After discovering nonevaporative ejections we watched the foam and stopped the runs when foaming became excessive. In that way nonevaporative losses of mass were totally eliminated.

High voltage electrolysis results

Curiously, the foaming seems to be worse during ohmic heating than during plasma operation. It seems that the shocks of the plasma action are breaking the bubbles faster. Table 2 is the summary of experimental plasma electrolysis results. The most important numbers are in the last column; they are the values of COP calculated according to the formula (5). The mean COP, and the standard deviation, turned out to be 1.00 and 0.02, respectively. The table shows that the value of the electric power, P, is not predetermined exactly by the applied voltage. This is probably caused by progressive decomposition of the cathode and by chemical changes taking place during consecutive tests.

TABLE 2 (Voltages, Powers and values of COP's)

volts	P(electric)	Pv (evapor)	Pc	Pe + Pc	COP
250	249.0	155.5	94.4	249.9	1.00
250	338.0	240.8	94.4	335.2	0.99
300	626.4	512.6	94.4	607.0	0.97
300	521.0	424.4	94.4	518.8	1.00
300	563.0	466.4	94.4	560.8	1.00
325	718.8	640.3	94.4	734.7	1.02

350	998.2	934.8	94.4	1029.2	1.03
350	859.7	748.0	94.4	842.4	0.98
350*	331.2	246.9	94.4	341.3	1.03
400*	323.9	243.5	94.4	334.0	1.03

*The last two lines in Table 2 refers to experiments in which the concentration of the electrolyte was reduced drastically (from 0.2M to 0.02M). This reduced the foaming and sloshing inside the cell significantely, most likely due to the unusually low electric electric current (low P). The cathode, however, still achieved a bright incandescent temperature. Thus, even at 400 volts, the COP was still very close to unity. Time dependencies of P_{in} and P_{out} associated with two lines of the table are shown in Figure 7. As in Figure 5, one can see that the evaporated mass increases linearly with with time, according to the value of P_{in}. The values of P_{out}, during plasma electrolysis, are not as constant, as it was when the 360 W ohmic heater was used. At point B that heater was turned off manually and the potential difference of 300 V was applied to electrodes. The power level jumped to nearly 600 W and the rate of evaporation increased accordingly. The voltage v(t) remained constant but the power drifted slowly toward nearly 500 W. Rapid fluctuations of electric power (plus or minus 5%) were due to fluctuations of electric current, i(t). At point C the voltage was increased to 325 V and the power level jumped to nearly 700 W. The rate of evaporation increased accordingly. The direction of the power drift changed and the intensity of rapid fluctuations increased (to about 12%).

The data collection was stopped manually at point D because of intensive foaming. The trend toward more rapid drift and stronger fluctuations of $P_{in}(t)$ continued when potential differences were increased to 350 and 400 V. This was associated with intense arc-like explosions inside the vessel. Obtaining reproducible data became more and more difficult above 350 V. Excessive arcing was unpredictable but short time intervals without excessive arcing at higher voltages -- our rare “windows of opportunity” -- were sometimes available to make measurements. No evidence of excess heat at higher voltages (up to 400 V) emerged from these quick explorations.

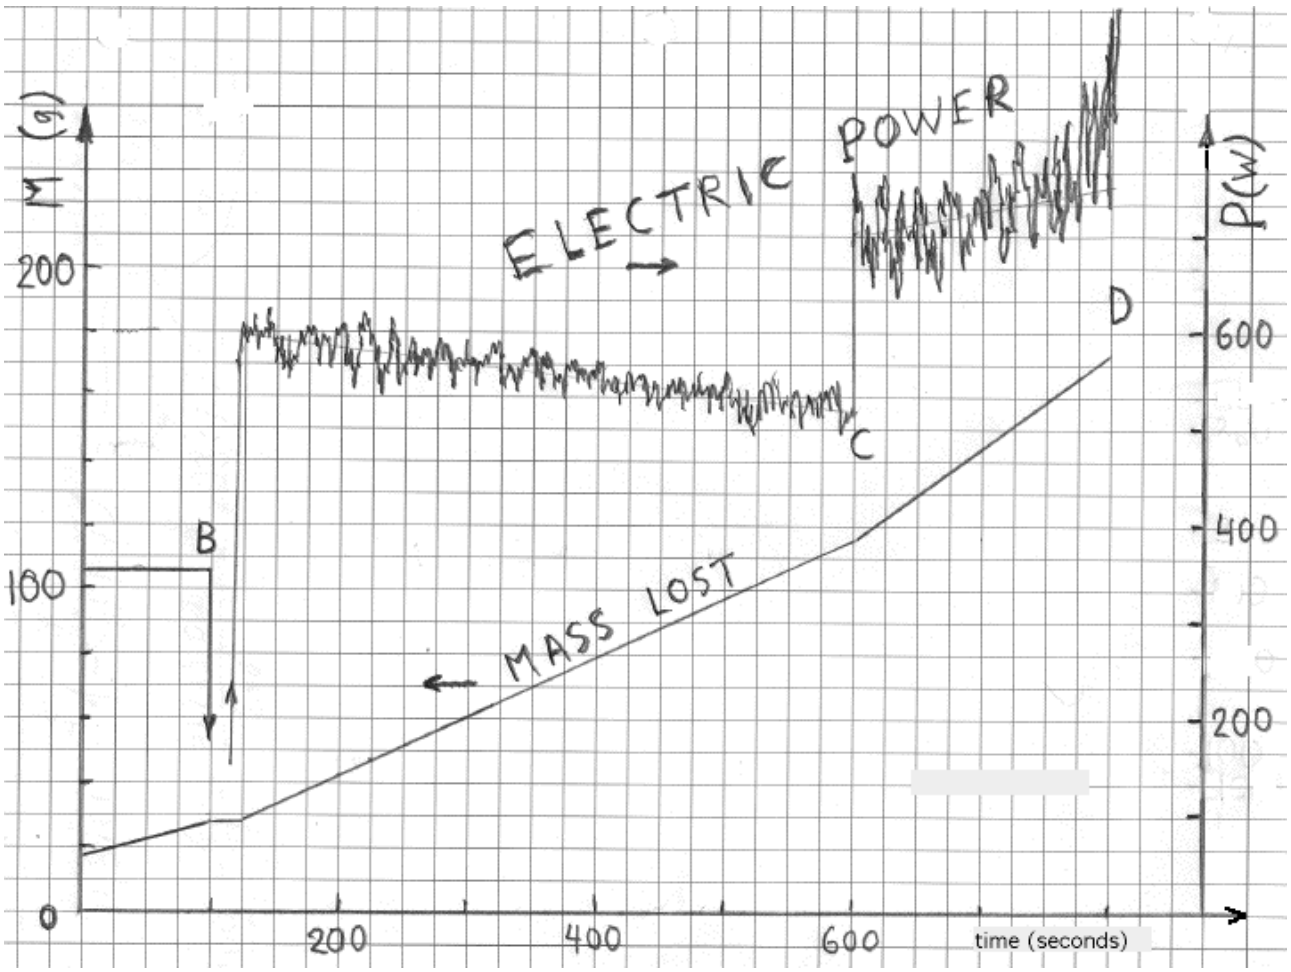

Figure 7

Time dependence of the electric energy received and of the mass of evapoated water at 300 V (between B and C) and 325 V (between C and D) during plasma electrolysis. Note that the values of $P_{in}(t)$, at constant voltages, were not as stable as when the ohmic heater was used to sustain boiling.
= =

Discussion:
Our experiments show no sign of the large excess power reported in (1,2,3,4,5,7, and 8). But they confirm findings reported in (6). It is remarkable that the COP's at 200 V and 250 V, reported in (8), are very close to ours. Discrepancies, however, become progressively larger at higher voltages. Splashing of the electrolyte also becomes more significant at higher voltages. This suggests that unnoticible loses of the electrolyte, from an open vessel used in (8), might be responsible for differences between the two set of results. Other discrepancies are worth mentioning. According to (5), the excess energy can be much larger than in (8), even below 200 volts. The COP of the cold fusion reactor of Naudein (CFR1.1), for example, was reported as 1.85 at 150 volts and about 2.5 A. The electrolyte used in CFR was exactly the same as in (8). Let us also mention that the COP's values between 1.2 and 1.4 were recently reported in (7). The corresponding voltages, however, were not specified. The issue of foaming, most likely associated with formation of CO_2 at boiling temperature, (11) was, unfortunately, not addressed in (5), (7) and (8).

The challenge presented by ejection of liquid water is indeed very serious becase the latent heat of evaporation is large. Mist ejection, at the rate of 50 milligrams per second, results in the overestimation of P_{out} by 2260*0.05 = 113 W. This, however, is only one possible explanation of discrepancies. Another might be associated with microexplosions we occasionally observed during plasma electrolysis, expecially at higher voltages (see Appendix 3). Such explosions are accompanied by loud popping noise and very intensive arcing. We suspect that escaping hydrogen and oxygen occasionally combine under the influence of arcing. That could be a possible non-nuclear source of excess heat repored by several researchers.

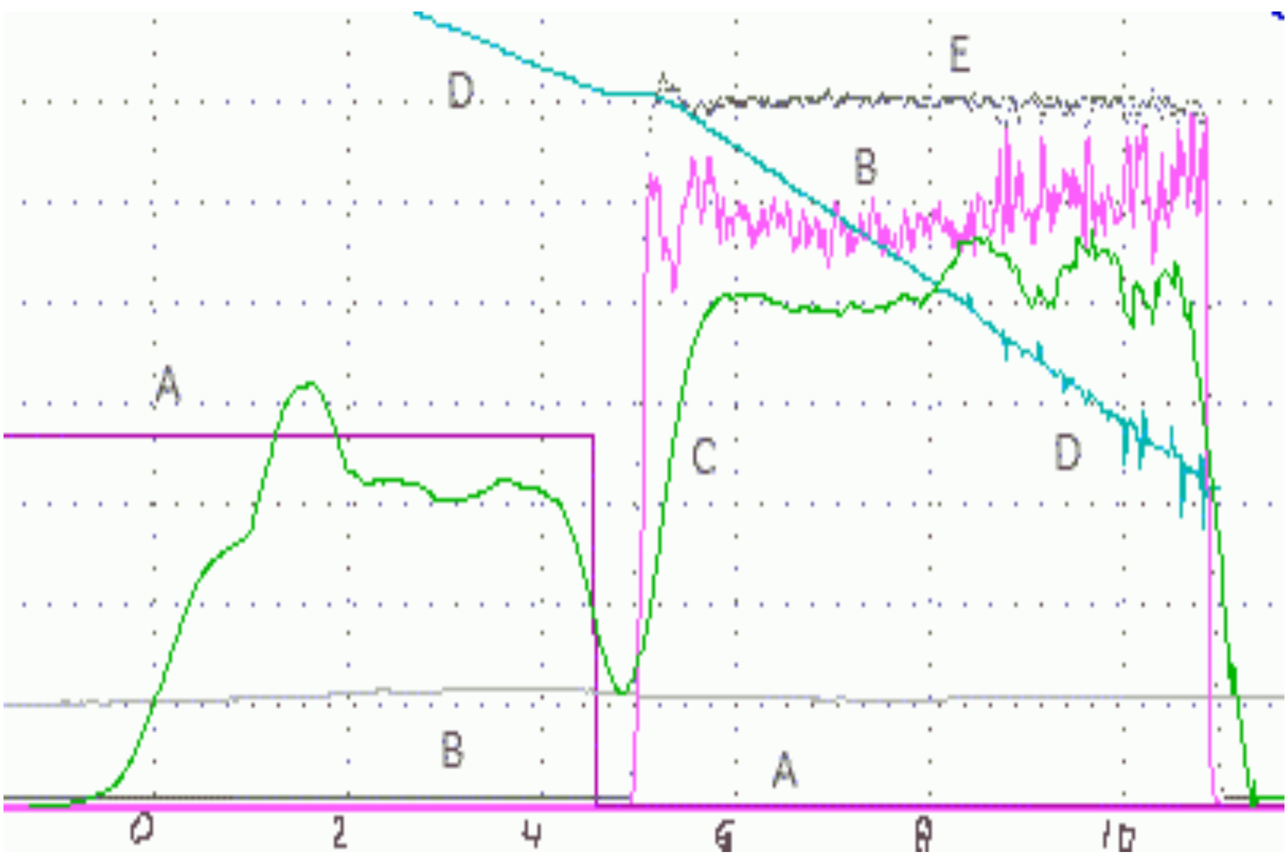

Figure 8
Time dependencies of several parameters. Trace A is the ohmic heater power, initially 360 W and then zero. Trace B is the P_{in}, the electric power during plasma electrolysis. It was initially zero and then fluctuated near 700 W, more or less

as in Figure 8. Trace C, shows the values of P_{out}. Unilke other traces on this figure, each data point along the C is the average power from many intant powers (30 seconds on the left and 30 seconds on the right). That explains why oscillations along the trace C are relatively slow. Note that the boiling temperature was reached shoerly befotr t = 0. Trace D is the decreasing mass of the cell; it can be used to calculate instant the rate of evaporation. Trace E shows that the applied voltage, 350 V, remained essentially constant. The unlabeled gray trace is irrelevant, it shows the temperature in the water reservoir (above the cell lid).
= =

Anticipating a possibility of hydrogen burning our tests were manually interrompted as soon as arcing became extensive. Fortunately, prolong arcing is accompanied by thermal instabilities (large fluctuations in Pout) that can be recognized when data are analyzed after experiments. This is illustrated in Figure 8. It shows that P_{out} was stable between t=6s and t=8s. After that it became unstable, due to arcing. Microexplosions can also be identified by oscilations along the mass trace, D. They are caused by dynamic effects on the scale during microexplosions. In this case data at t > 8s were ignored.

INSERTED on 11/16/05:

1) A different description of the above experiment has been posted at the EarthTech website: <http://www.earthtech.org/experiments/Inc-W/Fauvarque>

2) Richard Slaughter, an electrical engineer in Boulder, Colorado, set up an experiment similar to that set up by Scott Little. I participated in his experiments. This work is described in unit #270 (to be posted in a day or two). The COP values, as you will see, remain very close to unity, even above those listed in table 2.

APPENDIX 1: Measuring electric energy

Electric energy delivered to a cell, is the integral (over a test duration) of i(t)*v(t)*dt. The instrument we used, Clarke-Hess model 2330 power analyzer, sampled the v(t) and i(t) about 2000 times per second. As expected, the voltage between the cell electrodes, v(t), was essentially constant but the current i(t) was highly irregular. Digitized samples of v(t) and i(t) were recorded by the computer and the cumulative input energy was displayed during the data acquisition, as shown in Figure 7. A highly irregular nature of the i(t) waveform guarantees random sampling and the average energy, over a time longer than several seconds, is highly reliable. To verify this we also used an a.c. watt meter at the input of our d.c. power supply. The a.c. energy measured with that instrument was only slightly larger than the d.c. energy. The difference, was consistent with what is necessary to operate the power supply when it is not loaded. Electrical connections are shown below. The Clarke-Hess meter adjusts the sampling frequency to avoid beats with the current and voltage signals.

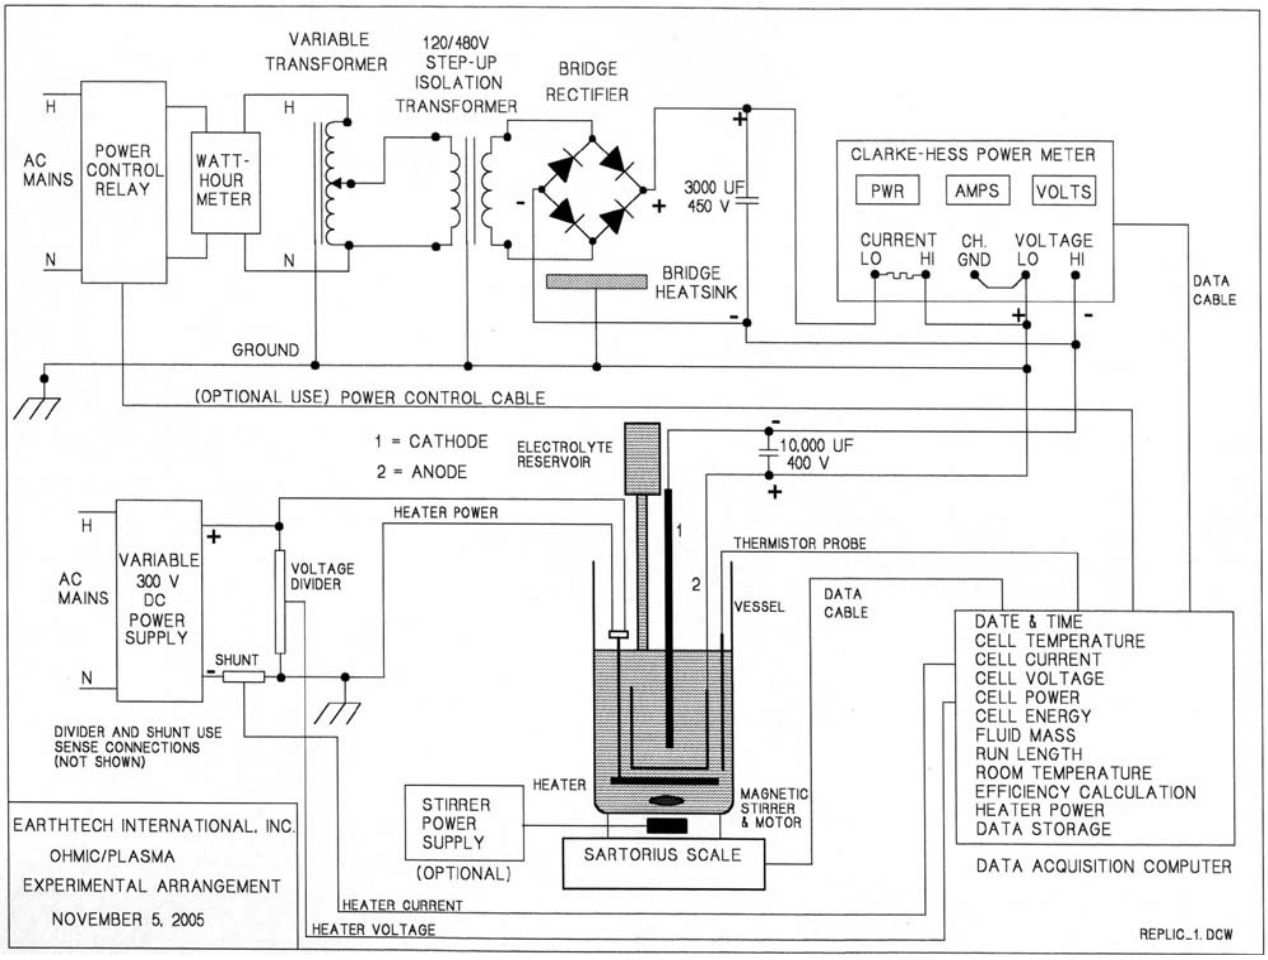

FIGURE 9
Electrical connections.

APPENDIX 2: Discussing Condensation of Steam

Is it possible that condensation of steam inside the cell, for example on the inner walls and on the lid, is responsible for the underestimation of excess heat? The answer to this question seems to be negative. First, condensation is likely to take place near the outlet of the exhaust pipe where the temperature is relatively low. Water condensed near the ending of the pipe does not return to the electrolyte. Second, consequences of condensation, if it were significant, are not as serious as one might think. Heat released in condensation of one gram of steam is the same as heat used to evaporate one gram of water. Thus each gram of condensed water brings back 2260 Joules of heat. Heating of the electrolyte by condensation is not distinguishable from heating it electrically. Thus, in the first approximation, condensation has no effect on the CPU. In reality some heat released in condensation is removed by conduction and convection. But, as in (8), the nonevaporative losses, P_{loss} were measured. In other words, the effect of condensation on COP is practically eliminated. Unfortunately, this cannot be said about splashing; unaccounted splashing might lead to exaggerated values of CPU, and to an illusion that the CPU increases with voltage.

APPENDIX 3: Microexplosions

Using 0.2M K_2CO_3 electrolyte, our cell consumes nearly 1000 watts at 350 volts. The resulting plasma is so violent that the electrolyte sloshes all over the place and periodically exposes the cathode. When that happens an arc, possibly accompanied by a H_2 +O_2 explosion occurs and a small hole is melted in our anode grid. The shock from these explosions is so violent that, even with our present shock-mounting of the cell, the Sartorius balance is unable to provide stable mass readings, thus ruining our data collection.

Despite these difficulties we have tried running at 350 volts about 6 times now (our Pt-coated Nb mesh anode has about 50 small holes in it now). On most of these attempts something inside the cell broke apart or the balance was so disturbed by the shocks that its data was meaningless. But we were lucky enough to catch the cell "behaving" well enough on two of these runs and we got "reasonable measurements" from them.

Another problem is that 1000 watts is out of the power range (0-550 watts) that we can explore with our existing ohmic heater. Thus we are forced to extrapolate the heat losses and that could be erroneous. On the other hand, if we dilute the electrolyte to 0.02M K2CO3, then the cell consumes about 300-400 watts at 350 volts and all of the measurement strategies we developed specifically for this experiment work satisfactorily.

To date we have made three "good measurement" runs at 350 volts. The COP's observed on the two runs with 0.2M K_2CO_3 were 0.98 and 1.03. The COP observed with 0.02M K_2CO_3 at 350 volts was 1.03. As it turns out none of these COP's is significantly different than 1.00.

268) A message from a reader

Ludwik Kowalski (11/9/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Several weeks ago I asked a reader of this website for a permission to quote a message received from him. That permission was given but I forgot to append it to the unit on which I was working at the time. But I did post his message on a private list of cold fusion researchers. In doing this I suggested that somebody might be interested to discuss the topic with the author, Dean Sinclair, PhD in chemistry.

To keep my promise I am creating this unit. It is the trace of my correspondence with him. On Oct. 20, 2005, at 4:55 PM, Dean Sinclair wrote:

> Dear Dr. Kowalski-

My replying to the above was: I asked:

”1) Can I have permission to append your last message to the next unit on my website?
2) Would be OK to add this sentence:

‘From previous correspondence with Dean, whose life circumstances are not favorable to conduct research, I am nearly certain that he would be happy to receive comments. Here is his email address: <deanlsinclair@gmail.com>’ ”

Dr. Siclair wrote “Sure, go ahead. Thanks.”

On Nov 4, 2005, at 4:25 PM, dean sinclair wrote:

Hi, Ludwik,
I was just looking at a couple of the papers on your site. It seems that no one has pointed out that, in the "relativity" of nuclear particles the proton actually has a very small charge density in comparison to the electron, and an much smaller mass density. There seems no reason that electron orbitals could not pass right through the protons. Also, there seems no reason that protons cannot interpenetrate far more than is usually thought. The "Coulumbic barrier" to intereaction may be virtually nonexistent. Ciao. Dean L. Sinclair

My reply was simple: “Thanks for the comment. Interesting. But discussing such things is far above my level of confidence.” That was my last message to Dean. And his last, very informal, message was: “Oh, well, discussing such things is probably well beyond my level of COMPETENCE, but I'm stupid enough or crazy enough.... ”

Perhaps a theoretically inclined person will contact Dr. Sinclair and discusses the topics with him. Once again I apologize for not posting his first message earlier.

269) About some analytical instruments

Ludwik Kowalski (11/21/05)
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) In this unit I want to to collect information about "new and fancy" analytical methods used in CMNS field, particularly in the CT (cold transmutation) sub-field. Early in November Frank Gordon sent me an Excel table listing these methods. The document is too wide to fit here and I will turn it into a different format below. But first let me quote what Jean-Paul Biberian wrote about two of these methods, ICP-MS (inductively coupled plasma - mass spectrometer) and SEM (scanning electron microscope).

2) On November 16, 2005, at 4:58 AM, **Jean-Paul Biberian wrote:**

a) ICP-MS uses a mass spectrometer to analyze the components of the plasma. This is a very sensitive technique that can easily detect parts per billions. Also one interesting aspects is that it can do isotopic analysis. Unfortunately, there is a problem with the argon which might interfere with other masses for example calcium.

ICP emission on the other hand analyses the light produced during the discharge. This is also a very powerful tool for chemical analysis. However the sensitivity is lower than ICP-MS, but almost all elements can be measured. There are equipments that do both. In order to analyze a material, it needs to be in solution. Therefore for metals, they are dissolved in acid and then fed in the plasma.

b) SEM stands for Scanning Electron Microscope. This is an electron microscope that produces physical images of the surface by measuring the intensity of the secondary electrons produced by the scanning electron beam. The secondary emission varies with material composition and angle of incidence. The lateral resolution can be very high, almost atomic. In order to obtain chemical information, an X-ray detector measures the X-rays produced by the incident electron beam. Therefore a local chemical analysis can also be performed. However, because the incident beam has a relatively high energy, typically 30 keV, a depth of about one micrometer is analyzed. Almost all elements can be detected that way.

3) And here is **information from F. Gordon's table** mentioned at the beginning:

IC -IOS (Inductively induced plasma - optical emission spectrometer)
liquids,
benefits --> used as screening tool
detriment --> liquids only
high maturity
low cost
informs about bulk composition
useful at ~100 ppb level

NNA (nuclear activation analysis)
liquid or foil
benefits --> definitive for analyzable isotopes nondestructively

detriment --> some molecular interference
maturity high
cost low
informs about bulk composition
useful at ~10 ppm level

ICP - MS ((inductively coupled plasma - mass spectrometer)
liquids,
benefits --> used to identify isotopes
detriment --> liquids only
high maturity
low cost
informs about bulk composition
useful at ~200 ppt level

GD - MS (glow discharge mass spectrometer)
foils
benefit --> used to identify isotopes
detriment --> some molecular interference
maturity high
cost low
informs about bulk composition
useful at ~ppb level

XRF (X-ray fluorescence)
foil or powder
benefit --> non-destructive gross screening tool
detriment --> sensitive only in first ~10 micrometrs (of depth)
maturity high
cost low
bulk composition
useful at~10 ppm level

TEAMS (trace elements accelerator mass spectrometry)
dry powder or foil
benefits --> definitive differentiation of molecular Interference
detriment --> surface only
maturity median
hight
surface composition
useful at ~40 ppt level

RBS (Rutherford backward spectrometry)
foil
benefits --> surface screening tool
detriment --> insensitive if impurity > Pd present
maturity high
low
surface composition
useful at ~10 ppm level

XPS (X-ray photoelectron spectrometry)
foil
benefits --> non-destructive surface screening tool-chemical information-depth profile

detriment --> marginal sensitivity
maturity high
medium
surface composition
useful at ~1000 ppm level

AES (Auger electron spectrometry)
foil
benefits --> non-destructive surface screening tool-chemical information-depth profile
detriment --> marginal sensitivity
maturity high
medium
surface composition
useful at ~1000 ppm level

SEM (scanning electron microscopy)
foil
benefits --> compare surface topography
detriment --> marginal sensibility
maturity high
medium
surface structure

SEM/EDAX (scanning electron microscope/energy dispersive analysis of X-rays)
foil
benefits --> gross screening tool
detriment --> sensitive in first 10 microns
maturity high
medium
bulk composition
useful at ~10 ppm level

TEM (transmission electron microscopy)
standard TEM preparation
benefits --> phase definition
detriment --> small field of view
maturity high
cost medium
microstructure

SIMS (secondary ions mass spectroscopy)
foil
benefits --> depth profile
detriment --> molecular interference
maturity medium
cost medium
bulk composition
useful at ~100 ppb to 10 pm level

NRA (nuclear reactions analysis)
foil
benefits --> definitive for one isotope at a time
detriment --> measures 1 isotope at a time
maturity low

cost medium
surface composition
useful at ~100 ppm level

MALDI (matrix assisted laser dispersion and ionization)
foil
benefits --> detects high molecular weight species
detriment --> wrong mass sensitivity
maturity high
cost low
surface composition
useful for organics

PIXE (proton induced X-rays analysis)
foil
benefits --> screening tool
detriment --> lacks sensitivity
maturity high
cost medium
surface composition
useful at 100 ppm level

4) Appended after the ICCF12

Yokohama, near Tokyo, is the place where the ICCF12 (International Cold Fusion Conference #12) will begin tomorrow Actually it started this afternoon, in the form of a set of “tutorial” sessions. Four leading CMNS researchers reviewed areas in which they have been working. One of them was Yasuhiro Iwamura, a researcher from Mitsubishi Heavy Industries in Japan. First he described his findings in the area of cold transmutations, then he focused on analytical instruments used in that kind of work. He said that such instruments can be subdivided into two broad categories: those for identifying elements (by the energy levels of atoms) and those for determining atomic masses. The figure below is from a slide Iwamura used in his presentation.

Note that column 3 names the “driver;” the kind of radiation, or particles, used to bombard the analyzed atoms. The column 4, in turn, lists carriers of information; such as X rays whose energy spectra must be analyzed, etc. Regions accessible to individual instruments are listed in the last column. Iwamura is certain that he identified several unexplained nuclear transmutations, such as Cs turning into Pr.

In general, Iwamura said, a transmutation research project begins with a qualitative examination. The goal is to find out if the elements in which one interested are present or not. If they are present then one must conduct a qualitative analysis (to find out if it is an impurity or a product of a nuclear reaction). Once the impurity is ruled out one must conduct additional qualitative analysis. The distribution of products (on the surface, in depth, and as a function of time) must be studied to infer what happens. Most scientists are extremely skeptical about nuclear transmutations without fast projectiles, such as neutrons or protons. That is why convincing them that nanograms of new material, such as Pr or Mo, generated in specially prepared foils, is very difficult. Fortunately, modern instruments are very sensitive and, at least in principle, Iwamura's findings should be reproducible in other laboratories. The pictures below were given to me by Iwamura; they were used in his tutorial lecture.

P.S. Iwamura, after seeing the above, asked me to mention that slides were not his own; he found them on the Internet and added some words.

P.P.S. Iwamura has been studying CMNS transmutations for many years. His work dominated all three International Cold Fusion Conferences that I attended (ICCF10 ICCF11 and ICCF12). **His papers can be downloaded from the library at <http://www.lenr-canr.org>.**

5) Contribution from Mark Tsirlin (12/15/05)

Let us observe some experimental proofs of low-energy nuclear reactions (LENR) presented repeatedly in reports at conferences and in papers published in journals of CF community. The main analytical methods applied in this case are various modifications of SEM-EDS and SIMS methods. Let us remind their potentialities.

1. SEM-EDS

This method provides a surface image at the magnification of tens thousand and sometimes, under especially favorable

conditions, – up to 200-300 thousand. Electron beam ~1 micron in diameter excites X-ray irradiation generated by a small volume of substance approximately equal to the volume of a sphere 1.5 micron in diameter. The generated X-ray irradiation is recorded using a silicon spectrometer. Thus, we obtain information on the qualitative and quantitative composition of in the small volume of the substance. Detection limits of the method are 0.1-1%. Apparently, the sensitivity of the method is not very high and approximately corresponds to that of the X-ray diffraction method.

However, due to high localization, the method provides rather efficient detection and analysis of heterogeneous materials, especially those containing microscopic inclusions or multilayered structures. It is worth mentioning that the sensitivity and accuracy of the method are essentially reduced at the analysis of rough surfaces. In my opinion authors reporting detection of some "new" elements e.g. in Pd after D absorption or after the passage of D flow (by using this method) must experimentally demonstrate that:

a) the mentioned "new" elements were absent in the initial metal. This requirement does not seem strange taking into account the fact that Pd in its initial state contains a large number of microscopic inclusions entering the latter at various stages of metallurgical processing. In particular, our experience shows that such inclusions of various nature and origin contain many elements detectable (sic!) by EDS method. Among these elements, we can mention carbon, alkali and alkaline earth metals, silicon, oxygen, aluminum (alumo-silicates of various compositions), chlorine, fluorine, sulfur, tungsten, titanium, etc.

b) details and components of the apparatus could not be a source of "newly formed" elements. This requirement is especially topical for high-temperature processes (glowing discharge, Mizuno-type experiments, etc.). Besides, the map of newly detected elements distribution on the metal surface should be carefully examined. Finally, last but not least, it is highly desirable to coordinate the nature and amount of newly formed elements with the respective nuclear transformations and their gross power output.

SIMS

The method is extremely sensitive (with the accuracy of ppm). That imposes additional responsibility on a researcher. He has to analyze carefully all possible sources (even minor ones) of surface contamination with foreign elements, since it is practically impossible to avoid such contamination working with Pd. Moreover, the specific character of the mass-spectrometric method entails the danger of mixed estimations. Thus, molecules of different nature and mass (including those of organic origin) adsorbed on the metal surface can turn into vapor phase after partial destruction or, on the contrary, polymerization, in the course of ion bombardment in the instrument chamber. Unfortunately, the mass-to-charge ratio of such fragments can coincide with that of an elementary isotope of one or another element.

Usually, modern mass-spectrometers are equipped with respective software and databases facilitating the process of identification of such mixed estimations. Nevertheless, this process is rather labor-consuming and requires special attention. Quantitative analysis within the SIMS framework is rather complicated. This is due to the nature of the method, namely, to the mutual influence of all components of the substance on the ionization cross-section of elementary or complex ions. At the same time, this method offers a possibility to determine isotopic ratios of of various elements.

This remarkable feature is widely used for proving reality of nuclear reactions in cold fusion experiments. The above mentioned hindering factors, however, should not be ignored. One should be aware that different elements often have identical atomic masses and that molecules can be misidentified as elements. Unfortunately, these aspects of the SIMS methodology are not always discussed by those reporting discoveries of abnormal isotopic ratios. Discussing sources of potential errors, and convincing readers that such errors were not made, would strengthen the claims, especially in the eyes of experts from general scientific community.

P.S. (1/13/06)
Graham Hubler, a material scientist at Navy Research Laboratory (Washington D.C.), told me that a small accelerator, in his laboratory, has been modified to become an AMS instrument. They call it Trace Elements Accelerator Mass Spectrometer (TEAMS). I plan to write more about it.

New results and an ongoing excess heat controversy

L. Kowalski, Montclair State University, Montcalir, New Jersey <kowalskil@mail.montclair.edu>
G. Luce, EartchTech Inc. Austin, Texas <geolucetx@sbcglobal.net >
S. Little, EarthTech Inc, Austin, Texas <little@earthtech.org>
R. Slaughter, Advanced Energy Industries, Fort Collins, Colorado <rslaughter@compuserve.com>

Introduction:

This report describes results of two separate experiments, one conducted in the EarthTech laboratory (Austin, Texas) and another in the laboratory of Richard Slaughter (Boulder, Colorado). The purpose was to either confirm or refute the reality of excess heat in a plasma electrolysis cell. Experimental setups were similar to that of Fauvarque et al. (1). They consisted of electrolytic cells containing the electrolyte (K_2CO_3, 0.2 M) and two electrodes: a cylindrical anode (platinized niobium) and a tungsten cathode (welding rod). A constant difference of potential, for example 400 volts, was applied to electrodes and a glowing layer of gas was formed around the cathode. Three parameters were measured during each test: the electric energy delivered to the cell, E, the amount of heat lost through water evaporation, Q_1, and the amount of heat lost through conduction and radiation Q_2. The difference between Q_1+Q_2 and E, if any, is called excess heat. As in (1), our experimental results are reported in terms of the coefficients of Performance, COP. That coefficient is simply the ratio $(Q_1+Q_2)/E$.

Experimental results:

According to (1), the COP, at 350 volts, is approximately 1.35. Our results, shown below, conflict with that conclusion.

Table 1 Coefficients of performance at several voltages:

VOLTS -->	250	250	300	300	300	355	350	350	400	650
COP -->	1.00	0.99	0.97	1.00	1.00	1.02	1.03	0.98	1.05	1.02

The first nine results are based on experiments performed in Texas (2, 3), the 650 volt result is based on experiments performed in Colorado (4). The Colorado setup was similar, in principle, to that used in Texas except for the power supply (see Appendix 1). An important observation concerning both experiments can be seen in Appendix 2. The Colorado experiment was simply a two-liter beaker, mounted on a balance, with two electrodes as shown in Figures 1 and 2.

Another difference between our two experiments was that the diameter of the anode in Texas was 6 cm while in Colorado it was 3 cm. The range of potential differences in Colorado was from 500 to 700 volts. The mean value of COP in that region turned out to be 0.90 +/-0.2. The last value 1.02, shown in Table 1, resulted from eight separate tests. The standard deviation calculated from these high voltage tests turned out to be 0.11. It is interesting that foaming and splashing in Colorado was so insignificant that an experiment could be conducted in an open beaker. We believe that this was due to the differences between the power supplies used in two experiments.

Figure 1
The cathode (shorter tungsten rod) and the anode (welded to the longer Ti rod), suspended by a nylon thread, are being lowered into the beaker. Rigidity was assured by two plastic disks (sterilite remains rigid at 100 C). The second function of the lower disk was to act as an antisplashing baffle, inside the electrolyte.

Figure 2
The cathode and the anode inside the two-liter beaker during a 700 volt test.

Discussion:

Favarque et al report observing COP's up to 1.41 in their experiments. Similar values were observed by other researchers. Clearly we have not replicated such results. How can this be explained? By experimental errors (measuring E, Q_1 and Q_2), or by unrecognized, but significant differences in experimental setups. Conditions under which experiments were performed might also have been different. Our anodes, for example, were made from platinized niobium while the anode used in (1) was made from platinized titanium. Instruments used to measure E were also very different. Accurate measurement of the electrical input power during plasma operation is complicated by the highly erratic current.

In Texas, for example, the average current drawn by the cell was 2-3 amps but the waveform peaks frequently exceeded 10 amps. A sophisticated Clarke-Hess instrument was able to recognize overloads and signal them by flashing. On a less sophisticated instrument such conditions might be overlooked and will lead to underestimation of the average power being delivered to the cell. (Overloads were observed during the initial testing; they were eliminated by placing a large filter capacitor between the Clarke-Hess instrument and the cell, as described in (8). Possible errors in measuring Q1 and Q2 are discussed in (3).

Let us mention that appearances of the cathode glow discharge in Texas and in Colorado were quite different. In the first case we occasionally observed white light flashes coming from large regions inside the cell, in the second only a steady yellow light was seen from a small region surrounding the cathode. Intense white light coming from large regions inside the electrolyte can also be seen on the Internet pictures of similar experiments performed by other researchers. Another difference worth mentioning was the fact that a typical current (for a given voltage) in Texas was about four times higher than in Colorado. The plasma differences between the Texas and Colorado experiments were probably due to the arc suppression abilities of the Colorado power supply (see Appendix 1).

Why is excess heat observed in some recent experimental setups (1, 5, 6, 7) and not in others (8)? Are the discrepancies due to experimental errors or to unrecognized, but essential ingredients present in some setups and absent in others? It is difficult to answer such questions. Scientific disputes are not resolved by voting but a large number of confirmations of excess heat, by qualified researchers in many countries, should not be ignored. The existing controversy would be

eliminated if a highly reliable portable excess heat generator could be built. Such generator would then be studied in different laboratories. How else can a consensus be reached?

Referring to the issue Jed Rothwell (9) wrote: "This is more art than science. Direct, hands-on learning may be the only way to grasp these things; Mizuno himself does not know what is going on in many ways. Building devices on the basis of described protocols does not seem to be sufficient." That is a very good point. A tentatively accepted theoretical model would certainly synchronize our dispersive efforts to make sense out of what is going on in the CMNS field. Trying to confirm or to refute claims made by individual researchers is certainly much less effective than testing various aspects of a tentatively accepted model.

P.S. (12/2/05, by Ludwik Kowalski):
Unfortunately, one important detail, about the protocol used by Fauvarque et al., was not specified in (8). As I learned from Pierre Clauzon (at the ICCF12) -- the voltage applied to the cell must change gradually, typically in 20 V increments every minute or so. During that time the cathode was said to be preconditioned to produce excess heat. Clauzon said that they also failed to confirm reality of excess heat without preconditioning.

P.S. (1/3/06, by Ludwik Kowalski):
In a private message Richard wrote to me that his 30 new attempts to generate excess heat were not successful. He is in contact with Pierre Clauzon. I hope that the contoversy will eventually be resolved. How can it faile to be resolved when two honest and edicated researchers are willing to travel and work together, if necessary? I plan to write about this later.

Appendix 1; Pinnacle, a power supply that prevents arcing:

The power supply used in Colorado was a Pinnacle 20kW (10). Although the supply was designed for other purposes it seems to be ideal for GDE (Glow Discharge Electrolysis) experiments. Its typical applications include dc sputtering with RF bias, basic magnetron sputtering, cathode-arc deposition (sputter etching and dc-biased RF sputtering). The special features of the Pinnacle are:

1) High line to load efficiency 91%
2) Power factor > 0.9 for loads greater than 1.2kW
3) Quick response to changes in the load
4) Extremely low stored energy in the output filter
5) Fast arc-suppression
8) Ability to preset joules to be delivered to the load
9) Provides up to 20kw of continuous power (we did not exceed 2 kW).

The supply provides very accurate power measurements and the ability to control how the power is delivered to the cell. The Pinnacle can be used as a source of constant voltage, constant current or constant power, depending on what is chosen. The other two parameters are then determined by the load. The output voltage, current or power will hold to within +/- 1% as long as the load impedance stays within the voltage and current limits of the unit. Our tests were performed by using the constant voltage mode, in the voltage range between 400 and 800.

The low stored energy of the output filters of the Pinnacle allows the regulation system of the supply to rapidly respond to changes in the cell impedance. The low stored energy also prevents the supply from dumping large amounts of energy into the cell as its impedance changes. The low stored energy is probably one reason that foam, white light and violent reactions, observed in Texas (see Figure 3) were not seen in Colorado. The other reason was probably the built-in arc suppression.

Figure 3
Foam and white light observed at 350 volts in Texas were not observed at 700 volts in Colorado (see Figure 2).

The pinnacle has several methods of arc suppression. The one we used is called "micro arc suppression." When an arc of less than 10 microseconds occurs, the stored energy is diverted from the cell and the growing arc is extinguished. The voltage is restored, approximately 5 microseconds later. This ability is used in industry to maintain steady even plasma that are required for precise deposition of material on the manufactured product.

This arc suppression in combination with the low stored output energy of the Pinnacle was most likely the reason that we were able to increase the potential difference to over 700 volts without the violent reactions in the electrolyte. The arc suppression might also be a reason that our results are different from those reported in (1). According to (9), Mizuno says "anyone can generate plasma with hundreds of volts. The trick is to generate it and then gradually reduce input power to the minimum." In one of his papers he writes: "Some researchers have attempted to replicate the phenomenon, but it has been difficult for them to generate large excess heat. They have tended to increase voltage to a very high value, around several hundred volts, but they measured no excess heat." Mizuno also indicates that when the cell begins to produce excess heat the conditions inside the cell are placid. These are the same conditions that we observed in Colorado.

We recognize that the cost of the Pinnacle would make it prohibitive for most experimenters. There are, hpwever, less expensive techniques for arc suppression that could be added to power supplies. It is likely that arc suppression will help to minimize the power delivered to the cell, at a given voltage. This might be an important precondition for the generation of excess heat, as indicated by Mizuno.

Appendix 2; On condensation of steam inside cells.

A critical reader might notice that Fauvarque et al.(1) used an open beaker while the cell used in Texas had a lid on top of it. Can this possibly be a reason for the discrepancy between the outcomes of the experiments? The fraction of steam condensing in a cell with a lid is certainly larger than in a nearly-open cell. The rate at which the mass is lost is used in the calculation of COP. Therefore, a critical thinker might say, the difference in the reported values of COP is not surprising. This issue was discussed in (3). The conclusion was that no significant errors are expected from condensation of water inside the electrolyte, provided the non-evaporative losses are also measured, as in (1). But that was only a logical conclusion based on certain assumptions. Here is how the conclusion was experimentally validated in Colorado.

a) One liter of water was placed into a two-liter beaker standing on a scale, as in (1). An ohmic heater was used to

sustain boiling. The cell had no lid. The mass lost in 350 seconds was found to be 40.1 grams.

b) The cell was then covered with a plastic plate. That plate had 8 holes (about 1 cm diameter each) plus a hole for the ohmic heater cable. The amount of water lost in 350 seconds turned out to be 26.1 grams. That confirmed the obvious - condensation is enhanced by covering a cell.

c) A pair of plasma experiments was performed -- one with a nearly open cell and another with a nearly covered cell. The calculated COP turned out to be 1.00 when the cell was closed (to prevent anticipated splashing that did not materialize) and 1.07 when the cell was essentially open. This pair of tests, by the way, was conducted at 700 volts. Pairs of tests at 600 and 550 volts also showed that the values of COP are nearly identical and very close to unity.

Appendix 3; On reporting negative results:

After finishing Colorado experiments, one of us (L.K.) called a friend and talked about the discrepancy between our results and results reported by other investigators of plasma electrolysis. This prompted him to write the following message: “I am a retired physics teacher interested in all three CMNS phenomena: CF (cold fusion), CT (cold transmutations), and EE (excess energy). We know that there are two kinds of experimental results: unreliable and reliable. Unreliable data are obtained when experiments are being set up and when we are not yet sure that things work properly. Once the initial difficulties are overcome researchers think that results are reliable.

Suppose that reliable experimental data were obtained in ten experiments. Two of these experiments confirmed the expectations and eight did not confirm them. How should such situation be handled? What should a scientific conference report contain, only two positive results or all results? I know that our natural tendency is to focus on the most interesting new results. But is this appropriate? I do not think so. Negative results should not be confused with unreliable results..... ”

But the situation is complicated by the fact that some researchers might be hesitant to publish negative results. They might fear that negative statements, taken out of context, can be quoted by pathological skeptics criticizing the field. In our opinion such fears are not justified; benefits from sharing all reliable results far outweigh negative consequences of self-imposed secrecy. Unscrupulous critics, such as Dr. Richard Park, should not be feared by honest researchers. The issue of publishing negative results goes to the heart of scientific methodology. Here is what Ed Storm wrote about publishing negative results (a private message, 11/19/05): “I would like to throw out some counter thoughts. I think publishing negative results is a waste of time unless these results reveal a useful pattern. For most phenomena, millions of ways are available that will fail to generate the desired results. In contrast, many fewer methods will give the desired results. When isolated negative results are reported, they provide no guidance because they are only a few of so many possible ways to fail. The negative results must be shown to relate to a pattern or a general characteristic. For example in CF, if the H_2O content of the electrolyte is too high, the results will be negative over a wide range of concentration. Unless this fact is related to a positive result obtained when the H_2O content is low, the observations have little value. My point is that people reporting negative results should be required to show an understanding of their meaning just as people reporting positive results must show what their results mean. However, this does not mean that negative results can be used to deny the possibility of positive results. The two kinds of results have very little relationship to each other until the positive results are well understood, because as I said at the start of these comments, many ways exist for a real result to fail.”

We do not agree with this. Negative results are worth sharing and discussing. In this report, for example, one of us (R.L.) speculated that our negative results might be associated with the absence of arcing (collecting data when arcing was not too intensive in Texas and suppressing arcing electronically in Clorado). Is it possible that arcing superimposed on the quite glow discharge is an essential component of a device generating excess heat? R.L. plans to answer this question experimentally in the near future. We think that negative results are worth sharing because, like positive results, they guide our attempts to understand what is going on.

At one point two of us (R.L. and L.K.) were discussing the magnificent Naudin's report: The scatter plot called "efficiency . . . " shows results from a large number of experiments that were similar to ours. We noticed that in all 22 experiments (performed at 200 V or above) the excess heat was larger than 20% of the input energy. That is a highly

significant result; the voltage-dependence trend seems to be consistent with what was reported in (1). That is how the issue of "publishing positive results only" came about. Negative results were not mentioned. We assumed that the impressive 22 data points represent 100% of reliable experiments. But what if this were not true? We would be much less impressed if these 22 data points represented only 30% of all reliable experiments. Negative results, if any, are important indications of encountered difficulties.

P.S.
Subsequently Ed wrote: "You may quote me and even use my name. However, your counter argument to my comment missed the point I was making. As I said, "I think publishing negative results is a waste of time unless these results reveal a useful pattern." The "useful pattern" is the important aspect of my comment. In your reply, you showed that your negative results were being used to reveal a useful pattern, i.e. that the nature of arcing was a possible important variable. .....During my present study of the F-P effect, I have had many "negative" results. However, I know that certain variables are important and must be controlled. For example, no excess energy is possible unless the D/Pd ratio in the surface is very high, which is a difficult condition to achieve. Therefore, I'm investigating the processes that affect this composition. If I report all the negative results without relating them to the important variables, I would be wasting everyone's time.

271) Are we now confirming French EE results?

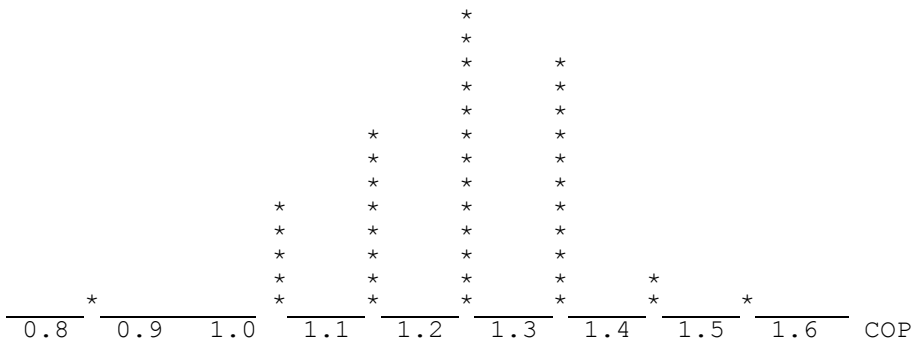
Ludwik Kowalski; 3/16/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction and tentative conclusions:

The controversy about the excess energy (EE), described in the item #270, remains unresolved. Let me tell you about a recent attempt to resolve it. The idea of repeating the experiment under the protocol used in Paris was discussed with Pierre Clauzon during the 12th International Conference on Cold Fusion (ICCF12) in Japan. He, and other researchers, including Mizuno himself, said that our kind of plasma was very different to what they were working with. About a months ago Pierre invited me to work with him at CNAM in Paris. Come to learn how to produce desired orange-red plasma, he wrote. My suggestion was that he comes to the US. A confirmation in another laboratory, I said, would be more convincing than repeating an experiment in my presence. That is why Pierre came to work in Richard Slaughter's lab in Boulder, Colorado. He brought his own electrodes and his own potassium carbonate. During the first four days we had many difficulties. But on the day #4 the situation changed and we started confirming French results.

We learned how to recognize favorable conditions under which results become very reproducible. It is the end of day #8. Out of 41 experiments, performed at voltages ranging from 300 V to 350 V, only 6 resulted in the COP smaller than 1.1 (generating "excess heat" at the rates less than about 50 W). The mean COP and the standard deviation turned out to be consistent with a bell-shaped curve whose mean COP and standard deviation are 1.24 and 0.13 , respectively. Note that 1.24 is significantely higher than the COP at 300 V reported by the French team at the ICCF12. The histogram below shows 14 cases in which the COPs are consistent with what was reported for 350 V.

Why I am using the quotation marks for the "excess heat? " Because I am aware of possible interpretational errors, both in Paris and in Boulder. It is better to be prudent than sorry. Additional verifications will follow. So far we are happy that similar experiments produced similar results.



It will be useful to invent labels for different projects. The French investigation we originally failed to replicate will be referred to as Paris-1 experiment. Our subsequent investigations, described in the unit #270, will be referred as Texas-1 and Colorado-1 experiments. Our French-American project, now in progress in Boulder, will be referred to as Colorado-2 experiment. I believe that project Paris-2 and Texas-2 will start after the end of the courent experiment. So far reality of excess heat in a setup similar to that in Paris-1 seems to be confirmed. But Colorado-2 results did not confirm that the COP at 350 V is between 1.3 and 1.4, as claimed in the Paris-1 experiments. The mean COP from five tests at 350 V was not significantly different from the main COP at 300 V.

My Internet messages (appended on 3/21/06):

In what follows I will show messages that I posted on the restricted Internet discussion list. The operational definition of the COP can be found in the appendix.

Message 1:

1) We have runs with the COP (coefficient of productivity) above 1.20 at voltages between 300 and 350 volts. But there were many traps on our path. Four days ago I was nearly certain that we are again not seeing excess heat. Here is one illustration. Two days ago we ended the first sequence of consistently large COPs (at least 10 runs). The next morning we worked for about 6 hours and every single COP was nearly one. Frustrated we started to think about all possible differences. Then we realized that the diameter of the W cathode was 2.4 mm yesterday and 3 mm this morning. With the 2.4 mm cathode we again had a sequence of consistently large COPs.

The essential thing is to create conditions under which the electric wattage and the electric voltage are not too different. For example, 350 volts and about 1 or 1.5 A. This happens when the cathode looks as a uniform yellow-orange cylinder and the tip of the cathode is nearly as yellow-bright as the sun. These details were supplied to us by Jean Louis Naudin who seem to be ahead of everybody in this game. According to Pierre, he has a setup that performs "on demand; in his laboratory." He turns the switch on excess heat starts coming, like after turning a bathroom heater. We are still very far from such comfortable situation. Perhaps Naudin will share some details about this device here.

2) Here is our protocol, more or less.

a) Our container is an ordinary two-liters beaker. The level of the K_2CO_3 electrolyte (0.2 M, as we had) is about 1.2 liters. The beaker is open and fresh hot water is added when the level fols to about 1.0 liters, or more often. There is no splashing at all (or very little, less than one gram for 50 grams evaporated. We do have splashing when power is too high at 300 or 350 W. Under such conditions the COPs are always close to 1.0. Under favorable conditions, on the other hands, we hear a steady sizzling roar. The surface of the electrolyte is surpassingly quite. We do not stir the liquid; intensive boiling takes place only between the electrodes, mostly near the very hot cathode. The thermometer, situated near the wall, shows the temperature of between 89 and 91 C.

b) Mizuno told me that the rate at which the voltage is increased progressively should be small. Here is how we arrive to favorable conditions:

aa) Apply 100 V for about 15 minutes.
bb) Apply 150 V for the next ~5 minutes
cc) Apply 200 V for the next ~15 min
dd) Apply 250 V for the next ~15 min
ee) Apply 300 V for about 60 min
ff) Apply 350 V and start measuring the COP (5 min per run)

Transitions from one voltage to another were also slow, typically in one or two minutes. At stage (bb) blue sparks become visible at the tip. At stage (cc) the entire cathode (initially about 20 mm below the ceramic tube) is orange-red. The inner diameter of the ceramic tube is larger than the cathode and we can push the cathode when what is left become ~5 mm or less. Allowing the cathode to become too short leads to large splashy ark-like booms.

We use distilled water but ordinary water is likely to be acceptable. At one point our beaker was broken and we used a plain glass container. The COP was 1.3 at 350 V. At present we are using a plastic container (the lower part of a large bottle in which the windshield wiper fluid is sold. It works very satisfactory.

What else is important? Our non-evaporative losses are between 66 W (in the now broken beaker) and 95 W in a wider glass container. The losses seems to be more or less proportional to the open area of the container. This indicates that what is lost via conductivity through the walls is only a small fraction of the total non-evaporative loss. This is confirmed by the fact that the plastic foam isolation of the wall does not result is a large reduction of the overall non-evaporative losses. The dependence of our non-evaporative losses, Pl, for our wrapped plastic container on the electric wattage, Pe was as follows:

Pe (W)	Pt (W)	
406	53	measured
688	73	measured
848	84	measured
260	30	extrapolated
200	20	extrapolated

Non-evaporative loses are, very approximately, are about 10% of the electric power. A good indication of the potential success is to see a very small change in current (preferably going down) when the voltage is changed from 200 to 250 Volts. There is a lot of what we do not understand but at least we know what conditions should be avoided. We suspect that occasional white "explosions" (producing strong splashes) are due to ignitions of hydrogen bubbles. It is important to make sure that hydrogen does not accumulate below the anti-splashing shields. Fountains of water were often seen escaping from the ceramic tube containing the tungsten cathode. The inner diameter of the ceramic tube should be 2 to 3 mm larger than the tungsten cathode. That allows the cathode to be cooled by the rising electrolyte. A teflon disk above the ceramic tube, mounted on the tungsten rod, stops the rising fountains.

3) The radius of the anode does not seem to be important; we used Pierre's anode (diameter of about 4.4 cm) and Richard's anode (diameter 8 cm) at 300 V and obtained very similar COPs, about 1.2 or so. Pierre's anode is platinized Ti while Richard's anode is platinized Nb.

4)The rate at which cathodes are consumed are low when favorable conditions (low input power) are found. We do not even start measuring the COP when the current is higher than about 1.8 A (at 300 V). We reduce the voltage, wait a little and hope for the best. Sometimes favorable conditions (described above) are found rapidly but most often one has to make several attempts before finding them. Results are very reproducible under favorable conditions only. Our protocol does not guarantee favorable conditions. But we now know how to recognize unfavorable conditions, more or less. The COP is nearly always one when we see a lot of white light light and a lot of splashing.

5) The length of the cathode, sticking out of the ceramic tube, should be about 2 cm, initially. Richard has a nice way of pushing the cathode rod down manually, when necessary.

6) Unfortunately, frustration has not been eliminated; we still cannot say that a Mizuno-type experiment can perform "on demand." Looking for a reliable protocol should be part of future efforts. We are counting on help from other experimentalists..

7) Data collected under favorable conditions are in agreement with what was reported by Fauvarque et al. We constructed a histogram of the COP distribution for the run performed at 300 and 350 V. So far it has 33 data "bricks." It shows 24 results with the COP between 1.2 and 1.4, 3 results with the COP between 1.4 and 1.4, 10 data points with the COP between 1 and 1.2, and one result with the COP of 0.81 I hope this description will be useful to many.

8) Another detail worth mentioning is that ordinary tungsten cathodes perform as well as those that have 2% of Th added. This is good news for those who might wish to detect nuclear particles. And to those who might think about possible health effects from consuming too much thorium. Tungsten we use is from the welding supply store; it costs about $50 to buy a box with 10 rods. The fact that 2.4 mm rods work while the 3 mm rods do not work is an indication that even thinner rods (or wires) might perform better. The local strength of the electric field (V/cm) increases rapidly when the diameter becomes smaller. A thin wire will perhaps produce good COP plasma at lower voltages.

Message 2:
Here is how a "watmeter" was calibrated yesterday in our ongoing Mizuno type experiment. We essentially repeated a procedure developed in CNAM in Paris. The electrolytic cell (producing typical glow discharge current) was connected in series with a resistor of about 100 ohms and with a constant-voltage power supply. The average current was, for example, 2 A, depending on the total voltage. The UNIGORE 390 instrument (that we wanted to calibrate) was measuring the electric energy (in W*h) received by the resistor. That resistor was immersed in a second beaker containing boiling water. The function of the electrolytic cell, connected in series was to produce the randomly fluctuating current. The amount of water evaporated, for example, in 20 minutes, was measured at the same time. Knowing that amount, and knowing the rate of non-evaporative losses (conduction and convection)we were able to

determine thermal energy generated during the same 20 minutes.

The difference between the thermal energy and the electric w*h better turned out to be 0.43%. Knowing the about 1% uncertainty associated with our determination of thermal losses we concluded that the electric energy measure with the instrument can be reliable at the level of about 1.5%. We are lucky that Pierre Clauzon, who developed the method, was with us, in Richard Slaugther's lab. We hope that the ongoing French-American cooperation will soon resolve the controversy that developed last summer. That controversy, by the way, was published in the form of two reports at the ICFF12. It is also described in the unit #270 at my CMNS website:

http://blake.montclair.edu/~kowalskil/cf/

Note that the calibration was performed under the worst possible conditions; both i(t) and v(t) were variable (while the total voltage on the power supply was constant). Is there any reason to doubt that the uncertainty of less than 2% (determined as above) cannot be trusted? Comments will be appreciated. The small portable Unigore 390 multimeter, by the way, costs about $1000, I was told.

P.S.
In reading my own message (shown below) I see something that should be specified. The thermal calibration of an electric energy measuring device is valid provided this device is not used in thermal measurements. That was not exactly true in our case. Let me elaborate on this. The thermal energy generated consists of two components, heat lost via evaporation and heat lost by conduction and convection. Only a scale is used to determine the first component, which is dominant. But the second component was determined by methods at the same time, one with Unigore 390 and another with other instruments. I do not have the numbers to report at this time. But the results were nearly the same. Pierre just reminded me that the very same instrument was calibrated many times in Paris and results were also very satisfactory. Let me add that current experiments are done with the open vessel. More about this will be written later.

Message 3:
1) Can it be that tiny droplets (primage in French) are responsible for the illusion of excess heat? During one experiment we placed two paper towels, of known weight, on the table next to our active container for exactly 2 minutes. Comparing the amount of water lost during that time with the tiny increase of the mass of the paper towel we concluded that no more than 2 +/- 1% of water was lost in the form of droplets that were large enough to hit the towels (smaller droplets evaporate in air).

In principle such tests should be perform during each experiment. But this was practically impossible. We plan to perform another test to address the same issue. What else is worth checking in anticipation of future criticism?

2) Here are five more data points for our histogram; all at 300 C.

COP=1.15, 1.19, 123, 1.19 and 1.21

3) We had only 5 points at 350 V (to stay away from possible troubles. The mean value is not significantly different from what one gets at 300 volts. But we do get the COP of unity at low voltages. This is a very strong argument that instruments are reliable.

4) About our tungsten -- in case somebody might be interested. It was manufactured by Osram Sylvania Inc., Towanda, Pennsylvania, 18848, USA.
The label on the box (purchased today for $43) is: 2 7033 275 53 3/32X7

Message 4:
Prompted by comments about tiny droplets, presumably escaping with the steam, we performed an additional experiment. It was our last test together; Pierre is returning to Paris tomorrow morning, Richard is going back to work tomorrow (after using 1/2 of his yearly three weeks of vacation) and I will start writing a unit about this "Colorado Project" for my CF website. As suggested by somebody on this list (sorry for not remembering the author), we took a very fine stainless-steel screen and covered the cell with it. The holes in our screen represented about 60% of the entire

surface, the rest were wires. Each rectangular hole was about 0.2 by 0.2 mm. This would allow the steam to escape but would probably stop most of the drops (both small and large).

The COPs, measured at 300 W, while the cell was ~90%-covered by the screen, turned out to be: 1.20, 1.26 and 1.46. These were more or less the same values as for the open cell. If the excess heat, measured with the open cell, was apparent (due to droplets escaping from the cell) then the COPs would be lowered significantly when the screen was used. But this did not happen. We concluded that the excess heat was not due to droplets. A similar comparison was made with the ohmic heater. The COPs turned out to be the same (1.0) with and without the screen. In the case of the ohmic heater ~95% of the surface was covered by the screen.

Message 5 (posted by M.J. from France)
"I have another concern: non-evap losses surely depend not only on the temperature but also on the convection speed, couldn't this speed be higher for some reason when calibrating with the ohmic heater than during the run, leading to overestimating non-evap losses occurring during the run, and therefore overestimating excess heat? " [That is a very good question. Paris-2 tests, now in progress, will probably provide the answer. The vessel used now is a thermos. The non-evaporative losses will probably be negligible. Will the COPs still be close to 1.24? We will see.]

Message 6:
1) In an earlier message I said the noise one hears from plasma, under favorable conditions, is "like from a machine gun." A more appropriate description is to say that it is like when something cold is placed on a large frying pan with very hot oil, for example, when frying an egg. That sizzling noise is not as regular as from a machine gun.

2) Reading messages posted today I was thinking about a branch of science called plasma physics. Most of us performing Mizuno type experiments are not event amateurs, as far as that discipline is concerned. Very sophisticated methods of plasma diagnostics have been developed in the last 50 years. Experts in plasma physics would have no trouble in the identification of the red-orange-sizzling-machine-gun-like plasma we were lucky to produce in the Colorado-2 tests. They probably have a short name for it. And they would have no trouble with creating a device generating excess heat on demand. The only person on our list familiar with plasma physics, as far as I know, is George Miley. I would like to know what he thinks about our Mizuno type experiments.

3) Yes, I know what many plasma physicists said about CF in the past. And I recall what Gene Mallove wrote about their selfish motivation. But we should be looking into the future, not into the past. It is silly that we are working in the darkness when powerful sources of light are available. How can we benefit from what is known to real plasma physicists? How can we find access to their sophisticated tools? How can we gain support from at least some of them?

Message 7:
Here is a little rough calculation worth sharing. In our typical 5 minutes test (input electric energy = 400 W * 0.0833 h = 33.3 Wh) the amount of excess heat is about 6.5 w*h (if the COP=1.2). This translates into $1.46*10^{23}$ eV. The estimated mass of tungsten lost during the same time is about 0.5 grams. That translates into $1.63*10^{21}$ atoms. Thus the excess heat per atom of tungsten seems to be close to 100 eV. That is about two orders of magnitude larger than what I associate with common fuels.

What happens to our spent tungsten? Part of it probably melts and then solidifies in the electrolyte. If so then pure tungsten must be found in the cell (in the deposits we see at the bottom, after some waiting). Suppose that 50 % melts and the rest combines with other atoms or ions. Not being a chemist I might be allowed to postulate that all possible chemical reactions are equivalent to one representative exothermic reaction. Suppose that our excess heat is due to that reaction. What would the Q value of the representative reaction be? It would be 178 eV. That is a lot !

The Q value would be two times larger if only 25 % of tungsten was used in chemical reactions while the rest was simply melted. This shows that Q increases when more tungsten is melted. At the other extreme the Q value would be 89 eV if nothing was melted (all consumed in exothermic chemical reactions). Even this number is unusually high. Did I make a wrong assumption, or a numerical mistake, somewhere?

I think it was Pierre (or was it Richard?) who suggested I make this kind of calculation. Fortunately, a possible 100% error (in the estimated loss of mass lost) would still support the conclusion -- the unusually high energy per atom of tungsten. In the future experiments cathodes should be weighted before and after individual tests. This would provide a more accurate result.

The "what if" fantasizing:

Let me assume, very optimistically that Scott Little, and other investigators, will confirm that excess heat is real. What should be done next to convince mainstream scientists that at least one so-called "cold fusion" phenomenon is worth studying? The answer is obvious -- it is to publish a good paper in a serious refereed journal. But editors of these journals are biased against cold fusion. They already know that our research is pesudo-science and do everything possible to block publications. How to overcome the bias of the editors? How to overcome the bias of the referees?

The first thing is to write the article very well; all possible objections should be anticipated and addressed. We should clearly state, in the introduction, that we have no evidence of nuclear origin of excess heat. The error made nearly 17 years ago should not be repeated. It is not difficult to imagine what would happen if Fleischmann and Pons did not speculate about chemically induced nuclear reactions. Instead of discussing theories scientists would focus on validity of experimental data. That would probably lead to subsequent confirmations and open the door for additional research to understand excess heat. Our paper should be strictly experimental and we should be honest about having no idea what causes the observed plasma anomaly. The term cold fusion should not even be mentioned.

We should also not rush toward publishing the paper. We should write and rewrite the draft, discuss is among the CMNS scientists and perform additional experiments, if necessary, to back our claim. Announcing the discovery too early was another big mistake of Flieschmann and Pons. It will probably take a year to check and double-check everything, and to collect supportive evidence from other researchers. We should publish consecutive paper drafts on the restricted discussion list for CMNS researchers. And we will ask them not to refer to our ongoing investigations. I am assuming that everybody on our list will respect our wishes. The paper should not be submitted before we have a setup which demonstrates excess heat in at least 75% experiments. That is why I think it might take another year before we are ready to publish the paper in a reputable journal. A journal should be carefully chosen to avoid editors who are likely to biased.

Appended on 3/22/06:
In a message sent to Richard this morning I wrote: "I think that the 'Fantasizing' part, in the unit #271, should be expanded. What will we do if Scott's results turn out to be negative? Please draft a paragraph about such eventuality. Then we will discuss it."

His reply was: "I think it is very unlikely that Scott's results will be negative. ..... But if they are then we must first assist him by phone, internet, photos and web video. If we could set up the web video I really believe we can walk him to positive results. We should also be prepared to send him our anodes and cathodes. Pierre's assembly has produced the best results. Could we get Pierre to build and test a second assembly and have it ready for Scott? It doesn't have to be identical but should use the same material and have the same size for the anode. Perhaps Pierre wants to build a new assembly and Scott could use the old one? I will also build and test a second assembly but my results so far have been smaller than Pierre's. If Scott still can not get positive results then one of us has to go to Texas and assist him in running the experiment. I would like to go but don't think it will be possible, I only have so much vacation time remaining. But I would be able to fly down for a three day weekend to assist. I think that we should discourage Scott from publishing negative results until we all agree that something was wrong with the French-1, Colorado-2, French-2 and Italian experiments. It would be best if we could discover exactly what was wrong before any publication. We want to avoid giving the field a black eye due to a defective experiment. It we can fix the experiment that would be ideal if not then we should post the negative results and our conclusion as to why the experiment is flawed. It might be best to just do this on your website and on the CMNS list as a discussion thread. CMNS members may have insight into fixing the experiment or challenge our conclusion."

Well, I think that Richard's strategy, about what to do if the Texas-2 results are negative, is correct. We will try to identify the cause of disagreement. But what if the cause is not found? How much time and effort should we invest

before publishing a paper describing the situation? Perhaps it would be better, at some later time, to submit two papers to the same journal, our and his. Let us hope that Scott's results will also show some excess heat.

Appendix:

Those who are not familiar with our jargon would probably appreciate if I explain what the COP (coefficient of productivity) is. Imagine a bathroom heater consuming electric energy at the constant rate of 1000 W and releasing heat at the constant rate of 1100 W. Such magic heater would have the COP=1.1; it would produce 10% more energy at the output (heat) than it received at the input (electricity). The term "magic" is used because, according to the low of conservation of energy, we expect a zero difference between the energy going in and the energy coming out. But suppose that such heater is invented. Would this be a device demonstrating that sometimes the energy is not conserved? Not at all. It would mean that some hidden source of energy exists and it is responsible for the unexpected excess heat.

The COP, in our setups, is simply the ratio of the electric energy received by the cell and the thermal energy released by it at the same time. Our COPs were calculated as Pt/Pe, where Pt is the average thermal power (rate of evaporative and non-evaporative losses of heat), while Pe is the average electric power (rate at which electric energy was used), both in watts. Note that hydrogen is produced in our experiments. That hydrogen is a fuel and burning it produces additional heat. The rate of hydrogen production is sufficiently law to neglect potentially useful chemical energy of hydrogen. The COPs would be only slightly larger than the Pt/Pe if generation of hydrogen were also taken under consideration.

272) Trying again to confirm reality of excess heat

Ludwik Kowalski; 2/24/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction

Those who read previous items (#252, #253. #267 and #270) are probably aware of the fact that two recent attempts to replicate a Mizuno-type results failed. This has been reported, and discussed, at the ICCFF12. Pierre Clauzon, and other people at the ICCF12 (including Mizuno himself), think that we failed to generate excess heat because our protocol did not allow for sufficient loading of Pd with hydrogen. That must be true; the details of the protocol used in Paris were not described in the paper of Fauvarque et al.. That reminded me an observation made by Jed Rothwell last Summer. Jed wrote:

"I think the NEDO fiasco bears an important lesson for both Scott Little and Kowalski: first-hand on-site consultation and training with experts is essential to a test of this nature. You must look over people's shoulders and use their instruments and thoroughly familiarize yourself with the experiment before attempting to do it yourself. In the future, we hope that cold fusion will become more of a science and less of a black art, and more people will be able to do the experiment from a printed recipe. . . The discrepancy between Mizuno's results and Little's are a mystery. I do not think progress toward resolving this mystery will be made until Little and Mizuno spend several weeks working together, perhaps using some of both sets of instruments. Mizuno reportedly has a great deal more space these days in his new lab, so it should be easier to work with him."

After the conference Pierre did invited me to work with him in Paris. We discussed this and decided that working together in Richard's laboratory, in Colorado, would be more desirable. Confirming realty of excess heat in another laboratory, using different instruments, would be more important than observing excess heat again in Paris. Pierre is going to work with us and the purpose of this unit is to describe the results. Jed is right; nothing is better than personal cooperation and working in each others laboratory.

A Mizuno-type experiment, especially when excess heat can be measured in terms of the amount of evaporated water, can be relatively simple and relatively inexpensive. I hope it could be used to produce excess heat on demand. Suppose that Richard and myself convince ourselves that excess heat can indeed be generated at the rate of 50 W or more, as reported at ICCF12. If this happens then independent investigators will
be needed. I hope that some readers of this list will become our partners. The goal would be to demonstrate that a nearly 100% reproducible setup can be built in any lab and used by any qualified researcher. Then, perhaps, something will change in the attitude of mainstream scientists toward excess heat. But we should not repeat the old mistake by saying, prematurely, that the effect is nuclear. In describing and demonstrating the "excess heat on demand" the scientific question will be "what produces the totally unexpected heat?"

That introduction was composed on 2/25/06. I do not know what the outcome of the new sets of experiments will be. But, as suggested by Perre, our results, either positive or negative, will be published. Publishing negative results, as I wrote in unit #281, is as important as publishing negative results, especially when there is a controversy. The cause of discrepancy must be found; it will be either a faulty procedure we followed last Fall or a systematic procedural error in Paris. I think that a line between what is positive and negative should be clearly defined before we begin experimenting. Pierre wrote that the COP in Paris, at 350 V, is between 1.35 and 1.40. On that basis I suggest that any

COP>1.20 should be considered a confirmation of the French result. Any COP below 1.20, on the other hand, should be considered a failure to confirm. But that is only the confirmation aspect of our work. Consistent presence of excess heat at the level of COP>1.10 should be considered a great step forward. It would mean that both teams must continue working to determine limits of accuracy (maximum possible systematic errors) and levels of precision (standard deviation of COP values).

I am not going to write anything else here till the end of March. For the time being this unit will sit on the desktop of my computer. The situation will probably be clear to all of us after one week of intensive work in Colorado.

Appended on 6/29/2009

1) Results of our work were presented at the ICCF12, in Yokohama, Japan, 2005 (15th International Conference on Cold Fusion). The report can be downloaded from

http://lenr-canr.org/acrobat/KowalskiLsearchingfa.pdf

2) As described in Unit 358, a systematic error in measuring electric power with this watt-meter, was found by Clauson and his colleagues. Their most resent results, as reported at ICCF13, are consistent with negligible excess heat in Mizuno-type experiments.

273) A note on microbial transmutation

Ludwik Kowalski (11/29/05)

Montclair State University, Montclair, New Jersey

One of the fields of CMNS (Condensed Matter Nuclear Science) is CT (Cold Transmutation). And microbial induced transmutation is a small part of that field. Last year, during the ICCF12 (12th International Conference on Cold Fusion), I heard about Ukrainian - Russian experiments in that subfield. They were conducted in a laboratory near Chernobyl. Scientists from the University of Kiev and university of Moscow were able to transmute radioactive cesium - ^{137}Cs - into nonradioactive products. Today I learned that more recent phenomena (in the same laboratory) confirmed the earlier report. Radioactive salt was dissolved in water and some kind of bacteria, highly resistant to radiation, were introduced into small (20 cc) flasks. One half of each sealed flask was filled with the solution while the other half was air.

Gamma rays emerging from the loaded flasks was observed for 100 days. During that time radioactivity was reduced, typically by 30%. The half-life of ^{137}Cs, the most troublesome fission product, is 30 years. With the help of bacteria, according to the A.A. Kornilova and V.I. Vysockii report, that material can be eliminated much faster than by natural radioactive decay. Destroying ^{137}Cs, and other radioactive fission products, would be a tremendous boost to nuclear electricity. The problem of storage of radioactive waste would be simplified greatly if Cs and Sr could be destroyed. According to the report, the reduction of radioactivity, measured by several large Ge detectors, could not be due to changes in the counting geometry caused by progressive redistribution of radioactivity. That was my first concern. They used several large detectors; the total solid angle was about 2*Pi.

After hearing the news I said that such important invention, if real, would be a solution of our energy dilemma. Here is how that dilemma was summarized by Dr. Akito Takahashi, the conference organizer, in the opening talk:

a) Energy is an essential component of social progress. Sustained development of the world depends on available energy.

b) Energy resources are limited. Supplies of oil will end in about 60 years. Solar energy (including wind) satisfy no more (?) than 10% of our needs. Fuel for reactors based on ^{235}U will be exhausted in about 50 years. Fuel for breeder reactors will be also be exhausted, sooner or later.

c) Pollution, and climatic changes associated with coal, are very real. Economic developments in China and India depend mostly on burning coal.

d) Industrial hot fusion reactors will not be available for at least another 50 years.

e) Clean fusion devices, in this situation, might be the only possible short-term solution of the worldwide problems associated with energy supplies.

Future of reactor technology, in my opinion, does depend not only on availability of fuel; it also depends on social attitude of toward radioactive waste. Make your technology known to general public, I said to Alla and Vladimir, and those in charge of technological development will beg you for help. Not only would you become rich; you would be recognized as benefactors of mankind.

They smiled. They said that authorities know about their published results and that their proposals have been blocked by those whose business depends on existing technologies. I said that a way to overcome such conspiracies can be found. To convince a potential investor an inventor should also demonstrate willingness to share risks. Suppose, I said, an inventor is offering to invest 50% of his savings into a business if the big investors puts one thousand times more. Those who are able to invest big money probably need assurances that the inventor is serious.

Another thing to do, if a working microbiologic solution to the problem of radioactive waste were at hands, would be address general public. That is where a help from a journalist would be very useful. In a democratic society public opinion can become an important factor influencing what does and what does not happen. Trying to find a journalist, interested in the invention, would be an important part of my strategy. Another part of that strategy would be have a constantly-working setup. Using ^{137}Cs radioactivity, for example, from dry mushrooms, I would start a new experiment every year (for example in a museum).

If only 70% of initial radioactivity remains in the flask after three months then the biological lifetime is about six months. This means that only 25% would remain after one year, only 6% after two years, only 0.4% after three years, etc. Fresh load of bacteria would probably have to be added each year. Such result would be very convincing. Personally I would not stop testing when only 30% of the initial radioactivity is destroyed. I would keep collecting data for two years before announcing the result. Monthly meetings to discuss the results would be organized and students from local schools, as well as scientists, would be invited. Internet summaries of results would be published periodically at my webste.

After listening to the draft of this note, and after correcting my wording in one or two places, Alla and Vladimir told me about their strategy. With help from experienced lawyers they have submitted a patent application in Russia and expect its approval early in 2006. Russian government, if I understood them correctly, will become the co-owner of the patent and will take a large fraction of potential royalties. In exchange for this the government will protect interests of inventors. Recent changes in the Russian patent law make such arrangements possible.

Neither Alla nor Vladimir are biologists; they are nuclear physicists. Alla works at the University of Moscow while Vladimir works at the university of Kiev. They do cooperate with qualified microbiologists. The biologists, however, are only technical advisers; they are not partners. In their position I would try to find a partner who is a recognized authority in the area of microbiology. With that person I would go to microbiologic conferences to address biologists, rather than physical scientists. A proposal from a recognized authority in the area of microbiology would likely to be taken more seriously (by potential investors) than a proposal from a cold fusion researcher. In the present unfortunate situation an association with cold fusion is likely to result in more harm than good. People living near Yucca Mountain, and in other areas where radioactive waste is going to be stored, would naturally become my supporters. With their help turning a working scientific solution into desirable technology would not be difficult. But I would not do anything before being 100% certain that the effect is real.

Appended on 12/1/05
Let me add what another CMNS researcher, Jean-Paul Biberian, told me about microbial induced transmutation. Jean-Paul's laboratory is at the French University in Marseilles. He also conducted research on Microbial transmutation and is totally convinced that the phenomenon is real. I asked Jean-Paul to briefly describe his own research on biologically induced transmutations. Here is his input:

"I conducted biological transmutation experiments with seeds (wheat and oat in a sealed container containing microbes: lacto basilius and sea bacteria). Chemical compositions of material from containers with bacteria and from containers without bacteria were found to be different. No changes were observed in the homogenized material from cells without bacteria. Material in cells with bacteria, also after being homogenized, was depleted of silicon and enriched of calcium. The possible explanation is a nuclear reaction Si + C --> Ca. The growth of wheat seeds was accompanied by the decrease in the concentration of heavy metals, such as mercury and lead. Changes by the factor of nine or more were not uncommon. The homogenized material was analyzed with the ICP-AES and ICP-MS instruments."

That is very interesting. The ICP-AES methods are used to perform elementary analysis while the ICP-MS methods are

used to perform isotopic analysis. Jean-Paul did not study isotopic ratios because the cost of analyzing mass spectra are too high.
Neither the university nor the French government support cold fusion research.

Appended on 12/2/05:
What I did not know, when the above was written, was that Kornilova and Vysockii are deeply involved in the issue project. The hard to believe, issue claims are described on the company website <http://www.iesiusa.com> also (see items #216, #226, #229 and #237 on this website). Yang and Chai were present at the conference but, unfortunately, they preferred not to talk about the issue project. They were listed as coauthors of a paper presented by Vysotskii. The title of the paper was "Observation and investigation of ^{4}He fusion and self-induced electric discharges in turbulent distilled light water." I did not notice any information about generation of ^{4}He. Presence of helium "substantially above the background," was detected via optical spectroscopy. But this happened only when ^{11}B was added to ultra-pure water circulating In the setup.

Helium is presumably produced when protons react with ^{11}B. The origin of these protons is not clear to me. The^{12}C compound nucleus was said to break into three alpha particles releasing 8.7 MeV of kinetic energy. Was the amount of ^{4}He produced consistent with excess heat? This question could not be answered because investigations are in progress. But the abstract of the paper contains this sentence: "Initial calorimetric measurements indicate a significant evolution of thermal energy along with the production of helium, as expected from the mass deficit of the reaction products."

The first author of the paper, by the way, is Koldamasov. Contrary to what I wrote in #216, that Russian researcher is not dead. In a private conversation Kornilova told me that he has some health problems. She insisted on making Kopldamasov the first author because he deserves it. Vysotskii talk followed an extremely interesting presentation made by S. Krivit. Steven was one of those who were invited to visit the company test side. As a journalist he was allowed to film the event. The film showed the apparatus being tested. It also showed Martin Fleischmann (and several other CMNS researchers) desiccating the experiment with Yang and his coworkers. Unfortunately, Steven said, the signed nondisclosure agreement does not allow him to share what else he saw and heard.

After listening to Krivit's presentation I asked about two other claims described at the company website -- generation of hydrogen and the electric generator at Norwood foundry (producing electricity at the rate of 12 MW while using it at the rate of 2 MW). Steven said that he has no permission to answer this question. At that point Yang made an interesting general comment. He said that he is not involved in commercial aspects of the project; his role is to promote technology. At the same time he made it clear that scientific work, as opposed to practical engineering, is being conducted in Russia. I was really surprised to learn that my friends Alla and Vladimir are deeply involved in that project.

Contrary to what I expected, Vysockii's talk was mostly about a "laser-like" electromagnetic radiation (X-rays and visible). The "laser-like" term, in my opinion, was not appropriate. Most people would probably think that "laser-like" means "coherent." But no evidence of coherence was presented. High intensity, and a narrow beam diameter do not make light "laser-like."

274) Washington Post on Fraud in Science

Ludwik Kowalski; 1/9/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
An interesting article on fraudulent science has been published yesterday in an American newspaper. What follows is the letter to the editor I emailed last night. It is followed by my own comments, and by appendix in which the content of the original paper, sent to me by Jed Rothwell is shown.

My letter to the editor:

Dear Editor:

Please publish the attached letter; it refers to the "Trials & Errors" (written, on 1/8/06) by Bettyann Holtzmann Kevles.

Thanks in advance,
Ludwik Kowalski

The content of the attached file:

Accusation without evidence

To the Editor:

In "Trials & Errors" (January 8) Bettyann Kevles points to real dangers in science. But to suggest, without any evidence, that cold fusion (CF) claims are fraudulent is inappropriate.

As a retired physics teacher, and a nuclear science researcher investigating the CF field for more than three years, I have found no evidence of a fraudulent claim. Nor have I found the field pseudoscientific. Scientific methodology of validation is evident in nearly all publications I have read; they are downloadable from <http://www.lenr-canr.org>. At three International CF conferences I witnessed numerous debates and saw no difference between these debates and those at other scientific gatherings. A lot of healthy criticism reflected honesty and dedication. The CF field is unfairly discriminated; but it is alive.

In my opinion, however, that field is still not science; it is only a very promising proto-science. To become science the field needs at least one truly reproducible effect -- an effect recognized by many qualified mainstream scientists. Unfortunately, due to numerous errors made when the discovery was announced in 1989, validating a cold fusion claim became much more difficult than in other areas. This letter is sent from Japan where I came (at my own expense) to assist a university scientist investigating a CF phenomenon. The quality of his research is just as high as in other projects I have worked on.

Ludwik Kowalski
Professor Emeritus
Montclair State University
Montclair, New Jersey.

A message from Jed Rothwell:
Jed is a long time observer of the cold fusion. Last morning he posted the content of the Washington Post article. In a subsequent message he suggested that some of us write letters to the editor with comments about the unfortunate Kevles' article. I am afraid that my input will not be published. It will probably be ignored, like two other, recently submitted letters to editors, one to The New York Times and another to Physics Today. The editors seem to follow a "party line" according to which cold fusion letters should be rejected. This is not limited to letters; it applies to scientific papers as well. Fortunately, the LENR-CANR library, managed by Jed, preserved several hundreds of papers. Future generations of real historians of science will thank him for this work.

My own additional comments:
I suspect that the author of the paper, Bettyann Kevles, was simply not aware that cold fusion is still alive, as I was, up to about 3.5 years ago. This is rather surprising for a Yale University lecturer whose research interests seem to be in area of history of research. She is certainly not alone among those who took premature rejection of curious cold fusion claims for granted and stopped paying attention to what was going on in that field.

But, apart from labeling cold fusion a fraud, some of her observations are valid. Motivation for fraud is very well described by Kevles. She is right that we should be aware of it. She is also correct in saying that fraudulent episodes are not going to hurt established areas of research, such as paleontology. But the situation is dramatically different in proto-science, like CMNS, struggling for recognition. In that case even a single case of fraud can deliver a devastating blow to the entire discipline. The consequences of such episode would be difficult to repair.

One kind of potential fraud was not mentioned in the article. It is possible use of honest research to support fraudulent manipulations of financial investments. Secrecy is not compatible with science. But it is compatible with business; financial officers are not obligated to reveal work in progress before soliciting investments. Responding to a request for clarification they may say, for example, that "nothing can be revealed to protect a patent application". Secrecy makes us vulnerable. What would the effect of a disaster, in the area of financial manipulation of proto-scientific claim, be? Would it destroy reputation of honest scientists whose work has nothing to do with the disaster? How would it affect reputation of scientists whose work was actually exploited by financial wheelers dealers? That is difficult to predict. I hope, perhaps naively, that such things will not happen.

But danger is real. The big question is how to protect the CMNS field from fool's gold sellers. Hope for the best, assume nothing, suspect everything and ask good questions? That sounds like a good advice. But not in an area protected by secrecy. The essence of science is its methodology of validation, and its openness. And even that is not enough, as far as an individual is concerned. One has to be trained to ask right questions, and to understand the answers. Dependence on recognized authorities, and on institutions, such national academies, national laboratories, etc. is also very important.

A fraudulent scandal whose probability is small, will happen, sooner or later. Fortunately, nothing of that kind surfaced in the nearly 17 years since the discovery of cold fusion was announced. But it can happen any day. This might kill the entire field, unless it is no longer proto-science. Unresolved controversies about CMNS should be resolved as soon as possible. In my opinion an injection of research founds, combined with an official rehabilitation, would be perfectly justified at this level of development. Even a very modest support, less than one percent of what is being spent on hot fusion, would be a big help. Major CMNS researchers are old; their knowledge and skills will not be available in another decade or so. Young scientists, on the other hand, will not commit themselves to a highly discriminated field. They know that research in a "forbidden area" could hurt them, even if their work is excellent. That is the tragedy of the present situation.

Appendix 1:

Trials & Errors: Barely a Drop of Fraud; Why It Shouldn't Taint Our View of Science
From the Washington Post, Jan. 8, 2006; page B03.
By Bettyann Holtzmann Kevles

Seldom in our history have fame, fortune or a heady mix of the two tempted so many people into committing fraud. The halls of Congress are reverberating with the jingle of hastily discarded donations as elected officials distance themselves from lobbyist Jack Abramoff. Onetime employees have not forgotten Enron, WorldCom and the giant compensation packages of failed CEOs.

No surprise, then, that South Korean biologist Hwang Woo Suk, the putative creator of Snuppy, the first cloned dog, should come to occupy the spotlight of suspicion. There is doubtless a sense of schadenfreude among people envious of -- and at the same time fearful of -- scientists whose work they only partially understand but nonetheless depend on. Some are even asking whether biomedical research can be trusted.

But the specter of a cloud of fraud hanging over the microscopes and telescopes of scientists around the world is largely imaginary. It is true that there have been some great scientific misdeeds in the past. Who can forget Piltdown Man , the manufactured fossil skull that puzzled anthropologists for decades? Or the claims of the discovery of cold fusion in 1989 at the University of Utah? But those examples are famous because they are so rare. And, as the South Korean stem cell case shows, the scientific process means that frauds are typically revealed before they harm anything but the reputations of the perpetrators themselves. The far greater risk is that they erode our faith in science. . . .

THE REST OF THE THE KEVLES' ARTICLE WILL BE ADDED WHEN PERMISSION IS GRANTED.

P.S. (1/20/06)
I do not know why neither Washington Post nor Dr. Kevles replied to my messages.

Appendix 2: Added on 1/26/06

What follows are comments on Kevles' article made by Edmund Storms. His letter to Yale Daily News (first item below) was published in that newspaper on 1/13/06. The second item is the letter to the editor of Yale Daily; it has not yiet been published, as far as I know. Ed gave me permission to post his message, as below.

= =

I AM WAITING TO MAKE SURE THAT ED HAS NO OBJECTION FOR POSTING HIS PIECES HERE.

Appendix 3: Added on 1/29/09

What follows is a message that Dr. Robert Bass posted at a restricted Internet list for the members of ICCMNS (International Society of Condensed Nuclear Matter Science). Replying to my request for permission Robert wrote: "A friend pointed out that there IS a Yale connection [Dr. Mitchell Swartz's collaborator Dr. Alex Frank IS a Yale Graduate] so I have made a couple of minor additions/correctionsand wish now to submit for publication the following REVISED version:"

= =

Professor Kevles rebuttal still shockingly misinformed!

The letter from Prof. Kevles published on Tuesday, January 17 remains shockingly replete with demonstrably false statements. As Nobel Laureate physicist Julian Schwinger pointed out at the time, the claims of Fleischmann & Pons (F&P) did NOT "contradict the known laws of physics" because "the circumstances of cold fusion are different" than the circumstances in which the theoretical predictions pertaining to conventional hot fusion were made, i.e. in a

rarified gaseous plasma wherein fusion reactions between two deuterons can be treated as a collision between two isolated particles in a vacuum, contrasted with a periodic lattice of deuterons embedded in a Palladium lattice.

On my website www.innoventek.com, in the Science sub-site, the reader can find Schwinger's 1990 ICCF1 paper, together with my 2005 MIT Colloquium slideshow containing references to my paper at ICCF4 (Dec. 6-9, 1993), based in part on pro-CF papers by Schwinger and by Nobel Laureate physicist Willis Lamb, which passes the "Rabinowitz Acid Test" in that my theory ("albeit crude" in Schwinger's words) predicts that an F&P experiment of electrolysis with Pd cathodes will produce aneutronic d+d fusion & excess heat in the case of heavy water but will fail with ordinary water, whereas both d fusion & p fusion will work in a Nickel cathode. It is not true that the Utah legislature made available $1 Million to F&P; the Utah "National Cold Fusion Institute" was directed by former GE electrochemist Dr. Fritz Will, who did achieve a reproducible protocol for producing radioactive tritium via deuterium fusion in an F&P type of experiment before giving up, though this more conventional reaction established that contrary to Establishment dogma Low Energy Nuclear Reactions (LENRs) are indeed possible.

Distinguished electrochemist John Bockris of Texas A&M not only replicated the F&P aneutronic excess heat but found massive amounts of the nuclear "ash" (helium-4) in a Pd cathode which had been quick-frozen in liquid nitrogen while producing heat. Similarly electrochemist Dr. Melvin Miles of the Naval Research Labs not only duplicated the F&P excess heat but measured the helium "ash" in sufficient amount to "explain" the heat. Other early F&P replicators included Dr. Dennis Cravens, Dr. Edmund Storms (of LANL), Dr. Michael McKubre (of SRI International) and Drs. Mitchell Swartz & Alex Frank (of www.theworld.com/~mica/cft.html).

As documented in the recent books of Beaudette and of Krivit, which Prof. Kevles has evidently not read, the most notorious "failures to replicate," in the cases of Caltech, MIT, and Harwell (UK) reflect negatively upon those famous institutions. The neophytes at Caltech evidently had not read the earlier papers of F&P because they neglected to check that their "loading" had passed beyond alpha phase into the known beta phase. At the MIT Fusion Plasma lab there was outright criminal "fraud on the public" in that a curve which oscillated around 10% excess heat was, prior to publication, artificially moved down to oscillate around zero excess heat! As Dr. Mike Melich demonstrated at ICCF4, after he had prevailed upon Harwell to release their raw data for his study, they had given up prematurely because they had actually achieved positive results in the form of bursts of excess power using heavy water, but nonesuch ever when using ordinary water (and had been receiving active cooperation from Fleischmann contrary to Prof. Kevles's falsehood that F&P had "persistently refused" to supply colleagues with more information).

To verify the utter incorrectness of the Establishment version of this historical episode, which Kevles irresponsibly parrots, the reader need only read the cited two books & visit the cited websites and also visit www.LENR-CANR.org and www.newenergytimes.com for overwhelming documentation. For justified sarcasm about all this from a Nobel Laureate, visit http://jcbmac.chem.brown.edu/baird/coldfusion/schwinger.html. Shortly before his death in 1993, this Nobel Laureate physics professor wrote: "…my first topic, cold fusion, has caused many eyebrows to raise. Cold fusion? Isn't all that nonsense dead and buried? How can anyone be so insane as to talk about this totally discredited subject?" Sadly, Dr. Robert W. Bass, Prof. of Physics & Astronomy, BYU (1971-81, retired), donquixote@innoventek.com [no connection with Yale, though Dr. A. Frank mentioned above is a Yale graduate]

==========

P.S. (1/30/06): I am going to send the URL of this item to Dr. Kevles and ask her to reply to our comments. If she does then I will be happy to append her input. I do not think that she will disagree with our attempts to open a path of reconciliation between CF researchers and mainstream scientists. She was simply not informed (and not interested) in what others wrote about CF after the first two or three years of great excitement. I was in the same situation up to about four years ago. She will probably be with us, after learning that we are not charlatans or con artists. Her input below will probably enrich this document.

Appendix 4: Added on ???

PLACE RESERVED FOR DR. KEVELS, IF SHE ALLOWS ME TO SHERE HER REPLY.

276) Bars of errors

Ludwik Kowalski; 2/3/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

About three days ago I posted the following message on the restricted list for CMNS researchers:

In reading it again I decided to add a short tutorial. How can a retired teacher resist an opportunity to share what he learned recently. First something well known then something that I was not aware of. I will use a Geiger counter as an illustration.

1) Suppose that the number of counts, from a single experiment, is N = 100. We then say that the expected distribution of N (if the experiment could be repeated many times) is Gaussian whose standard deviation is the sqr(100)=10. We can say, at the level of 68% confidence, that the true value is between 90 and 110 (mean plus or minus one sigma). And at the level of 90% confidence the true value is between 80 and 120 (mean plus or minus two sigmas).

2) But this approach is valid only when N are not too small. How to establish the range of values (bar of expected errors) corresponding to the 90% level of confidence when N is smaller than 10? By using the following table:

	90% confidence
0	0.00-2.44
1	0.11-4.36
2	0.53-5.91
3	1.10-7.42
4	1.47-8.00
5	1.84-9.99
6	2.21-11.47
7	3.56-12.53
8	3.96-13.99
9	4.36-15.30
10	5.50-16.50

If N=4 then we can say, "at the confidence level of 90%, the true value is between 1.47 and 8.00." Likewise, if N=9 then we can say, "at the confidence level of 90%, that the true value is between 4.36 and 15.30. That not exactly what we would say if the error bar range was +/- 2*sqr(N). For N=4, for example, the range of values would be 0 to 6 instead and not 1.47 to 8. For N=9, the range of values would be 3 to 15 and not 4.36 t0 15.30. The differences become less and less significant as N becomes larger. I did not penetrate the mathematical derivation but I accept the rule because I know that a Poisson distribution of random counts become practically indistinguishable from the symmetric Gaussian distribution for a large N. A similar table was constructed by statisticians for the 95% level of confidence, as shown below.

	95% confidence
0	0.00-3.09
1	0.05-5.14
2	0.36-6.72
3	0.82-8.25
4	1.37-9.76
5	1.84-11.26
6	2.21-12.75
7	2.58-13.81
8	2.94-15.29
9	4.36-16.77
10	4.75-17.82

I think that my illustration on how to use these two tables is correct. But I am not sure. Please correct me, if necessary. The document with mathematical derivations, from which these two tables were taken, begins as follows: "Revised

April 1998 by F. James (CERN); February 2000 by R. Cousins (UCLA); October 2001 and October 2003 by G. Cowan (RHUL)." The footnote of the first page states "CITATION: S. Eidelman et al., Physics Letters B592, 1 (2004) available on the PDG WWW pages (URL http://pdg.lbl.gov/) June 17, 2004, 10:56"

3) It should be obvious to most of you that I am addressing the issue of precision (random errors) and not the issue of accuracy (systematic errors). The issue of systematic errors has to do with the concept of reproducibility.

For small N the bar of error becomes larger above the plotted point than below the point. What about the way of establishing bars of errors when the background is subtracted. The estimated net result, R, is always calculated as

R = A - B

where A is the apparent value and B is the background value. For A=100 and B=36, for example, R=64. We want to say, for example, that, “at the confidence level of 95%, the true value is between x1 and x2.” How to calculate x1 and x2? The well known rule, when A and B are not too small, tells us x1 and x2 should differ from R by two standard deviations. In this illustration, x1=64-2*11.66 = 40.68 and x2=64+2*11.66 = 87.32. That is because the standard deviation of R is the square root of A+B.

But how should x1 and x2 be determined, for a chosen level of confidence, when A and B are very small numbers, for example, 9 and 4? I know that distributions of A and B, for small mean values, are Poissonian rather than Gaussian. But I do not know how to turn this into a practical rule for calculating x1 and x2.

277) A strange outburst of messages

Ludwik Kowalski; 2/7/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction:
What is the essence of the CF (cold fusion) controversy? It is not the excess heat per se; it is its nuclear origin. This topic surfaced in a recent outburst of messages that appeared on the restricted CMNS list. The first message was posted Jed Rothwell, the author of a book about cold fusion. That book, by the way, is downloadable (as a pdf file) from the library at < www.lenr-canr.org>.

Long time ago Jed gave me permission to quote anything he posts on the CMNS list. That is why only contributions from two of us are shown below. Others also contributed to the outburst but I am not going to ask them for permissions. On Jan 28, 2006, quoting the Desert News, newspaper at Salt Lake City,

2) Jed wrote:
. . . He [Jones] continues to do research on cold fusion, which he prefers to call metal-catalyzed fusion "to distinguish it from the claims" of former University of Utah chemistry professors B. Stanley Pons and Martin Fleischmann, "which we do not accept as verified. This is the first time I have been pleased to see someone attack cold fusion in the press. I would not want someone who supports cold fusion to be associated with Jones' views about 9/11. [Jones' views are described at:]

http://www.physics.byu.edu/research/energy/htm7.html

It does not surprise me that Jones reached this conclusion. The 9/11 disaster has been investigated in more depth, by more experts, than any other disaster in history. Their findings are based on massive, irrefutable evidence grounded in basic physics and engineering. The same is true of cold fusion, of course. Cold fusion is actually even more solid, because it has been independently reproduced in hundreds of laboratories with full instrumentation, whereas the 9/11 building collapse only happened two times, and will never be reproduced full-scale again. It takes a special kind of imagination to ignore the scientific method and to deny the reality of overwhelming physical evidence.

3) In another message (Feb. 4, 2006) Jed wrote:
Steve Jones has often gone on record claiming that all excess heat results in cold fusion are wrong. See, for example:

http://www.lenr-canr.org/acrobat/JonesSEchasingano.pdf

He often claims that all heat is caused by recombination. Several people, including me, have asked him how this can be true with closed cells such as McKubre's. As far as I know he has never answered this question.

4) In another message Jed wrote (in part):
Steve Jones has often gone on record claiming that all excess heat results
in cold fusion are wrong. See, for example:

http://www.lenr-canr.org/acrobat/JonesSEchasingano.pdf

That was one example. There are many others in his papers and e-mail messages. His claims that recombination can

explain McKubre's results, for example, are elsewhere. He refers to x-ray film as "crude." There are two problems with that: It is not a bit crude. It is completely reliable and very sensitive. It is all that most researchers can afford, as the Russians pointed out at ICCF12. Jones has campaigned and pulled strings to prevent funding for CF, reducing researcher to shoestring budgets. Then he has the chutzpah to say the results are not good because the budget is too small! You have to know the background. He wrote: "It is disquieting that some researchers select open electrolytic cells over closed cells, and excessively long sampling intervals (e.g., 5-minute sampling intervals for input voltage used by Pons and Fleischmann in calculating excess heat over a 10-minute boiling period [3])."

This is outrageous nonsense, but Jones has repeated it ad nauseam. He has taken one measurement out of context, ignored all the other measurements and instruments including oscilloscopes, and ignored the implications of this particular measurement, and the fact that it was repeated 64 times in each run, and the runs were repeated many times. A 10-minute boiling period repeated several hundred times adds up to a large number of data points. Plus later boiling runs lasted for weeks, not 10 minutes. Fleischmann himself showed Jones the oscilloscope data at a conference, in person, while lecturing in front of dozens of people, but Jones will never admit that or discuss it.

This is not a controversy. Jones has a right to his opinions, and I have no problem uploading his papers to LENR-CANR.org. He categorically denies that any cold fusion experiment anywhere has ever produced excess heat. He has told me that many times, in person, and he has written it. Many other people such as Taubes and Park agree with him. I am not accusing him of anything; I am merely reporting his opinions. He may not wish to emphasize them here, but he has never hidden them as far as I know. I assume he is sincere. He honestly believes there is no heat, just as he honestly believes the Twin Towers disaster was caused by explosives, not airplanes. To paraphrase Chesterton, when a man stops believing experimentally proven facts, he doesn't then believe in nothing, he believes anything.

. . . There is no question about the origin [of excess heat]. Many cells are closed, and others are gas loaded, so recombination is ruled out. No cold fusion cell has ever had any significant amount of chemical fuel, and no chemical ash has ever been found, so chemical heat is ruled out. Hundreds of cells have produced tritium, x-rays, helium, and transmutations, so obviously a nuclear reaction is occurring. The only possible explanation for the excess heat is that it comes from an aneutronic (or nearly aneutronic) nuclear reaction. Any other explanation is out of the question, absurd and illogical..... ”

5) In another message Jed wrote:
I wrote: “Jones has campaigned and pulled strings to prevent funding for CF, reducing researcher to shoestring budgets. Then he has the chutzpah to say the results are not good because the budget is too small! “ I should explain what I mean, for the benefit of people who do not closely follow the dismal & petty inside story of cold fusion politics. The views of Jones and his allies dominate the DoE 2004 review --

http://lenr-canr.org/acrobat/DOEreportofth.pdf

where it says: "A second area of investigation is the use of state-of-the-art apparatus and techniques to search for fusion events in thin deuterated foils. Several reviewers specifically stated that more experiments similar in nature to those that have been carried out for the past fifteen years are unlikely to advance knowledge in this area." In plain English, this means: Stop looking at excess heat! No more calorimetry! Let us do Jones' style experiments looking for particles, and let us pretend that Sigma 90 excess heat is marginal, or better yet it never happened."

Also: "The current reviewers identified a number of basic science research areas that could be helpful in resolving some of the controversies in the field, two of which were: 1) material science aspects of deuterated metals using modern characterization techniques, and 2) the study of particles reportedly emitted from deuterated foils using state-of-the-art apparatus and methods..... " Translation: Heat is not controversial; it simply does not exist. And oh by the way, if Melvin Miles asks us for funding to find it again, we will blow him away. See:

http://www.lenr-canr.org/acrobat/LENRCANRthedoelies.pdf

You have to read between the lines a little. It helps to know the players.

(6) Ludwik wrote: (referring only to what he underlined in Jed's message)

a) The sensitivity of an X-ray film is not as good as that of a photo-multiplier; some P.M. tubes can be used to count single photons.

b) A film can only tall us that some radiation, able to produce latent image, was present. All by itself a film does not tell us anything about the kind of radiation. A darkness on a film exposed to beta particles, for example, is not at all distinguishable from the darkness due to X-rays, gamma rays, visible light, neutrons, protons etc. Neither does a film provide information about the energy of particles or photons (except when filters are used).

c) There are instruments that provide more information about radiation. That is why I tend to agree that, in some cases, films are crude detectors.

d) X-ray films recording cumulative darkening should not be confused with thick nuclear emulsions, or other track detectors.

e) For many purposes X-ray films are highly appropriate. That is why a statement about them ("crude" versus "completely reliable") may or may not be correct. I would prefer to discuss such statements in the context of information needed in particular experiments.

f) Do not forget that radioactivity was discovered by Becquerel by using crude photographic films.

g) Suppose an x-ray film, wrapped in dark paper, is applied to a Pd cathode, after it was used to generate excess heat. Suppose that darkness is observed at some locations. That would be a strong indication that parts of the film were exposed to some kind of radiation. Dark paper is a filter and visible light can be excluded, unless it was somehow produced inside the dark paper envelope. Very soft particles can also be ruled out. What is left? X-rays, gamma rays, neutrons and particles able to traverse the paper.

h) Normally initial observations would be followed by repeating the experiment and by using different kinds of detectors. But such luxury does not exist in our field. Nothing serious can be done unless experiments become reproducible.

(7) Jed replied:
You can learn a lot more from film than most people realize. Some of the Italian ENEA papers describing x-ray film findings have described the radiation in great detail, using computer modeling, based on things like the shadow of the anode and its diffraction." The people at BARC who made the image shown here:

http://www.lenr-canr.org/Experiments.htm#AutoradiographsMSrinivasan

also used sophisticated detectors on this and other samples. And they made about 100 images of this sample over a year, which can be compared to learn more. They took elaborate precautions to exclude the effects of light or chemistry. The Italians have also use film plus other instrument types. .....The experiments were reproducible enough to do these studies back in 1990. . . .

8) Ludwik's message:
Jed Rothwell wrote: "The only possible explanation for the excess heat is that it comes from an aneutronic (or nearly aneutronic) nuclear reaction. Any other explanation is out of the question, absurd and illogical." Why do you exclude a possibility that the excess heat is due to a form of energy that is not yet recognized (neither chemical not nuclear). The only convincing evidence of nuclear origin is compatible amount of new elements and new isotopes. . . .

9) Jed asked:
Do you mean something like ZPE or the Mills hypothesis? I concede they are remote possibilities, but I think they are ruled out by the nuclear effects. I know little about theory, but I gather Mills is generally considered impossible. . . . That would be nuclear fusion, right? What is your point?

10) Ludwik:
No, I did not mean ZPE (zero point energy) or the Mills hypothesis. I was simply saying that, by definition, nuclear energy is energy released when a nuclear transformation takes place. A nuclear transformation is a process in which new isotopes or new isobars are created. Such isotopes and isobars, by the way, are usually called "nuclear ash." By accepting such restricted definition one should agree that the only convincing argument for the nuclear origin of excess heat is production of new elements or new isotopic ratios.

Why is this definition restricted? Because gamma decays are also nuclear processes. And we know that neither Z (number of protons) nor N (number of neutrons) changes in gamma decays. Most often gamma decays follow nuclear processes in which either Z or N (or both) change, as in beta decay or alpha decay. That is why I think that generation of excess energy of nuclear origin must produce a corresponding amount of "nuclear ash."

The confirmed evidence of that kind, as far as I know, is accumulation of 4He releasing ~23 MeV of heat per atom. It was reported by several researchers in several countries. Such accumulation can be logically explained by the D-D fusion facilitated
by some kind of screening (lowering of the effective coulomb barrier in condensed matter). Yes, the 2D+2D --> 4He reaction is not-neutronic, not-protonic and not-alphonic. Yes, 4He is a new isotope and its accumulation, at the rate consistent with the rate at which excess heat is generated, is a very convincing argument. I used this reaction as an illustrative example. Other nuclear processes have been mentioned at our CMNS conferences. In my opinion the next "official" investigation of CF should be focused on generation of 4He from 2D. That is the strongest existing argument for the nuclear origin of excess heat.

P.S.
11) Ludwik, after reading replies from several people:
It was interesting to read what others think about the 9/11/02 tragedy, or about the ongoing war, etc. But such topics are not related to the purpose of our CMNS list. What I would prefer to hear from those who participated in this thread were comments on my statement. Let me repeat it again: **If nuclear reactions are defined as processes in which "nuclear ashes" are produced then the most convincing arguments, for the nuclear origin of excess heat, are demonstrations showing presence of "nuclear ashes."**

(a) Do you people agree that accumulation of helium at the rate of one atom per ~23 MeV of excess heat is our best argument so far? Accumulation of 4He was reported many times, by many people, in many labs. (b) "Excess heat without nuclear ashes" would be a clear indication that something else (not nuclear reactions) is responsible for excess heat. Do you agree?

12) Jed:
You wrote: “Do you people agree that accumulation of helium at the rate of one atom per ~23 MeV of excess heat is our best argument so far? Accumulation of 4He was reported many times, by many people, in many labs.” I quibble with this. Measuring helium is difficult, and only a few researchers have the equipment needed to do a convincing job. The "best argument" is a somewhat nebulous concept, and partly a matter of taste. You might argue that tritium or x-rays are the best proof that cold fusion is nuclear. (Or, at least, that it must have a nuclear component.) Some cold fusion reactions do not produce measurable amounts of tritium. But because tritium is radioactive, it is much easier to detect than helium, and because it sometimes appears in massive quantities no one can deny it is there.

I expect that all cold fusion reactions produce helium, but that is impossible to confirm, because measuring helium is difficult and because many experimental setups preclude the possibility of measuring it. In other words, I vote for evidence which is strong and convincing, rather than always present. Evidently, cold fusion is complicated and the reaction products vary -- sometimes it makes tritium, and sometimes it does not. When tritium is present and you record something like the autoradiograph from BARC, I would say that is the best proof. See:

http://lenr-canr.org/Experiments.htm#AutoradiographsMSrinivasan

2) You wrote "Excess heat without nuclear ashes would be a clear indication that something else (not nuclear

reactions) is responsible for excess heat. Do you agree?" How can you be sure there are no nuclear ashes? It is easy to confirm there is no commensurate chemical ash is easy, because it would have to be present in macroscopic amounts. But trying to prove there is not 1 ppm of extra helium sounds like an exercise in futility.

Cold fusion might be a nuclear effect plus something else. Perhaps the tritium is only a side effect of Mills' shrinking atoms, or what-have-you. But whatever else it may be, it also affects the nucleus, and transmutes elements. We can be absolutely sure it is not a chemical reaction, or recombination, or a mistake. That is decisively ruled out. At present that is all we can be sure of. If a theory emerges that can be experimentally tested and proved, then we will know what sort of nuclear effect cold fusion is. Until then we must live with a degree of uncertainty.

13) Ludwik:
You wrote: "Measuring helium is difficult, and only a few researchers have the equipment needed to do a convincing job. The "best argument" is a somewhat nebulous concept, and partly a matter of taste. You might argue that tritium or x-rays are the best proof that cold fusion is nuclear. (Or, at least, that it must have a nuclear component.) Some cold fusion reactions do not produce measurable amounts of tritium. But because tritium is radioactive, it is much easier to detect than helium, and because it sometimes appears in massive quantities no one can deny it is there."

Tritium, 3H, is a nuclear ash and Jed is correct that it is easier to measure, even in very small amounts, than 4He. I am aware of several reports on generation of 4He at the rate close to one atom per 23 MeV of excess heat. But I was not aware of similar reports about 3H. On the contrary, several people emphasized that the rates of accumulation of 3H are always many orders of magnitude smaller that what would be consistent with the D(d,p)3H reaction producing excess heat. Here is a numerical illustration.

The Q of the D(d,p)3H reaction is about 4 MeV. But only 50% of D+D fusion events generates 3H. So on the average we expect 2 MeV of excess heat per fusion. Suppose that 1,000,000 fusion events take place in each second. The corresponding rate of generation of excess heat would be 2,000,000 MeV per second. Knowing that 1 MeV is the same as 1.6*10^-13 J we translate this into 0.32 micro-watts. Suppose the excess heat is generated at the rate that is one million times larger (0.32 watts). That would produce 3H at the rate of 10^12 atoms per second. If the experiment lasts about 3 hours (10000 seconds) then the number of 3H atoms produced would be N=10^16. For that amount of nuclear ash the activity would be 17.8 billion beta particles per second. Jed is correct, " tritium is radioactive, it is much easier to detect than helium." But, as far as I know, those who reported reproducible excess heat never observed such levels of 3H radioactivity. That is why I still think that the best argument for the nuclear origin of excess heat is accumulation of helium at the expected rate.

You also wrote ". . . How can you be sure there are no nuclear ashes? It is easy to confirm there is no commensurate chemical ash is easy, because it would have to be present in macroscopic amounts. But trying to prove there is not 1 ppm of extra helium sounds like an exercise in futility." But is it not true that accumulation of 4He, at expected rates, has been reported by several CMNS researchers?

We should not confuse two very different kinds of claims: (a) Nuclear signatures -- tritium, neutrons, protons, alpha particles, gamma rays, and (above all) abnormal isotopic ratios -- have been reported by CMNS researchers. (b) CMNS researchers presented evidence for nuclear origin of excess heat.

14) Jed:
You wrote: "But is it not true that accumulation of 4He, at expected rates, has been reported by several CMNS researchers? " Not that many, but some have been convincing. The ones I recall include Miles, Bush, McKubre (especially with the Case cell), and several researchers at ENEA Frascati. Some researchers have reported helium-4, but they have not tried to correlate it with heat. I think Chein (1992) is an example.

You also wrote: "We should not confuse two very different kinds of claims: (a) Nuclear signatures -- tritium, neutrons, protons, alpha particles, gamma rays, and (above all) abnormal isotopic ratios -- have been reported by CMNS researchers. (b) CMNS researchers presented evidence for nuclear origin of excess heat."

This strikes me as a false distinction, or one that serves no purpose. There is no telling which type of evidence will be

more valuable to a theoretician, and there is no telling which is actually "better" or "the primary origin of the nuclear events." Perhaps there is no primary origin, and many different reactions produce heat. Suppose someday a theoretician looks at the tritium and the heavy-element transmutations in Iwamura's cells, and suddenly this theoretician sees how these two apparently disparate products fit together in one picture, and how a single underlying reaction produces tritium in one situation and Mo in another. Extreme or "outlier" effects are sometimes more useful to establish a theory than more common effects. Helium may be produced by every CF reaction, whereas Mo production only occurs in special circumstances, but the Mo may still tell us something that helium does not.

Furthermore, even if helium does always occur, the Mo transmutation may not be a "side effect" in any sense. Yes, perhaps it is a side-effect caused by particles from the primary helium-generating reaction. Then again, perhaps it is the primary CF reaction in this case, and no helium is involved. We do not know yet. Iwamura is not able to measure helium, as far as I know. Tritium is also impossible to judge at this stage. It may be that reactions on some areas of the cathode produce tritium but not helium. Perhaps both of these reactions also produce heat (at different rates). Both are nuclear signatures, and for all we know both may be the nuclear origin of excess heat. In other words, this question may be like asking: "In a pile of burning tarpaper and firewood that produces black and white smoke, you have two different combustion reactions occurring, with different products. Which of these two reactions is producing the excess heat? Which points to the origin of combustion?"

15)Jed:
There is one nuclear signature which probably is ether secondary or completely unrelated to cold fusion: neutrons. Ed Storms and others have speculated that the neutrons observed in CF experiments may be produced by very low level conventional reactions such as fracto-fusion. I think Ed believes Taleyarkhan's sonofusion effect is also probably a form of plasma fusion with no connection to CF. Perhaps the neutrons from Ti reported by Jones et al. are also caused by low level hot fusion, and cannot help us discover the origin of heat producing CF reactions. See:

http://lenr-canr.org/acrobat/JonesSEneutronemi.pdf

In other words, it isn't that CF reactions produce anomalously low levels of neutrons; actually they produce no neutrons all, and a few neutrons have been caused by coincidental hot fusion. This seems intuitively likely to me. I have never understood why neutron production would be reduced by 11 orders of magnitude but not 12 or 15 or 20 orders. Why would there be just enough neutrons left to detect in some cases? If the cold fusion reaction can combine deuterium without emitting a neutron, why would it fail to do that once in 1E11 cases, and suddenly "revert" to a hot fusion path? (Of course the notion of "reverting" is silly. It refers to the fact that people discovered hot fusion first. It is not as if the cold fusion reaction learn how to generate itself in 1989, and from time to time it forgets that it is not hot fusion.) Given all the attention paid to neutrons in the early days of the research, it would be ironic if this turned out to be the case.

Ludwik, 2/9/06
. . . I guess I know what XX has on mind. But I am not sure. He is certainly correct that all ideas are worth exploring. I would like to hear from people who did study generation of 4He associated with excess heat. Do they agree with the suggestion than the most convincing argument in favor of "nuclear origin of excess heat" is generation of 4He at the rate of several MeV per atom? It does not have to be exactly 23.67 MeV, considering the difficulties mentioned by YY. The curves I have seen did have large error bars. But they displayed many experimental data points. The trends were compatible with the expected Q value of the pure D+D-->4He. Is this still a correct observation? I would also like to know if the accumulation rate of 3H (tritium) has ever been reported as compatible with at least one mW of excess heat. If the rate of tritium generation is compatible (even within one order of magnitude) with the rate of producing excess heat then Jed is correct that production of 3H should be a more convincing argument (for the nuclear origin of excess heat) than accumulation of 4He. Small quantities of 3H are certainly much easier to measure than comparable quantities of 4He.

Jed's reply:
This [adjective “non-chemical”] makes no sense to me. Obviously, cold fusion is a nuclear effect! It changes the nucleus. It produces tritium, helium and heavy element transmutations. That makes a nuclear by definition. Perhaps it is a combination of fission and fusion, but it definitely is nuclear, as anyone can see. Why try to hide that fact by

changing the name? Calling in "non-chemical" is a kind of euphemism. A euphemism is a substitute word intended to cover up some embarrassing or awkward reality. . . .

Ludwik:
Once again I want to emphasize that the two issues: (a) “nuclear origin of excess heat” and (b) “cold fusion is a nuclear effect,” should not be confused. In this thread I am focusing on (a), not on (b). What is our best evidence that at least one kind of excess heat has nuclear origin? For the time being I still think that it is the D+D-->4He fusion (at the rate of several MeV per 4He atom). But I want to hear from those who performed D+D-->4He experiments. Why don't they defend their reports on this list? Neither Jed (?) nor myself have experience with that kind of work. My position is based on several reports, not just one.

Jed:
The best evidence is that the heat exceeds the limits of chemistry by many orders of magnitude. When Fleischmann and Pons saw this they knew they were seeing a nuclear reaction, not a chemical reaction. Even though we do not know the exact nature of the nuclear reaction, we can be certain it is nuclear. I am, of course, assuming that only three sources of heat exist: (1) Mechanical, (2). Chemical and (3) Nuclear.

I do not understand what you mean by, "at least one kind of excess heat." I assume there is only one kind of excess heat, and it must be nuclear. Perhaps there are some varieties or different paths of nuclear reactions, but as I said in my analogy to combustion, they are fundamentally the same.

Not only does the heat prove beyond doubt that cold fusion is a nuclear effect, it is also, as Fleischmann says, the "principal signature of the reaction." That is to say it is the most prominent, the easiest to detect, and the most certain proof that the reaction is nuclear. As a general rule, if you do not detect heat, you cannot be sure a cold fusion reaction is occurring. You should confirm the heat before you begin to look for helium and other nuclear products. Otherwise you may be fishing in a dry hole. The only exceptions to this rule so far has been the Claytor and Iwamura experiments. The signatures in these experiments are tritium and transmutations, respectively, but I assume the reactions also produce excess heat. However, the heat it too small to be detected, and their instruments preclude calorimetry in any case.

Ludwik:
That explains our disagreement. Nature, however, is more complex. Two days ago ZZ promised to contribute to this thread. I am probably not the only person interested in what he is going to say about the nuclear origin of excess heat. Contributions from other experienced researchers will probably also be appreciated by many on this list.

Jed:
I hesitate to ask, but what other sources are there? Energy comes in several different forms, such as heat and electricity, but as far as I know it only originates from these three sources. "Chemical" is shorthand for anything that affects only electrons and molecules, not the nucleus. "Nuclear" would include fission, fusion and falling into a black hole I suppose.

Ludwik:
Heat can be produced by slowing down electric charges, by moving magnets or electromagnets, by annihilating antimatter, etc. Even sound can produce heat in a wall, usually very little. Radio waves also produce small amount of heat, even in our bodies (but much more in a frankfurter placed in microwave ovens). The E=m*c^2 is not limited to nuclear reactions. Other forms of energy will probably be invented to explain things to be discovered. Energy is not a simple concept. I was thinking about this recently, but not in the context of CMNS.

Ludwik (not posted):
A well known CMNS researcher, who commented on this thread, summarized difficulties associated with helium work. That researcher thinks that although accumulation of 4He is a strong argument (for the nuclear origin of excess heat), the accumulation of 3He, resulting from the decay of 3H, in the Arata/Zhang experiment, is even more convincing. I already wrote about Arata's experiment in item #23. But I do not recall that the amount of 3He detected was said to be consistent with the amount of the excess heat produced. Perhaps this was reported in a paper that I have

not seen. The Arata and Zhang 1999 report on 4He, entitled “Anomalous production of gaseous 4He at the inside of “DS-cathode” during D2O-electrolysis” is downloadable from the library at <www.lenr-canr.org>.

My conviction that the accumulation of 4He is the most convincing argument (in favor of the nuclear origin of excess heat) was based, mostly, on experimental results summarized by P. Hagelstein et al. in a 2004. Their report entitled "New Physical Effects in Metal Deuterides," can be downloaded from the library at <www.lenr-canr.org>. The report was written for scientists selected by the DOE to investigate the CMNS field. To my taste, experiments performed by several teams of scientists, from different labs, are more convincing than experiments performed in one laboratory.

Ludwik: (blue is from Jed, green is him quoting me, black is from me now.)
On Feb. 11, 2006, at 3:03 PM, Jed Rothwell wrote:
>Ludwik Kowalski writes:
>> Heat can be produced by slowing down electric charges . . .
>That falls in the "chemical" category. (That is awkward.
>Perhaps I should call it "electron level reaction.")
I was thinking about radiation, such as light or X rays, that can then be absorbed producing heat.

>> . . . by moving magnets or electromagnets
> Mechanical movement changes electrons.
I was thinking about a copper tube being heated when a magnet is falling down inside of it. An identical nonmagnetic cylinder (same shape and size) does not generate heat. unless there is also some mechanical friction.

>>by annihilating antimatter, etc.
>I forgot about that antimatter. It is nuclear; it affect the nucleus. It annihilates the nucleus.
I was thinking about annihilation of an electron and a positron only. No nuclei are involved.

>>Even sound can produce heat in a wall, usually very little.
>Sound is mechanical. It is motion that does not involve changing molecules or
> electron states. (Intense sound can break molecules, but that's another story.)
Yes, sound is a mechanical motion. The energy moves along the direction of propagation but individual molecules oscillate about equilibrium positions, for example, inside a wall.

>>The E=m*c^2 is not limited to nuclear reactions.
> Right. Every energy release, including mechanical energy, involves
> a mass-energy conversion. When you wind up a spring the mass
> increases by a tiny amount, much too small to detect.
Yes again.

>Other forms of energy will probably be invented to explain things to be discovered.
> I was listing sources of energy, not forms. The form of energy released by CF is heat.
> We already know that. Perhaps RF and other forms are also released.
OK, I should have said "other forms of energy convertible to heat"

Jed, I think we now understand each other. I am glad that X shared his personal preference. I did fetch the 2004 review paper he mentioned (Hagelstein et al.). In reading it I see that generation of 4He was presented (to the DOE) as the most convincing argument for the nuclear origin of excess heat. Arata and Zhang experiment on "massive" production of 3He, resulting from 3H, is not mentioned in that paper. Do you know where I can learn what the word "massive" stands for? Does it mean at least one 3H for each MeV of excess heat? I hope so. That would indeed be a very convincing argument. The half-life of 3H is about 12 years. Only a very small fraction of that ash would be turned into 3He during a time interval shorter than one year. I am sure that the authors took this fact under consideration.

As far as 4He is concerned, I find Figure 6 on page 8 (in Hagelstein et al.) to be extremely powerful. It shows that 4He is accumulated at the rate of one atom per 31 +/- 13 MeV of excess heat. The uncertainty of 13 MeV probably corresponds to difficulties mentioned by Mike. The expected value, 23.67 MeV is inside of the error bar. I suspect that

my opinion about "the most convincing argument" was solidified when I read the 2004 review for the first time. A subsequent conversation with Russ George also played an important role. He showed me that the measured relative concentration of 4He exceeded what is normally found in the atmosphere. I am surprised that he decided not to participate in this discussion. What I say, and what you say, is much less important than what the authors of reports say. They know all the details and difficulties; we do not.

P.S. (replying to ZY)
If experimentally observed excess heat has nuclear origin then nuclear ashes of some kind must be generated, in the corresponding amounts. Where are the ashes? This question has been asked as early as 1989, as illustrated in Peter's 1992 report. The 2004 answer to that question can be found in the report to which ZX referred earlier today. As stated above, that answer seems to be "production of 4He -- in some excess heat setups." Is this still a correct answer? Do we already have something more convincing today? That is what I am trying to find out.

P.P.S. (not posted)**:**
I just read the 2004 report (Hagelstein et al.) again. Reality of excess heat, in setups similar to those of Fleischmann and Pond, is discussed first, its origin is discussed in the following section. The title of that section is "Helium and Excess Heat." About 20 references to original reports are given. Here is the ending of that section; it is a comment on the experimentally determined rate of 4He accumulation, approximately one atom per 24 MeV of excess heat.

". . . This value remains the most accurately determined in this field (in the sense that contributions from both the gas stream and the metal are included), but it suffers from the criticisms that the numbers of samples were few, and the largest value of 4He measured was less than 50% of that in air. We note that 4He has been produced numerous times in excess heat experiments at levels above that of the concentration in air. One example is shown in Figure 6. This plot illustrates the real-time correlation between excess heat and the growth of 4He concentration in a metal-sealed, helium leak-tight vessel. ..... Because of the importance of this result, it is discussed further in
Appendix B."

The report shows that accumulation of 4He was viewed (in 2004) as the most convincing argument for the nuclear origin of excess heat. Is there any reason to abandon that position today? I am not aware of any recent experimental results that would be more convincing.

Addendum (2/12/06):
Steven Krivit commented on what I wrote. That was yesterday. This morning I asked for permission to quote him here. In what follows I will show what he wrote (in blue) and comment on it (in black). I will continue replacing some names with X, Y, Z, etc. because I did not ask for permission to show names of those who decided to contribute to the thread.

Ludwik, [X] tried to make a point. I want to emphasize it. Charles wrote a whole book about this: It's called Excess Heat. His point was twofold: (1) Huizenga, Close and Taubes wrote books all about cold fusion, yet they paid no attention to excess heat. (2) As Martin [Fleischmann] says, "excess heat is the principal signature of cold fusion."

If you are pre-disposed to the idea that fusion evidence must conform to what nuclear physicists expect, you will have a long, frustrating and unsatisfying road ahead of you in your earnest quest to become comfortable with the idea of low energy nuclear reactions.

I think that scientists should always try to understand new facts in terms of what is already known. Then they should explore other alternatives. Fleischmann and Pond did try to explain the unknown in terms of known when they hypothesized nuclear origin of excess heat. The accumulation of 4He, in commensurate amount, is a confirmation of their hypothesis.

If you, however, consider that excess heat has been measured by experts, with precision instrumentation, by people who are of sound mind, then you have your answer as to what is the best evidence for cold fusion. . . .

Yes, non-specialists, and many specialists, usually have no choice but to rely on the reputation of recognized experts.

Will this perspective be satisfactory to people who choose to dismiss calorimetry? No. You will note that in Charles' book, a reporter asks Nathan Lewis of Caltech, "Should reporters disregard calorimetry?" Lewis' response was "Absolutely." . . .

How can anybody “dismiss calorimetry?” It is one a recognized branches of physical science. Joule used to discover important facts about natural phenomena. What Lewis responded makes sense only if one replaces the word “calorimetry” with “claims for excess heat based on calorimetric measurements.” Personally, I am not dismissing anything in this thread; I am taking reality of excess heat for granted. I do not know why several people, like Steven, ignored my question (about nuclear origin of excess heat) and replied as if I were questioning reality of excess heat in this thread.

I will take the bold step to say that such a question is no different than the catholic church fathers being asked by the public if they should avoid looking through Galileo's telescope to see the rumored imperfections on the surface of the moon. The telescope was *the* tool for this investigation. Not only that, but only the best telescope, with lenses made by the best, state-of-the art methods was capable of providing an accurate view. Honestly, when should any good scientist indiscriminately discard data?

Lewis' comment was from 1989, by the way. When I attempted to interview him in 2004, he declined, writing, "I've been out of that area for a decade or so," Lewis said. "Consequently, I have no basis for commenting on anything that has happened in that period of time sciencewise." I consider his 2004 response to be quite honest and respectful.

Now consider Karabut's attitude: "The problems of the skeptics are their problems. I measured excess heat, nuclear products and penetration radiation (X-ray emission) with 100 % reproducibility." (Karabut is a specialist in Heat Physics, Nuclear Rocket Engines, and Nuclear Material Science at the LUCH Association at Podolsk, Russia, November 12, 2003).

Karabut's paper had profound effect on me; my renewed interest in CMNS was triggered by his paper. That was more than three years ago. And now I know that many of his findings (in cooperation with Kutcherov and Savvatimova) were known to cold fusion researchers as early as 1992. What puzzles me is that no other cold fusion researchers tried to replicate his experiments independently. Nearly every CMNS phenomenon (see item #13 on this website) was demonstrated with a setup which was clearly described and which was not too difficult to replicate. Findings of Podolsk scientists, however, are not at all mentioned in the 2004 report written for the DOE. Should I assume that this is an indication that findings of Karabut et al. were not confirmed by cold fusion researchers in other laboratories? If they were confirmed then Russian experiments would probably be more convincing. How can a flow calorimeter be wrong when excess heat is generated at the rate of 10 watts? It was shown to be roughly compatible with the rate at nuclear ashes (not 4He) were accumulated.

. . . Consider the words of Italian physicist Antonella De Ninno: "I believe that cold fusion is like the finger pointing the moon, only silly people look at the finger, wise people look at the moon. This phenomenon sheds a new light on the physics of condensed matter and can really be the gate for a new revolution in physics. Don't believe that physics is just the challenge in measuring with higher accuracy what is already known."

Ludwik (2/13/06):
Several people made interesting contributions to this thread today. What follows is my post; it was reaction to what they wrote. In particular, Steven Krivit asked: "... So who really knows all or even part of the origin/mechanism/theory? . . . "

As I wrote to Brian, trying to construct a theory makes things more complicated than necessary. In this thread we address experimental facts, such as generation of excess heat and production of 4He. Are the facts qualitatively consistent with each other? That is our topic. I think they are. They were shown to be consistent, more or less, and that was a giant step toward better understanding of CMNS. In this thread I would like to hear comments on reliability of facts, especially from "old-timers" who made significant contributions. Y already outlined great experimental difficulties. But I viewed this as an explanation of why the Q value, expected to be 23.7 MeV, could not be determined

better than 31 +/- 13 MeV. His comment about the highly abnormal 3He/4He isotopic ratio (factor of 40,000) is also very important.

Is there any reason to believe that unacceptable experimental errors were made by measuring either the amount of excess heat or the amount of 4He produced at the same time? There are about 20 references to relevant publications in section 3 of the 2004 report presented to the DOE. I note that at least one 4He atom per several MeV of excess heat has been reported by more that one team of researchers. That is why I still think that the 4He ash is the best indicator of the nuclear origin of excess heat (in Fleischmann-Pond kind of experiments). Those who disagree probably think that more convincing evidence exists (and has also been confirmed by several researchers). Please share your information. But some might be convinced that no experimental evidence is consistent with the nuclear origin of excess heat. It would be interesting to hear from them as well.

I suggest that a separate thread is devoted to the topic "chemically activated nuclear transmutations." And another thread on "where is an accepted CMNS theory." No progress can be made when we chaotically jump from one topic to another. Yes, Iwamura's findings are extremely important but, as far as I know, they can not be used to argue that excess heat has nuclear origin. And having an accepted theory would be highly desirable and extremely useful.

Jed:
You wrote: "That is why I still think that the 4He ash is the best indicator of the nuclear origin of excess heat (in Fleischmann-Pons kind of experiments)." That depends on how you define "best," and as far as I know there is only one kind of experiment. I do not know what other kind you have in mind. Many methods of producing metal hydrides have been used to demonstrate that Fleischmann-Pons effect: that is, excess heat, helium, tritium, transmutations, etc.

You also wrote "Yes, Iwamura's findings are extremely important but, as far as I know, they can not be used to argue that excess heat has nuclear origin."

Iwamura's present experiments cannot be used to argue this, because he does not try to measure heat. (It is not possible with this apparatus.) However, in his earlier experiments he performed calorimetry and he also looked for host metal transmutations, and he always observed both. Therefore his evidence is as definitive as helium. As far as anyone knows, all cold fusion reactions produce helium, and they all transmute the host metal. I do not think anyone has ever looked for both helium and heat and not found both together; and by the same token I do not think anyone has ever looked for host metal transmutation and heat, and not found both together.

Many people have observed heat without trying to look for helium or transmutations. These tests do not prove anything either way. Neutrons and tritium do not always accompany heat. But as far as I know helium and host metal transmutations always do. Perhaps the ratios vary. I do not think there is enough data to determine this.

Jed:
I wrote: "Iwamura's present experiments cannot be used to argue this, because he does not try to measure heat. (It is not possible with this apparatus.)" I mean that strictly speaking, taken in isolation, these particular experiments do not prove that the heat and heavy-element transmutations have the same origin. As a practical matter, based on common sense and Occam's razor, it is obvious that they do have the same origin. It would be absurd to argue that although metal hydride systems produce a thousand times more heat than any chemical system does with no chemical ash, and they also produce transmutations, these two phenomena are unrelated. They cannot be a coincidence! You might as well argue that daylight and the sun have no causal connection.

If you are curious to know the roots of this debate . . . Ludwik, in the grand tradition of the Cartesian French philosophers, is trying to establish a logical or theoretical connection between helium and/or transmutation and the heat. I am content with Hume's empirical definition of causality, perhaps because I come from a long line of English inventors and statisticians, and to us there is no other kind. Strictly speaking, you can never be certain that you truly understand a logical causal connection, and strictly speaking -- purely from a philosophy-of-science viewpoint -- the only reason we know for sure the sun will come up every day in the East is that it has always done so in the past. (This sounds facetious but it is not.) We assume that Newton's first law ensures that the earth will not spontaneously reverse spin or stop, because nobody has ever seen the first law violated. Repeated observations are all we have to go on.

There is no deeper proof. As Newton himself put it: "I have not as yet been able to discover the reason for these properties of gravity from phenomena, and I do not feign hypotheses. For whatever is not deduced from the phenomena must be called a hypothesis; and hypotheses, whether metaphysical or physical, or based on occult qualities, or mechanical, have no place in experimental philosophy. In this philosophy particular propositions are inferred from the phenomena, and afterwards rendered general by induction." - Principia Mathematica.

(This is usually translated "I make no hypotheses.") Perhaps string theory or ZPE or something like that will eventually "explains" momentum, but that will only be theory, and theory might always be wrong. Empirical proof is the only kind that exists in reality, and you can never be 100% certain of it any more than you can have a 100% pure sample of iron.

XXX (2/15/06):
Regarding the relationship between excess energy and helium production, polyneutron theory gives various ratios depending on the nuclear fuel.

Consider for example oxygen-18 in the electrolyte as a fuel. Let (18O) represent a nucleus of oxygen-18, and let (An) represent a polyneutron containing A neutrons. Successive polyneutron reactions are:

```
(18O) + (An)  --->  (16O) + ((A+2)n)        (neutron transfer)
(18O) + ((A+2)n) ---> (16O)+((A+4)n)        (neutron transfer)
((A+4)n) ---> (An)+(4He)  (double beta decay + alpha decay).
```

The polyneutron acts as a catalyst for transmutation. Its contributions to excess energy cancel out. The overall reaction is

2(18O) ---> 2(16O)+(4He) + 5.5 MeV

and the energy per helium atom is 5.5 MeV.

Other possible sequences:
Many electrolytes contain lithium. For lithium-7 as the fuel the polyneutron reactions are:

```
(7Li) + (An) ---> (4He) + (1H) + ((A+2)n)
(7Li) + ((A+2)n) ---> (4He) + (1H) + ((A+4)n)
((A+4)n) ---> (An)+(4He).
```

The overall reaction is

2(7Li) ---> 2(1H)+3(4He) + 8.0 MeV

and the energy per helium atom is 2.7 MeV. When lithium-6 is the fuel the polyneutron reactions are:

```
(6Li)+(An)  --->  (4He)+(1H)+((A+1)n)
(6Li)+((A+1)n)  --->  (4He)+(1H)+((A+2)n)
(6Li)+((A+2)n)  --->  (4He)+(1H)+((A+3)n)
(6Li)+((A+3)n)  --->  (4He)+(1H)+((A+4)n)
((A+4)n) ---> (An)+(4He).
```

The overall reaction is

4(6Li) ---> 4(1H)+5(4He) + 15.1 MeV

and the energy per helium atom is 3.0 MeV. Deuterium fuel generates more energy per helium atom.

```
(2H)+(An)  --->  (1H)+((A+1)n)
(2H)+((A+1)n)  --->  (1H)+((A+2)n)
(2H)+((A+2)n)  --->  (1H)+((A+3)n)
(2H)+((A+3)n)  --->  (1H)+((A+4)n)
((A+4)n) ---> (An)+(4He).
```

The overall reaction is

4(2H) ---> 4(1H)+(4He) + 21.0 MeV

and the energy per helium atom is 21.0 MeV. In a light water electrolyte containing lithium (and a trace of deuterium) all of these reactions are expected. The overall release of energy in the electrolyte will probably be in the neighborhood of 4 MeV per helium atom. On the other hand in a system employing heavy water electrolyte and in which deuterium is concentrated in a palladium cathode, reactions in the cathode can lead to 21 MeV per helium atom, comparable with that for deuterium fusion. (Here I have neglected energy contributions from transmutation of the cathode material, which are probably small.)

Ludwik (not posted):
I think that this long thread is over. And I hope that theoretical predictions, as from XXX above, will be discussed in future threads. What are the main experimental CMNS issues?

In my opinion they are:**(a)** Is excess heat real? Some say that experimental errors are responsible for excess heat. Most often that heat is generated at the rate of about 1 W or less. **(b)** Is the rate of generation of excess heat commensurate with the rate of producing nuclear ashes? Some say that these two processes are not commensurate. **(c)** What evidence do we have that a chemical process can trigger a nuclear process? This issue is not limited to nuclear reactions responsible for excess heat. Some say that this is not possible because the energy scales are very different (millions of eV versus several eV). **(d)** How to explain unexpected, but experimentally observed, nuclear processes? No accepted theory emerged from the CMNS field, so far. **(e)** What to do to overcome administrative discrimination of CMNS by our scientific establishment? The establishment consists of (but is not limited to): fund granting agencies, editors of peer-reviewed journals, and administrators of national laboratories. Each of these five issues deserves a separate thread.

Bill Collis (quoting with permission):
I appreciate XXX' skepticism. I appreciate YYY honesty. It's people like these who keep us in the real world. We need dissent. We need constant reexamination of our cherished dogmas and beliefs. We need an open mind. The heresies of the early 90s such as light hydrogen anomalies and transmutations have steadily become acceptable. Who knows what the future will bring? So much for the philosophy. Let's get down to specifics. . . .

278) Tabletop fusion devices

Ludwik Kowalski; 2/16/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

After being away for nearly three months I went to a meeting at the university. That was three days ago. Three people who I met independently commented on new tabletop experiments. They knew about my interest in cold fusion and they thought that new reports were confirmations of reality of cold fusion. Each time I explained that these are new "hot fusion" devices. The next day a message of the same kind (see below) was posted on the restricted Internet discussion list for CMNS researchers. The CMNS, by the way, stands for Condensed Matter Nuclear Science. It is a new name for what used to be called cold fusion. Personally I identify three CMNS subfields: cold fusion (CF), cold transmutations (CT) and excess energy (EE). Contrary to what many think, research in these areas did not end after cold fusion was declared to be pseudoscience (more than 15 years ago).

= = = = = = = = = = = = = = = = = = =

1) It started when X1, who is an amateur scientists, quoted (see below) what was posted recently (2/13/06) at:

<www.scienceblog.com/cms/ny_team_confirms_ucla_tabletop_fusion_10017.html>

Researchers at Rensselaer Polytechnic Institute have developed a tabletop accelerator that produces nuclear fusion at room temperature, providing confirmation of an earlier experiment conducted at the University of California, Los Angeles (UCLA), while offering substantial improvements over the original design. The device, which uses two opposing crystals to generate a powerful electric field, could potentially lead to a portable, battery-operated neutron generator for a variety of applications, from non-destructive testing to detecting explosives and scanning luggage at airports. The new results are described in the Feb. 10 issue of Physical Review Letters.

"Our study shows that 'crystal fusion' is a mature technology with considerable commercial potential," says Yaron Danon, associate professor of mechanical, aerospace, and nuclear engineering at Rensselaer. "This new device is simpler and less expensive than the previous version, and it has the potential to produce even more neutrons."

The device is essentially a tabletop particle accelerator. At its heart are two opposing "pyroelectric" crystals that create a strong electric field when heated or cooled. The device is filled with deuterium gas -- a more massive cousin of hydrogen with an extra neutron in its nucleus. The electric field rips electrons from the gas, creating deuterium ions and accelerating them into a deuterium target on one of the crystals. When the particles smash into the target, neutrons are emitted, which is the telltale sign that nuclear fusion has occurred, according to Danon.

A research team led by Seth Putterman, professor of physics at UCLA, reported on a similar apparatus in 2005, but two important features distinguish the new device: "Our device uses two crystals instead of one, which doubles the acceleration potential," says Jeffrey Geuther, a graduate student in nuclear engineering at Rensselaer and lead author of the paper. "And our setup does not require cooling the crystals to cryogenic temperatures -- an important step that reduces both the complexity and the cost of the equipment."

The new study also verified the fundamental physics behind the original experiment. This suggests that pyroelectric crystals are in fact a viable means of producing nuclear fusion, and that commercial applications may be closer than originally thought, according to Danon. "Nuclear fusion has been explored as a potential source of power, but we are not looking at this as an energy source right now," Danon says. Rather, the most immediate application may come in the form of a battery-operated, portable neutron generator. Such a device could be used to detect explosives or to scan luggage at airports, and it could also be an important tool for a wide range of laboratory experiments.

The concept could also lead to a portable x-ray generator, according to Danon. "There is already a commercial portable pyroelectric x-ray product available, but it does not produce enough energy to provide the 50,000 electron volts needed for medical imaging," he says. "Our device is capable of producing about 200,000 electron volts, which could meet these requirements and could also be enough to penetrate several millimeters of steel." In the more distant future, Danon envisions a number of other medical applications of pyroelectric crystals, including a wearable device that could provide safe, continuous cancer treatment.
Dan Kawasaki
= = = = = = = = = = = = = = = = = = =

2) To which X2 replied: "This is conventional thermonuclear fusion. So, yes, we can again be happy that the hot fusion people are confronted with tabletop alternatives to their otherwise mega projects."

= = = = = = = = = = = = = = = = = = =

3) X3 commented: "Actually this is not thermonuclear fusion because the system is not in thermal equilibrium."

= = = = = = = = = = = = = = = = = = =

4) A veteran CMNS researcher, X4, made a very interesting observation: "Actually, these folk (and Puttermann at UCLA and Taleyarkhan? at Purdue) need to adhere to the same standards the high temperature folk set for us: measure the yield of both neutrons and tritium (and demonstrate that 4He is sparingly seen) before they claim a hot fusion result. When they do, they might be surprised at the results."

= = = = = = = = = = = = = = = = = = =
5) Ludwik Kowalski:
X4 made an interesting observation. Perhaps the authors of the papers know that mentioning a possibility of a CMNS mechanism would be detrimental. Would a paper mentioning cold fusion be sent to objective referees by the Physical Review Letters? Probably not.

Two kinds of standards are worth emphasizing. Why do newspapers describe some discoveries as interesting and scientific while other discoveries are totally ignored? Production of 4He, associated with generation of excess energy, is not less interesting as tiny crystal-based accelerators of deuterium ions. The same for the discoveries of Iwamura. The answer is clear, the newspapers' editors discriminate against the CMNS topics because they have been convinced that research in that area belongs to pseudo-science. The editors of mainstream journals do not even send CMNS reports to the impartial referees. This created a vicious circle. The claimed CMNS discoveries are criticized on the basis of not being confirmed by other scientists while, at the same time, other scientists are prevented from seeing CMNS papers.

Illustrations of unreasonable rejections of CMNS papers are described in items #33, #88, and #153 at my website at:

http://blake.montclair.edu/~kowalskil/cf/

Please send me other illustrations and I would be happy to append item. Exposing unfair discrimination should be an important part of our public relation activities. What else can we do to break the vicious circle? Most people are fair and they want others to be fair. That is why I am optimistic; fairness will prevail.

X5 wrote:

This is sad, profound and hilarious -You all know how initially cold fusion got off to a bad start because people thought it was a "colder" form of thermonuclear fusion? And how the name cold fusion stuck, regardless of the mistaken identity? Well, judging by the popular culture out there -- believe it or not -- hold onto your seats -- history is repeating itself again, this time in favor of cold fusion. The recent attention about the pyro and bubble fusion is being called "cold fusion" by many people. I think we all know that it's not, but consider the spill-over positive attention the field -and the name -- is getting! I realize the *real* cold fusion is not getting this attention, but that makes no difference. The NAME cold fusion is losing its stigma through this process. Thank you, Seth Putterman and UCLA !"

6) X3 again: "I remember when Taleyarkhan et al. did compare tritium and neutron yields in 2002 paper, the neutron yield was lower, which caused a controversy at Oak Ridge. The discussion was all about the efficiency of the neutron detector. Do you think there's more to it? I thought we had settled that Pyro and Bubble Fusion is definitely hot. But your point is quite good and I'm glad I hear it."
= = = = = = = = = = = = = = = = = = =

7) X4 again: "It is just a hunch, and I am being mischievous. But the so-called "heat" from hot fusion is actually measured from neutron flux (and then back-calculated). They never saw any heat or tritium. And the neutron could come from lots of sources other than d-d or d-t (i.e. wall interactions or semi-coherent fusion in the so called plasma instabilities - which are actually stabilities). I guess my point is the same requirements and standards of proof are not held for the hot and cold operating regimes. But I do not believe it has been definitely shown that Pyro and Bubble fusion are hot. It would not upset my world view if they were and were proven to be hot fusion. My hunch is they are not."

279) The iesiUSA company seems to be in trouble. Will it hurt the reputation of CMNS researchers?

Ludwik Kowalski; 2/2/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

In unit #274 I wrote that even a single case of fraud associated with CMNS might "deliver a devastating blow to the entire discipline. The consequences of such episode would be difficult to repair." When this was written I was not aware how bad the iESiUSA business situation was. What follows was posted by Steven Krivit at the New Energy Times website:

http://newenergytimes.com/SR/IESI.htm

Steven is a journalist who has been investigating many aspects of CMNS field for at least four years.

New Energy Times Editorial Commentary (Feb. 1, 2006)

I've been investigating iESi since June 4, 2005. Most of the references on the "DIY" blog listed below appear to agree with my findings, though I have not yet looked at every reference in detail.

Since the start of my investigation, I have been, at various times, in direct communication with many iESi personnel including; Patrick Cochrane (CEO), Tom Bugg (President), Norman Arrison (Staff Scientist), Mark Boocock (U.K. Managing Director), Hywel Rees (U.K. Sales & Partnerships Director), Terry Dingwall (ex-President), Stephen Monaco (ex-Vice President), Hyunik Yang (ex-Senior Scientist), Nahm Cho (ex-Senior Scientist), Bill Harrington (ex-Staff Scientist), Alaine Liberty (Technician), and Ken Pierce (Technician).

I have seen several court documents pertaining to pending actions from the company against ex-employees, and also actions from the ex-employees, who are shareholders, and who are also acting on behalf of many of the other shareholders.

The "company," in this regard, is the board of directors; namely, Patrick Cochrane, Ronald Foster, Fred Dornan and Tom Bugg. They, and not the shareholders at large, appear to be fully responsible for the state of the company and the alleged misdeeds.

The former senior scientist, Hyunik Yang, told me last fall that he had been hastily appointed to the Board sometime around August. According to Yang, he subsequently resigned from the Board a month or two later, after starting to see the management problems. On Dec. 1, he informed me that he was no longer working with iESi.

The story behind iESi is certainly a fascinating one. It may not please many people. Certainly, the several hundred private investors who cumulatively contributed a few million dollars to the company may not be pleased to finally start learning about the troubles with the company. Some of the good-hearted employees of the company, like Norm Arrison, may be shocked and disappointed to hear about the mess the company is really in and some of the alleged

wrongdoings on the part of the remaining directors.

There is no certainty at the moment as to what will become of iESi, or its licensing claim to any intellectual property potentially conveyed by Hyunik Yang. I am told by several sources that there are 20 separate agreements between Yang and Cochrane, and Yang and iESi that govern the licensing of the intellectual property. I am also told that several of these agreements contradict each other. These matters are now in the hands of half a dozen attorneys on behalf of Yang, and probably as many on behalf of the iESi board.

Will the true owners of iESi, the hundreds of shareholders, ever see the development of the intellectual property and see a return on their investment? It's hard to say at the moment.

The iESi story is about wildcatters; bold businessmen willing to take high-risks, and like sharks smelling blood in the water, swarming to what they think is a vein of gold in an apparent cold fusion gold rush.

Is it fool's gold? I'm still undecided. The underlying science reported by Yang and Vysotskii at ICCF12 has multiple inexplicable characteristics. But they've been highly-secretive and have refused to reveal any hard data.

Has the iESi leadership contributed toward the progress and the development of this technology? For a while, at least, they most certainly did. Can they be credited for their willingness to take a risk on a new source of clean energy? Absolutely. Did they bring research funds into the field and promote progress? Yes, they can be given that credit as well.

However, does the current board of directors have what it takes to salvage this company? That is a question every shareholder should be asking right now. Unfortunately, it's too late to get your money back. That offer, made by the iESi board in the Dec. 8, 2005 shareholder's update, expired two hours ago, on Jan. 31, 2006, which coincidentally, was the same time my embargo agreement expired with iESi as well.

Is the leadership at iESi typical of businesspeople who are investing in cold fusion? Fortunately, no, but this is not the first, nor will it be the last of companies who are willing to make possible indiscretions on the way to hopeful cold fusion profits.

I am pleased to say that there are, in fact, several companies in the U.S., and some in Europe that are making careful, conscientious efforts to develop cold fusion. However, they are remaining private, and staying under the radar for now. They are not putting themselves in the predicament of taking money from public investors. This seems wise to me. I have little uncertainty that eventually cold fusion will be commercially viable, but which company, or companies will figure out the answers? That's anybody's guess.

As much as I'm a proponent of cold fusion, I would say that this is not a time to invest your life savings or your IRA in cold fusion. This is a time for angel investors who can afford to take risks and who want to possibly contribute to a great alternative to fossil fuels.

-Steven B. Krivit
Do-It-Yourself Due Diligence Blog (Feb. 1, 2006) New Energy Times Photos of iESi "Corporate Offices" (Feb. 1, 2006)

On Jan. 22, 2006 a New Energy Times (tm) reader informed us that the www.iesiusa.com Web site went dark.

"The website appears to be password protected. I checked and it appears that the password message that used to appear only for the private investor section now inhibits access to the entire site. Do you know what is going on?"

New Energy Times started investigating Innovative Energy Solutions Inc. (iESi) in June, 2005. At that time we signed both a nondisclosure agreement as well an embargo agreement. The embargo agreement expires in February and we will therefore be able to report our findings in our March 10 newsletter. We concluded the major part of our iESi investigation in November, 2005. New Energy Times does not have an ongoing interest in iESi at this time.

New Energy Times is continuing its interest and investigation of Hyunik Yang and the work he has reported at ICCF12.

As a courtesy to interested parties, we captured several of the key pages from the iESi Web site and we present them here, along with photos we took of their "corporate headquarters."

Appended on 11/21/06

I think that the following piece of information is worth appending. It was posted by New Energy Times journalist Steven Krivit on a restricted Internet discussion list for CMNS researchers in response to a prominent list member who had chided him to "Loosen up!" in response to Steven's vigilance of another "cold fusion" company. It a good reminder that waters surrounding scientists are infested by unscrupulous sharks. Steven has an in-depth investigation at this Web location:

http://newenergytimes.com/SR/IESI.htm

Many people were harmed from the actions of a few with regard to iESiusa. Millions of dollars from innocent, though perhaps somewhat eager and somewhat naive private investors were apparently lost. The reputations of some good people were harmed. One of the conscientious employees formerly involved with iESiusa spent what would have amounted to a year's tuition for his children's college fund to extricate himself from a meritless suit by the iESi executives. But for this fellow, he didn't know the facts until it was too late. He had encouraged the iESiusa board to operate within the law and when they refused, he blew the whistle on them to federal investigators. Even though he was protected under the U.S. whistleblower act, this action still cost him thousands of dollars in legal defense and much of his personal time.

The immediate collateral damage is that the CMNS community lost a potentially good ally. There is more collateral damage. It may have discouraged other potential allies from the business community to set foot into the CMNS community. I do not know the current status of iESiusa at the moment, but it appears that it is nothing but a skeleton. Their former Web presence http://iesiusa.com/ has now disappeared without a forwarding link. I learned that they have a new Web site at http://www.iesica.com/. Cochrane appears to be involved in several outstanding related legal challenges, Yang told me today that he is still fighting his legal battles with iESiusa [Cochrane and other board members]. I know of no scientists who remain with iESiusa.

Terry Dingwall, the former iESiusa President initiated a legal action against the corporation on behalf of the bulk of the shareholders in the fall of 2005 to protect the interests of the shareholders. According to Dingwall, the company that was formerly based in Nevada, USA, now exists as an empty shell, and at least some of the iESiusa board members have now started a new company. An Alberta Registrar of Corporations document shows Patrick Cochrane and Ronald Foster as directors of a company called IESI Energy Solutions (Alberta) ulc.

The web site says Arrison and one other fellow are part of their "team." I spoke with Arrison last week - he tells me me left the company almost a year ago. What about the other fellow still listed on the iESiusa site, Dumitru Fetcu? The one whose name iESiusa couldn't even spell correctly? This morning I obtained the following information from a European colleague, "Fetcu is no longer working with iESiusa. He had sent them a termination letter on June 30 this year because they had not paid him according to the contract."

When companies make claims such as “has amassed the best collection of cold fusion scientists in the world," they should back that up with fact. If they cannot, the public should know. When the owners of companies engage in shady business practices, the public has a right to know. And it is the moral and ethical obligation of the press to be the informant, if necessary, of bad news. Fraudulent and deceptive business practices hurt everybody; investors, scientists

and eventually even those who are guilty of such indiscretions."

It is clear to me that Steven is a very gifted journalist and a dedicated defender of general public. In fact, suspecting something inappropriate, he is now investigating another company. I do not think that this will turn out to be anything comparable with the iESi episode. Another way in which his online journal, New Energy, serves general public is publishing summaries of laboratory results. A good example of this is his report #7 at:

http://newenergytimes.com/news/2006/NET19.htm

My own unit #314, to be posted soon at my website, was prompted on that report. What a coincidence, just now, as I was about ready to append this piece, another message from Steven Krivit was posted on our restricted CMNS list. He was responding to someone who referred to unpleasant aspects of critical investigations and to "personal factors." Part of his reply is shown below. I hope Steven will again give me permission to be quoted. He wrote:

". . . I will continue to investigate and report as I see best, on behalf of the public's interest. What I report will not always be pleasant, but that is the way of the world and it is my choice to keep this community, and the world at large, informed of all matters pertaining to CMNS. The field is not the same as it was two years ago. Money is coming in. A journalist (Bruce Gellerman) recently got an award for covering the field -- the first in over a decade. New branches of government(s) are becoming interested (again.) National security concerns are being triggered. Secret meetings are being held. We are in for changing times, and to borrow a term from electrochemistry, a fair amount of disequilibrium. . . ."

Appended on 11/27/06

The paragraph below is from a paper that Robert W. Bass publishd in the Infinite Energy Magazine (Issue 67, May/June 2006).

http://www.infinite-energy.com/iemagazine/issue67/apsmeeting.html

The title of the paper, dated March 16, 2006) was: "An Afternoon to Remember: Cold Fusion Session of APS Meeting."

Investigative reporter Steve Krivit has been diligently exploring every plausible development in the entire CF field, and surprised me by having persuaded Hyunik Yang and his former Russian collaborator Vysotskii to disclose at ICCF12 some of the formerly closely-held information regarding Innovative Energy Solutions Inc., where in June 2005 Fleischmann, McKubre, Hagelstein, Beaudette, Krivit, and myself were privileged to witness what purported to be the first large-scale (20 kilowatts!) CF power demonstration. (Steve has a continuing interest in following developments at www.iesiusa.com, which, sad to say, has lately become distracted by intellectual property ownership issues and from which their former chief scientific manager Yang has now departed.) However, Steve refrained from mentioning iESi in his well-illustrated current-activity-survey slideshow, which I hope he makes available on his website cited above.

I would be very much interested in what other witnesses the "first large-scale (20 kilowatts!) CF power demonstration" think about the iESiusa episode today (especially Peter Hagelstein, from whom I first heard about iESiusa, and Martin Fleischmann). More specifically, it would be interesting to know at what stage they become suspicious that someone might be manipulating them, and other scientists, to impress naive investors. The issue is not simple. Business people are not scientists and many of them think that risky stock market operations are accepted parts of healthy economy. They are willing to lean on claims made by scientists; their only concern is to avoid doing things that are not legal. Scientists, on the other hand, often have good reasons for taking some claims seriously. Working in a field that has been discriminated against, they are willing to accept any promise of financial support for research.

Appended on 11/29/07

The original 2004 claim, recovering heat which would otherwise be wasted, was not unreasonable, as illustrated below. This piece was published at: http://entrepreneur.com/tradejournals/article/119368190.html

INNOVATIVE ENERGY FORMED TO DELIVER CLEAN ENERGY.
Worldwide Energy • August 1, 2004 •

Dr. Hyunik Yang, Dr. Dumitru Fetcu, Patrick J. Cochrane and other industry experts have launched a new venture to deliver innovative and clean energy solutions. The new , Innovative Energy Solutions Incorporated (iESi), has developed unparalleled patented technologies in the areas of hydrogen generation, low-cost heat generation and energy conservation. The company's first available solution, iESi Heat Pipe, is a unique patented heat delivery system enabling end users to recycle waste heat and dramatically reduce energy consumption.

iESi is organized into three broad divisions to maximize return on its intellectual capital and intellectual property. These divisions include hydrogen generation, heat generation and waste heat recovery.

In order to remain competitive in today's global market, businesses are forced to address the uncertainly of rising and volatile energy costs as well as concerns regarding the dependence on oil from the Middle East. Government controls have also added additional regulations and at times impeded exploration and the development of new energy sources. iESi solutions offer a viable alternative to traditional energy sources.

"The application of our patented technologies allows our customers to go from dependence on energy providers to energy self sufficiency," said Terry Dingwall, president, iESi. "Dr. Yang and our team are continually conducting research to enhance iESi's offerings. We plan to unveil revolutionary new technologies in the third quarter of 2004."

iESi's Heat Pipe product has established a reputation as a practical technology to utilize waste energy. The product is an innovative solution that recovers heat energy from a variety of industrial and commercial processes. Waste heat that is normally dissipated into the atmosphere can now be recovered and reused, enabling end users to reduce overall energy costs as well as greenhouse emissions. The patented technology of the Home Heat Exchanger saves the average consumer about 20-30 percent of their total heating bill and can easily be installed by homeowners on their fireplaces, gas stoves or furnaces.

As concern grows for the world's natural resources, energy efficiency is gaining worldwide attention. iESi is poised to be the leader in the development of innovative energy solutions through its safe and patented plasma processes which includes low cost hydrogen generation and low cost heat generation.

Dr. Yang holds a PhD in the field of mechanical engineering from Columbia University in New York. Dr. Yang has spent the last 17 years researching quantum energy, in addition to his responsibilities as an associate professor at Hanyang University in South Korea. Dr. Yang has been included in the Who's Who of Science and Engineering since 1998.

About iESi

Innovative Energy Solutions Inc. (iESi) is a leader in developing next generation clean energy technologies. iESi owns several patents related to heat pipe systems and hydrogen generation technology. Headquartered in Las Vegas, iESi also has offices in Canada, Europe and South Korea.

For more information, visit http://www.iesiusa.com or call. 913/707-2776.

This was fetched by Google today.
Also Dated as January 27, 2007. Here is a quote from this webpage:

. . . . Dr. Philipp Kanarev, chairman of Kuban State Agrarian University's department of theoretical mechanics, Krasnodar, Russia, developed a method of water plasma electrolysis that he sees as the best way to get cheap hydrogen from water. He tells why his 1987 report on it didn't reach news media nor the open literature about patents. Since his device was developed "at the enterprise of the military industrial complex", his certificate of invention was stamped "for service use only" and its content was not published openly.

At that time, the focus was on purifying and disinfecting water with the help of the plasma in his reactor. Two years later Drs. Stanley Pons and Martin Fleischmann announced they had excess energy output during a type of electrolysis. This renewed research efforts behind the former Iron Curtain as well as in the West. In 1996 one of Kanarev's co-authors on the 1987 certificate published results on the excess energy output from the plasma process. The next year they applied for a patent. Then a full group of Russian scientists tested the device and documented its output. Technical people can read more about Kanarev's theory in his books, such as Crisis of Theoretical Physics. Results of the plasma-electrolytic experiments were predicted by the theory.

The bottom line for us non-techies is that hydrogen can compete with fossil fuels as an energy carrier. Previously, existing methods of getting hydrogen from water required more power than is produced when hydrogen is burned. Kanarev says it is possible to get ten times more energy output than input, and he calculates that ideally more than 1,500 ampere-hours of electrical energy could be produced from each litre of water. Engineering the lab models into industrial models has been delayed by lack of money, he said this year. He was apparently too wrapped up in his research to attend this year's Berlin conference, but sent a paper.

Hal Fox of Utah has interviewed scientists in the former Soviet Union. He points out that the high-density charge cluster (HDCC) phenomenon first discovered by Ken Shoulders was also independently found by several others. When the process is refined into a reliable product, HDCCs may be used to harness 30 times more energy than is pulsed into the devices. Fox said his Emerging Energy Marketing Firm is promised enough funding to develop such technologies. They can be used to transmute both liquid and solid high-level radioactive wastes into safer substances. Shoulders received the US patent for HDCC methods, and later Alexander Ilyanok in Belarus and Russian scientists Mesyats and Baraboshkin also discovered charge clusters.

At the Berlin meeting Fox reported another patented Soviet-based invention. A.I. Koldomasov's device piezo-electrically vibrates a mix of waters through a special dielectric material to produce heat energy in more abundance than the energy which powers the oscillator. The device is reported to put out 40 kilowatts of heat energy with only two kilowatts of electrical input. Last year Dr. Josef Gruber described a visit to the research institute where Koldomasov is managing engineer. Koldomasov discovered the new energy source while observing cavitation – implosions in water such as found in "water hammer" in pipes. Gruber showed a photograph of the small device, filled with pure water mixed with only one per cent deuterium (heavy water). Although there are no spark plugs or similar equipment, electrical discharge could be seen. Energy comes out in the form of both heat and electrical current. "Depending on kind and location of the magnets, DC or AC (electricity) may be observed." Gruber said testing revealed 2000 per cent excess energy.

Don't more-output-than-input machines violate a law of physics? A few speakers said that "law" is invalid if a machine releases trapped potential energy from nature in previously-unrecognized ways. They cited zero-point fluctuations of the vacuum of space, vacuum spin or aether as the source of excess energy. The word "aether" is loaded with baggage from the nineteenth century, when aether was thought to be a static substance filling all space, just sitting there. In contrast, a new understanding is of a non-material dynamic primary background out of which the material world is created. This aether is seen as being incredibly dense with energy in constant motion.

Dr. Harold Aspden from England (www.aspden.org) is both a theoretical physicist and practical. In 1972 he was 30 years ahead of his time with his book Modern Aether Science. As patent director of IBM Europe and then a professor of electrical engineering, he could have taken the easy route of accepting consensus science. But he instead came up with a physical theory that applies to new energy technologies including magnetic motors and plasma discharges. . . . .

280) Another rejection

Ludwik Kowalski; 2/17/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

lllustrations of rejections of cold fusion papers and notes by editors of mainstream journals can be found in items #33, #88 and #233. Below is another illustration. In typing this new item I am thinking about the Soviet Union where research in genetics was considered to be pseudoscientific. Enormous administrative pressures were created to make sure that minds of people are not poisoned by degenerated Ph.D. scientists and academicians. The system was very effective.

The editors of our mainstream papers are certainly not subjected to the same kind of ideological pressure. But, somehow, they also act in unison when it come to rejections of information about research in the "forbidden" CMNS field. The CMNS, by the way, stands for Condensed Matter Nuclear Science, a better (but not perfect) name for what used to be called "cold fusion." What is the mechanism behind the unison action of editors and other administrators of "mainstream science?" They seem to follow some kind of a "party line." And this happens in many countries.

The social phenomena of organized discrimination of large groups of highly qualified researchers are probably worth studying. I do understand the mechanism of discrimination of geneticists in the Soviet Union but the mechanism of discrimination in the USA is not at all clear to me. Something is not right somewhere. What is it? The text below was e-mailed to the editor of a magazine on January 29, 2006.

To: Yale Scientific Magazine
P.O. Box 209117, Yale Station
New Haven, CT 06520
ysm@yale.edu

From: Ludwik Kowalski
341 Brook Avenue
Passaic, NJ 07055

Date: January 29, 2006

Dear editor: Please consider the following note for inclusion in your magazine.

Still proto-science -- but not pseudo-science.
And not a fraud.

By Ludwik Kowalski

About 40 years ago, as a postdoctoral researcher at Columbia University, I often participated in nuclear science experiments at Yale University. In 1968 my note entitled "The Use of Mica in Understanding Nuclear Reactions" was

published in Yale Scientific. I am now a retired professor emeritus, Montclair State University, NJ. The purpose of writing this short note is to make the readers aware of how I reacted to a Washington Post article by a Yale University historian, Dr. Bettyann Kevles. Although I found the article interesting I strongly disagree with what she wrote about "cold fusion" (CF), as explained at:

http://blake.montclair.edu/~kowalskil/cf/254fraud.html

Like most scientists of my generation, I was highly excited when the CF discovery was announced 17 years ago. And like most of them, I accepted the "official" Department of Energy position that CF is pseudo-science. But about four years ago I accidentally discovered that the field is still active. I started reading recent publications <www.lenr-canr.org>, participated in four CF experiments and attended three International CF conferences (ICCF10, ICCF11 and ICCF12). The evolution of my ideas about CF can be seen at the above website. I am optimistic that something good will emerge out of CF research. Unfortunately, instead of being encouraged and rewarded, honest researchers in the area of CF are often viewed as pseudo scientists. Dr. Kevles even compared the announcement of CF with the well-known fraudulent "Piltdown Man" episode.

Be aware of these facts, remain open-minded and protect honest scientists, even those who explore controversial claims. Researchers should be protected from those who discriminate against them, by denying access to peer reviewed journals, etc., and from fraudulent commercial manipulators. In my opinion CF will become science when at least one of its effects is "officially" recognized as truly reproducible. My personal attempts to contribute to such a transformation are described in items #267 and #270, at the above website. For the time being let good people benefit from your doubt.

This note was submitted about three weeks ago. Today, assuming that my message was lost, or forgotten, I resubmitted it. I wrote: "Dear editor: I am sending the attached file again. It was first e-mailed on 1/29/2006 but I did not hear from you. Assuming my message was lost I am sending the file again. Please confirm that the file was received. I want to know if my note is going to be published. Ludwik Kowalski Professor Emeritus, Montclair State University, Montclair, NJ, 07055"

Will the editor reply or will this professor emeritus be ignored again? This question will be answered here in about ten days, if you come back. Please describe your experience in dealing with administrators of mainstream science, editors, government officials, laboratory directors, fund granting agencies, etc. I will be happy to "advertise" your stories here. What can be done to eliminate a vicious circle: The claimed CMNS discoveries are criticized on the basis of not being confirmed by other scientists while, at the same time, other scientists are prevented from seeing CMNS papers.

To be appended; probaly in about ten days:

. . . . . .

No reply so far, 10/29/06

281) Reporting negative results

Ludwik Kowalski; 2/23/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Thanks to Tom, Scott and Dennis for permissions to quote from private messages. Yesterday **Tom Benson wrote**: "Hello Ludwik and Scott, How are you doing? I've just finished reading your (Ludwik's) unit # 267 in which your non-confirmation of the electrolytic experiments is shown. I'd like to thank you personally for publishing a good solid NEGATIVE report...CF people need to double-check each other's work more frequently and point out problems. ....."

Replying to the above, **Scott Little wrote**: "Thanks Tom. Both Ludwik and I agree that there is indeed value in publishing negative results. I just wish we had the opportunity to publish some positive results once in a while. .....To date, I have never really seen (i.e. confirmed) the excess heat effect in the Earthtech labs. Oh, there have been times when something positive-going occurred in our experiments but it was either an artifact that we subsequently identified or something very small near the detection limit that was never adequately explained and could not be repeated.

Over the years we have gradually improved our calorimetry to the point where we can now achieve +/- 0.1% relative accuracy with our latest instrument. We have run a small variety of CF experiments in this new calorimeter and none of them have shown even 0.25% excess heat. It is a great frustration for me to see the CF community claiming over and over again that there can be no doubt as to the validity of CF, yet I can't find/make an experiment that shows the basic effect.

But I have not tried Dash's recipe, nor the Szpak approach. We've worked a lot with Dennis Letts who takes the standard F&P cell and excites it with laser light. So far that has not shown excess heat in our new calorimeter. . . . Please keep our calorimeter in mind. It is currently available for work and we offer to test any viable CF cell in it for free."

The issue of reporting negative results was raised in my ICCF12 poster, as shown in the unit #270. The only person who commented on the issue was Ed Storms. He wrote "I think publishing negative results is a waste of time unless these results reveal a useful pattern." I disagree. If a positive result is an interesting fact, such as generation of excess energy, then the failure to confirm such result is also important. What is a "pattern?" It is something about how things are arranged. Right? An experiment describing a discovery and another, apparently identical, experiment confirming it, form a useful pattern to be aware of. The same should be true for a pattern consisting of a pair of reliable experiments contradicting each other. Withholding one kind of results creates an illusion of success; it is not scientific. I am certain that Ed will agree with this. The only facts not worth sharing are those which are suspected to be unreliable, for example, after discovering that an instrument became faulty, that a solution was contaminated, or something else of that kind.

Another issue on which I have mixed feeling, as far as Ed Storms is concerned, is the concept of NAE (Nuclear Active Environment) that he invented. It is something that remains to be identified. The rate of progress toward control and understanding of CMNS phenomena would certainly accelerate if the main cause of such phenomena were known. But what evidence do we have that all CMNS phenomena have the same cause? And how can we be certain that the cause is "nuclear?" How do we know, for example, that it is not electromagnetic or gravitational? Yes physicists did identify

three kinds of interactions (gravitational, electromagnetic and nuclear). But why should this be the end of the story? Perhaps the CMNS phenomena are due to something that remains to be discovered. But that is a separate issue.

Replying to Tom I wrote:
" If you are reading item #267 then go to item #270 as well. But this is not the end of the story. The experiment described in #270 is going to be repeated. The chance of success is higher this time. Pierre Clauzon, and other people at the ICCF12 (including Mizuno himself), identified something that was not done correctly. Our protocol did not allow for sufficient loading of Pd with hydrogen. As you know, a Mizuno-type experiment can be relatively simple and relatively inexpensive. I hope it could be used to produce excess heat on demand. That is why we are anticipating another attempt to replicate the French experiment.

In replying to Scott, I wrote:
I am glad that your highly sensitive, and very accurate, calorimeter is now available to researchers. But it does not seem to be appropriate for a Mizuno-type cell in which excess heat is measured by the amount of evaporated water. But the instrument is probably highly appropriate for measuring excess heat resulting from diffusion of deuterium through palladium. Several CMNS researchers reported on reality of such heat. In one case a Pd tube (with thin walls) was filled with the gas at the initial pressure of several atmospheres. Did you try to experiment with such setup? I did write to Dennis Letts and he provided additional details about what you mentioned.

As you know, Dennis was successful in triggering excess heat with a laser beam. This was reported at ICCF10. But the effect was observed only with palladium that he originally had. Last summer he told me that attempts to reproduce the effect failed with other stocks of that metal. So I asked Dennis what the present situation is. He wrote: "In November 2005 the effect returned in my lab with experiment 641--the laser triggered about a 1 degree cell temp increase with ambient temperature controlled to within +/- .05C and cell input power controlled to within +/- 10 mW on a 10 Watt input power. I started experiment 642 Jan 10, 2006 in MOAC [Scott's calorimeter] and so far the laser has had no effect on cell temperature beyond laser heating of about .1 degree C. "

Should such mixture of positive and negative results be known to other researchers? I thing so. Reporting about the 641 experiment and not saying anything about the 642 experiment would be highly inappropriate. In this case the new origin of Pd is the 'meaningful pattern.' But suppose the negative result is obtained in an experiment in which everything seems to be the same as before. Why should negative results not be reported when "meaningful patterns" cannot be identified? Nothing is strictly identical in nature. Unfortunately, we still do not know which differences are significant and which are not.

Anticipating a possibility of success, in the next set of Colorado experiments, I would like to know who would be interested in building similar devices in order to either confirm or refute reality of large amounts of "excess heat on demand." Once we have reliable Mizuno-type cells we can start demonstrating them at local high schools and universities. Experiments performed at scientific conferences, for example, during poster sessions, can also be very helpful. Concentrated effort of many might turn out to be very productive at this stage. Please write to me, if you are interested. Even 80% reliability would be a giant step forward toward the reconciliation with mainstream science.

I am glad that Dennis gave me a blank permission to quote. Here is how he responded when I asked for the permission yesterday. "You may use any material that pertains to me in any way you wish. I only require that you tell the truth as you see it. I think it is wrong for me to tell others what to print or withhold; I don't believe that represents academic freedom, freedom of the press , or my idea of freedom in general." Let us hope that Scott's calorimeter, called MAOC, will confirm reality of excess heat in Dennis' experiments. MAOC, by the way, stands for Mother Of All Calorimeters. It took Scott several years to build and test this superb instrument. I am honored to communicate with people like Dennis and Scott. How do some physicists dare to say that CMNS researchers are voodoo scientists. Failure to reproduce experiments does not turn a researcher into a pseudoscientist. But what should one think about an author who writes about something without making an effort to study it? The answer is obvious; such an author does not act as a scientist. Yes, I am thinking about Dr. Robert Park, the author of the Voodoo Science book. His crusade aganst real pseudoscience is highly valuable. But labeling cold fusion as voodoo science is not. Why didn't he come to recent ICCFXX conferences to learn about what is going on? Why are his arguments based on what was known in 1989 and not on what is known today.

282) Velikovsky's controversy

Ludwik Kowalski; 2/25/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The CMNS controversy is certainly not the first and not the last in physical sciences. In 1950 Immanuel Velikovsky hypothesized that Venus became a planet about 5000 years ago. This happened when big chunks of matter, presumably ejected from Jupiter, were progressively captured into a nearly circular orbit. As far as I know, the flame of conflict created by the publication of Vilekowsky's books extinguished itself, little by little. I hope that the CMNS controversy will not end in the same way. In 2005 a large archive of Velikovsky's papers and correspondence was donated to Princeton University Library. Will physical evidence supporting his hypothesis be found by future generations of scientists? I do not think so. And I hope that the CMNS controversy will not end in the same way in which the Venus controversy ended. But our fascination with CMNS topics might also become a forgotten episode. The only way to avoid this would be to find at least one truly reproducible effect in the next ten or twenty years. Most currently active researchers will no longer be available after that time.

Here is what one proponent of Velikovsky's theory, Dr.E.W. Mac-Kie, published in the British scientific journal, the New Scientist (January 11, 1973). Mac-Kie was referring to the unjustified negative reaction of mainstream scientists to Vilekovsky's hypothesis. ". . . Nevertheless, such understandable skepticism hardly explains the violence of the reaction against the book and its author, from certain quarters of the scientific establishment in the United States in the years following its publication. So outrageous were some aspects of this reaction when compared with the strictly rational ethics which is supposed to govern the scientist in his evaluation of new work that the situation eventually attracted the attention of psychologists. An entire special issue of the American Behavioral Scientist (September 1963) was devoted to this extraordinary story and this material was later expanded into a book, "The Velikovsky Affair (1966)."

And here is what somebody wrote about all this in wikipedia: "The plausibility of the theory was rejected practically unanimously by the physics community. Both the cosmic chain of events, and the fact that they left no known trace on Earth except as myths, were described as simply contradicting the basic laws of physics. More recently, the absence of supporting material in ice-core studies (such as the Ice-3 and Vostok cores) has removed any basis for the proposition of a global catastrophe of the proposed dimension within the later Holocene period.

Supporters contend that a few of Velikovsky's predictions have been validated. Amongst the most prominent is the prediction that Venus would be very hot. This argument has been countered by noting that Venus is indeed very hot, but not at all for the reasons proposed by Velikovsky. Critics further claim that the vast majority of Velikovsky's predictions turned out to be far from correct. His supporters have continued to claim counter-refutations, but space-probe results do not support the proposal.

In fact, Velikovsky started from myths and traditions of ancient peoples and cultures, postulated that they are based on actual events, including a chain of worldwide global catastrophes, and then he constructed an account to physically explain these events. He made no attempt to analyze his theory from a physical point of view — he was not a physicist — (a fact underscored by the content of Cosmos Without Gravitation) and often remarked that if they contradict the theories of physicists, then the physicists must correct their theories."

It is important to be aware of an essential difference between the hypothesis made by Velikovsky and the experimental discovery announced by Fleischmann and Pons. Velikovsky's ideas were developed to produce a scientific basis for several Biblical episodes. They were only speculations, not a theory derived mathematically from the known laws of nature. Velikovsky was not a physical scientist; he was a medical doctor and a biblical scholar. Fleischmann and Pons, on the other and, were recognized experts in the area of physical science in which the discovery was made.

283) A set of issues worth discussing?

Ludwik Kowalski; 2/28/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

What follows was extracted from a short power-point document. That document was used to discuss a set of selected topics. The discussion was limited because time was limited. But it did take place on November 28, 2005, during a meeting of ISCMNS members who attended the 12th International Conference on Cold Fusion in Japan.

Slide 1 Reproducibility is the soul of science!

Scientists take nothing on faith, they are skeptical. They like to check new claims in laboratories. Then they say "do as I did and you will see the same." That is the essence of the scientific method. But in the CMNS fields things still do not work that way. Why is this so?

Slide 2 Four steps of the ideal scientific method:

1) Discovering facts (reproducible observations).
2) Hypothesizing (tentative explanation).
3) Testing the hypothesis (verifying predictions).
4) Universal acceptance of the proposed model. Where are we in this process?

Slide 3 Why do we have problems with reproducibility?

It often takes time to learn how to control new phenomena:
1) Think about electrostatic experiments, before the role of humidity was recognized.
2) Think about first transistors.
3) Think about first light bulbs.
4) Think about first flying machines.
5) Think about cloning.
Please mention other cases. We need such cases to discuss CMNS issues with honest skeptics.

Slide 4 On the other hand we know that:

CMNS will not be recognized as science, unless at least one claim becomes 100% verifiable (by any qualified scientist, anywhere in the world). Is it not strange that 16 years and not a single 100% reproducible phenomenon has been identified?
WHY IS IT SO ?

Slide 5 My answer is: "because we work in isolation."

Meeting once a year, even if everyone is able to attend, is not a replacement for what is available to scientists working as teams, for example, in national labs and at universities. Coordination of efforts would help us to be more efficient.

Slide 6 Fortunately, we now have a discussion list.

A team of ~130 brains? Not really. Why not? Why is the number of active participants limited to about 10% of

subscribers?

Slide 7 I see two possible reasons:

a) linguistic barriers
b) technologically-oriented researchers prefer secrecy.

But at least 75% of subscribers know English very well.
Would electronic translators help?
What is the main reason of limited participation?

Slide 8 Peer reviews?

a) Yes, for obvious reasons we are deprived of benefits of peer review.
b) Can the CMNS list be considered a substitute for the formal peer review process?
c) What should happen to make this possible?

Slide 9 Why not?

Some are not aware of the list.
Some might think that only positive results are worth sharing; sharing negative results can hurt the CMNS reputation.
It is not polite to criticize others in public.
Fear of retaliation? What else ? ? ?

Slide 10 Mini-conference using the CMNS list

For example, every 6 months. Would this help?

284) Black Light Power calorimetry
Underground energy states of hydrogen atoms

Ludwik Kowalski; 3/1/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
Occasionally I receive messages from readers who I do not know. Here is a message received two days ago: "Dear Sir, I have been following this field since I first acquired Internet access in 1993. Having read both these items on your web site, I would offer the following as IMO the most likely scenario. The Russian device [see items #216 and #226] works as follows:-

The cavitation reaction works to produce a strong vibration in the dielectric material which is probably piezoelectric. This can produce initial charges which can indeed be separated by a flowing dielectric fluid (very pure water). The resulting high voltage at
the exit results in a plasma as stated. Now comes the new information:-

In the plasma, O++ ions are created which function as Mills catalysts for the shrinkage of the Hydrogen atom to hydrinos, or in the case of heavy water of Deuterium atoms to deuterinos. In either case, considerable amounts of energy are released. Occasionally a few deuterinos will shrink to the point where they may undergo a fusion reaction with a relatively short half life. However most of the energy probably comes from the shrinkage reactions. The Russians can't admit this without infringing upon Mills' patent(s).

Additional info:(1) The ionization energy of O+ is 35.117 eV, so a hot plasma is required to produce it, preferably combined with a strong electric field. The Russian invention meets this requirement. (2) Mills' website is www.blacklightpower.com. ..... (3) The major problem with the Russian device is likely that the dielectric material eventually self destructs as a consequence of the severe vibration. This may result in too short a lifetime to be commercially useful. Nevertheless, it could well serve as an illustration of what is possible, and may be capable of commercialization with some more work." I asked Robin van Spaandonk, about his background and asked for the permission to quote. He gave the permission and added: "I dropped out of physics after 2 years at the University of Leiden about 25 years ago, and fell into computer programming, like so many drop outs. I'm interested because it's going to be about a million times more important to humanity than the discovery of fire. How can I not be interested? You can find my own "take" on Mills' work at: <http://www.users.bigpond.net.au/rvanspaa/New-hydrogen.html>

The above massage prompted me to go to Mills' company's website

http://www.blacklightpower.com

I has several interesting items. I was glad that the company is still in business of conducting research and promoting promising technologies. I clicked on the "recent press" link and saw The Wall Street Journal article (1/9/06) about the company's business. The second item was an article from Guardian Unlimited (11/4/05) about fuel's paradise. Most downloadable papers on Mills' website deal with theoretical physics (from which the concept of hydrinos is derived) and with experimental spectroscopy (presumably confirming theoretical predictions). What attracted my attention was calorimetry and excess heat. That is what I want to describe here. But before doing this I would like to share some

observations.

Unlike the CMNS research the hydrino investigations seem to be based on a theory. Here is how this is described in the above mentioned Guardian Unlimited: "Randell Mills, a Harvard University medic who also studied electrical engineering at Massachusetts Institute of Technology, claims to have built a prototype power source that generates up to 1,000 times more heat than conventional fuel. Independent scientists claim to have verified the experiments and Dr. Mills says that his company, Blacklight Power, has tens of millions of dollars in investment lined up to bring the idea to market. And he claims to be just months away from unveiling his creation. The problem is that according to the rules of quantum mechanics, the physics that governs the behavior of atoms, the idea is theoretically impossible. . .

What has much of the physics world up in arms is Dr. Mills's claim that he has produced a new form of hydrogen, the simplest of all the atoms, with just a single proton circled by one electron. In his "hydrino", the electron sits a little closer to the proton than normal, and the formation of the new atoms from traditional hydrogen releases huge amounts of energy. This is scientific heresy. According to quantum mechanics, electrons can only exist in an atom in strictly defined orbits, and the shortest distance allowed between the proton and electron in hydrogen is fixed. The two particles are simply not allowed to get any closer."

It is unfortunate that critics focus on interpretation of facts rather than on the claimed reality of facts. In that respect the situation is not very different from that in CMNS. That field does not have an accepted theory and researchers were originally guided by a hypothesis of Fleischmann and Pons that excess heat has "nuclear origin." Instead of focusing on reality of excess heat critics focused on the fact that the hypothesis is not consistent with what is known about nuclear fusion. The history of CMNS would probably be very different if the authors wrote "we discovered excess heat of unknown origin."

As it stands, the CMNS is based on the assumption that excess heat has nuclear origin. The HS (hydrino science) does not make such claim; it is based on the idea of atomic origin of excess heat. Excess heat, according to Dr. Mills, comes from new kind of chemical reactions. These reactions are much more exothermic than reactions with which we are familiar. And here is another quote from the same article: "According to Dr Mills, there can be only one explanation: quantum mechanics must be wrong. 'We've done a lot of testing. We've got 50 independent validation reports, we've got 65 peer-reviewed journal articles,' he said. 'We ran into this theoretical resistance and there are some vested interests here. People are very strong and fervent protectors of this [quantum] theory that they use.' Rick Maas, a chemist at the University of North Carolina at Asheville (UNC) who specializes in sustainable energy sources, was allowed unfettered access to Blacklight's laboratories this year. 'We went in with a healthy amount of skepticism. While it would certainly be nice if this were true, in my position as head of a research institution, I really wouldn't want to make a mistake. The last thing I want is to be remembered as the person who derailed a lot of sustainable energy investment into something that wasn't real.' " Theoretical idea Dr. Mills are presented in a book he wrote; it can be downloaded (in the pdf) form the company website. I wish I were qualified to comment on the content of that book. But I can show the notes composed while browsing other files at that website.

My Notes

a) How does the blacklight process work? The H_2 molecules are broken into atoms. Ordinary hydrogen atoms are then reduced in size by interacting with catalysts. Transitions from the hydrogen ground states to the below-ground states liberate energy. "Products [are hydrinos] lower-energy H atoms, molecular ions, molecules, and hydride ions." The animation of the sequence is played in the <http://www. Hydrino_Animation.avi>

b) Explaining the release of energy (in the animation captions) they say: "First , energy is resonantly transferred from hydrogen to catalyst, which ionizes. Then the hydrogen atom shrinks to form hydrino and either releases a specific frequency of light or creates 'fast' (very hot) hydrogen." In the Step 4, labeled "disproportionalation' they say "A hydrino atom may also serve as the catalyst." The smallest hydrino shown is H/4.

c) What does the term "resonantly transferred" refer to? It refers to transitions from more excited to less excited states. In this case the "more excited" state is the ground state of an ordinary hydrogen atom while the "less excited" is a presumably existing state of lower energy. The role of the catalyst, an atom able to temporary absorb the energy released in the transition, is not clear to me. The catalyst, they say, must have excited levels matching the energy

released by the hydrogen atom. That is what the term “resonance” refers to. If the underground energy states exist then single hydrogen atoms placed in a vacuum should also be able to undergo transitions that are said to be energetically favorable. What kind of selection rules control probabilities of transitions to the Mills’ underground states?

d) The company will offer “a new energy source based on a breakthrough in hydrogen chemistry with paradigm-shifting applications.” Hydrinos are said to be hydrogen atoms whose binding energies, BE, are larger than for ordinary hydrogen atoms.

BE=13.6 (eV)/(1/p^2)

where p is an integer between 2 and 137. They are formed reacting with catalyst atoms whose “net energy of reaction is about m*27.2 eV, where m is an integer. The reaction results in release of energy and in the decrease of the size of hydrogen atom.

“Fractional Rydberg states” (underground states) have energies: E=13.598 eV /n^2 where n=1, 1/2, 1/3, 1/4, etc. . . These are states characterized by fractional quantum numbers. Emission lines corresponding to underground sates were presumably observed.

n=1 r=1.8660 A ioniz_energy=0.7542 eV lambda=1644 nm
n=1/2 r=0.9330 A ioniz_energy=3.047 eV lambda=406.9 nm
n=1/3 r=0.6220 A ioniz_energy=6.610 eV lambda=187.6 nm
n=1/4 r=0.4665 A ioniz_energy=11.23 eV lambda=110.4 nm

The wavelengths shown in the last column refer to the ultraviolet light light or to soft (not very penetrating) X rays. I suppose the the name “BlackLight process” was chosen to emphasize emission of the invisible electromagnetic radiation. Turning hydrogen into hydrinos, they say, releases much more energy than burning that amount of hydrogen (by a factor larger than 100).

e) The “in-depth tutorial” defines plasma as charged gas. Is it a mistake? Plasma is normally neutral; its positive and negative ions exactly balance each other on the macroscopic scale. They also say that “only certain atoms or ions are predicted to serve as catalysts for the BlackLight process, such as helium, potassium and strontium ions. The catalyst absorbs energy from the hydrogen atom (resonant energy transfer) which shrinks to become a hydrino atom. . . . Hydrino atoms then react to form new compounds. ..... These compounds are highly stable due to the higher binding energy of hydrinos. Once formed, hydrinos may sustain the reaction. For instance, two one-half hydrinos may react to form the one-fourth hydrino, a normal hydrogen atom and a net energy release of 68 eV.” Photons of such energies have been observed. They are, according to the tutorial, associated with dark matter.

f) In a section devoted to the business aspects of Mills’ scientific discoveries one can see the following statement: “ With water as the fuel, the operational cost of BlackLight Power generators will be very inexpensive. Moreover, rather than air pollutants or radioactive waste, novel hydride compounds with potential commercial applications are the by-products. The BlackLight Process offers a prospectively efficient, clean, cheap, and versatile thermal energy source. Two of the potential applications of its technology are in the heating and electric power production.

Heat generating prototypes have indicated the BlackLight Process to be competitive with existing primary generation sources over a range of scales from microdistributed to central power generation. ..... The BlackLight Process is a new primary energy source that has unique competitive advantages in all energy markets: electricity, heat, cogeneration (electricity production with waste heat recovery and utilization), and motive power.”

g) Should one worry about accumulation of hydrinos (and of their compounds) in our environment? I am thinking about a possibility that large-scale power plants, based on blacklight technology, will be used. What should we do with the “non-radioactive ashes” produced in such plants? The ashes are said to be very stable. But can they also be dangerous? Pure hydinos would probably be escaping from the atmosphere but molecules of hydrino compound would be gravitationally retained on our planet, even if they were gasses.

h) One obvious difference, between the situation in the CMNS and in HS (hydrino science), should be mentioned. CMNS researchers (experimentalists, theoreticians and inventors) act as independently working individuals. The HS researchers, on the other hand, seem to be highly organized under one leader, Dr. R. Mills. Organizational structure, and coordination of research, should be an advantage, provided the leader is knowledgeable, flexible and willing to learn from criticism. An effective leader should not act as dictator, s/he should listen what the coworkers suggest and coordinate their initiatives. Progress in the field of CMNS would probably be more rapid if an effective organizational structure could be established.

Calorimentry.
Those who read items #264, #267 and #270 know that last summer I participated in two investigations of excess heat. That explains why the 2003 paper of R.L. Mills et. all, "Plasma power source based on a catalytic reaction of atomic hydrogen measured by water bath calorimetry" attracted my attention. The article I downloaded was published in Thermochimica Acta, vol 4006, 28 November, 2003, pages 35-53. It describes a setup in which excess heat was measured calorimetrically. The electric power was delivered to the setup at the rate of 8.1 W while the heat was generated at the rate of 30.0 W. The excess power is reported as 21.9 W. That corresponds to a much higher COP (coefficient of performance=3.7) than reported by Fauvarque et. all. "The sources of error were the error in the calibration curve (+/- 0.05 W) and the measured microwave input power (+/- 1 W)."

The setup consisted of a quartz tube (inner diameter half-inch) that could be filled with a desired gas, for example, a mixture of 10% H_2 and 90% of He, at a desired pressure, such as 10 Torr. The tube was placed into a microwave cavity delivering electric energy to the gas at the frequency of 2.45 GHz. That resulted in the ionization of gasses. The electric energy, in the form of microwaves, delivered to the gas, for example, at the rate 30 W, was known. Measuring the input power was performed with power diodes, identical in all experiments. Rates at which thermal energy was generated, in a setup whose heat capacity was known, were determined from the rates at which temperatures were changing. Small thermal power corrections had to be made to account for the small conduction and convection losses.

The main purpose of the described experiment was to measure the temperatures of ionized gasses (plasma) on the basis of Doppler thermal broadening of spectral lines. The interesting conclusion was that, under identical conditions, "the average hydrogen atom temperature [in the presence of 98% of He] was measured to be 180-210 eV versus ~3 eV for the pure helium. The electron temperature for helium-hydrogen was 30,500 K compared to 7400 K for pure helium." Ionized helium is believed to be a catalyst for production of hydrinos, the process presumably responsible for excess heat. Hydrogen mixed with Kr and with Xe was also studied under identical conditions (input power 85 W).

P.S. (3/3/06)
I also looked into a more recent publication of R. Mills (March, 2005) downloadable from the above website. The link to this article is located at the end of the list of publications that pops up after one clicks on the "what is new" link. The long document (over 100 pages) is entitled "The Hydrino: Lower-level States of the Hydrogen Atom Which Have Remarkable Consequences." Near the end (why are pages not numbered) Mills refers to the Calvet calorimeter. The description states: "Calorimeter wall consists of thousands of thermoelectric elements in series. Thermoelectric elements transduce heat gradient to voltage which is proportional to energy released in cell. Highly sensitive and reproductive. The calibration curve, voltage (0 to 4 V) versus wattage (0 to ~16 W), is a nearly perfect straight line. The intercept is zero and the slope is 0.233 V/W.

That calorimeter was used to measure excess heat from electrochemical cells when potassium, rather than helium, was used a s catalyst. That is interesting in terms of what has been reported in items #267 and #270. We also used the K_2CO_3 electrolyte. If hydrinos are produced in Mills' cell then they should also be produced in our setups, as suggested by Robin van Spaandonk. By the way, contrary to situations described in the item #270, Richard is now reporting (so far in private) the excess heat of ~10% at 350 V. Mills seems to be studying low voltage electrolysis. Comparing two electrolytes he reported: "0.6 M K_2CO_3 electrolysis produces 0.4 watts of thermal energy above the control Na_2CO_3 during pulsed electrolysis." The wattage is small but the COP is ~2. All this is very interesting and worth confirming. Were calorimetric studies of Mills et. all confirmed by other researchers?

As I mentioned at the beginning, the excess heat from formation of hydrinos is not claimed to be nuclear. And it has

nothing to do with condensed (crystal-like) matter. But a small fraction of excess heat reported by Mills can be nuclear. I am thinking about H_2 molecules formed from two hydrinos. The atomic nuclei in such molecules are closer to each other than in ordinary hydrogen molecules. Thus a probability of under-barrier fusion of two hydrinos must be much higher than in common hydrogen molecules.

P.S. (3/4/06):
A friend who saw the draft of this item informed me that last year The Institute of Physics (London) has published a short article on hydrinos.....You can see it at: <http://physicsweb.org/articles/news/9/8/4> But this refers to the theoretical aspects of hydrino science only. I was disappointed by not seeing a single words about experimental facts discovered by Mills and his coworkers.

P.S. (3/4/06):
A friend who saw the draft of this item informed me that last year The Institute of Physics (London) has published a short article on hydrinos.....You can see it at: <http://physicsweb.org/articles/news/9/8/4> But this refers to the theoretical aspects of hydrino science only. I was disappointed by not seeing a single words about experimental facts discovered by Mills and his coworkers.

Another friend informed me that Mills discovered cold fusion in a cell whose cathode was Ni and whose electrolyte was K_2CO_3 dissolved in ordinary water. The reference sent was: Mills, R., and Kneizys, S. P. 1991. "Excess Heat Production by the Electrolysis of an Aqueous Potassium Carbonate Electrolyte and the Implications for Cold Fusion", Fusion Technology 20, 65. I went to the library at <www.lenr-canr.org> and discovered that it has not a single paper submitted by R. Mills.

Intrigued by this I wrote to Jed Rothwell and asked him why is it so. Here is his reply: "This is because Mills has not submitted anything. We are not excluding him. All of the papers in our library come from the authors, except in rare cases such as when the author is deceased. I believe Mills was the first to observe CF in a cell with the K_2CO_3 electrolyte in ordinary water and with the Ni cathode. I would like his paper, so if anyone is in contact with him, please ask him to send it to us." <JedRothwell@mindspring.com>

P.S. (3/6/06):
Another reader supplied this information: "Dr. Reiko Notoya of Hokkaido University gave presentations on her experiments with light water electrolysis setup with nickel and potassium carbonate giving excess heat and transmutation (this is just off the top of my head). These prsentations were at the ICCF-4, ICCF-5, and ICCF-6. As I understand it, she had an active light water demonstration table set up at the ICCF-4." Did Dr. Mills attend these conferences? I do not think so. He was probably no longer part of the cold fusion group.

P.S. (11/29/07):
Discussion of hydrinos started again at the CMNS list, as illustrated in unit 338.

This website contains other cold fusion items.

285) Private correspondence before Colorado-2

Ludwik Kowalski; 2/22/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction

The outcome of Colorado-2 experiment was described in the unit #271. While waiting for the outcome of the Texas-2 and Paris-2 I decided to prepare and post this unit. It is essentially nothing more than private Internet correspondence between participants of Paris-1, Texas-1 and Colorado-1 experiments. If findings described in the item #271 are confirmed then the correspondence leading to these findings might become historically important. I will assume that readers of this unit are familiar with contents of units #252, #267, #270 and #271. The appendix following the correspondence is about Mizuno's protocol, as described at the ICCF12 (12th International Cold Fusion Conference, November 2006, Japan.

= 1

Richard --> Ludwik+ Pierre + Scott + George (9/30/05)

Just to let you know that my CF setup is running. No excess heat yet. As you can see from the picture the reaction is a lot different then what we were seeing with the Pinnacle. This is more like what the other researchers were seeing. I'm convinced that the low stored energy of the Pinnacle changes the reaction. Hope the conference is interesting. If you get a chance you might ask other how long they took to ramp up the voltage. I can't really tell from the reports.

= 2

Richard --> Ludwik (12/11/05)

I thought you might find it interesting. Last night I had one test run that indicated excess heat COP=1.40. It seems to be important to ramp the voltage slowly to the critical region. I'm using two methods of measuring power. One method is a Kwh meter, that give a pulse every 2250 joules. The other is measuring volts and amps about 600 times a seconds and calculating joules. The two methods agree within 5%. This is just between you and me for the time being. Hope your experiments are going well.

= 3

Ludwik --> Richard + Pierre + Scott + George (12/31/05)

As you probably know, from postings at CMNS, I am still in Japan. There is nothing earth-shaking to report. But, for the first time in my life, I experienced an earthquake. Not a big one, fortunately. But my bed (on the 11 floor of a 13 floor building) was shaking strongly enough to wake me up in the middle of the night.

My understanding was that Richard continued exploring excess heat in a Mizuno type cell. What are your findings, Richard? People who heard our CMNS report said we did not load the cathode with hydrogen long enough. Can five of us come to a common conclusion about the possible reality of excess heat? Pierre said that he might be able to come to the US to perform an experiment with us, and to convince us that the effect is real. Another possibility is to work together in his lab in Paris. What do you people think about these suggestions?

= =

Richard --> Ludwik + Pierre + Scott + George (1/1/06)

The last couple of weeks I have not had a chance to try any new experiments. I've not seen any excess heat in the 30 test I've run. I would be willing to go to France and observe the experiment. I would like first to work closely with Pierre to try and replicate the experiment here. As a diversion I tried to replicate the APE experiment of J.L. Naudin. This experiment has just two tungsten rods in a solution of K2CO3. I sent Naudin a couple of emails asking several questions and I've not received any response. I'm back to working with an experiment closer to Clauzon. I have a couple of questions for Pierre:

How often do you start with a fresh K2CO3 solution?
I've been heating my solution with the CFR electrodes is this wrong?
Should I be using an ohmic heater?
Do you think the current density of the cathode/anode is important?
How do you raise the voltage to the operating point? Speed rate steps
How long does it take to reach the operating point?
How do you know your at the operating point?

I know you have already answered some of these questions. Since I've not been able to reproduce the results maybe a second explanation will help.

= 5
Richard --> Ludwik + Pierre + Scott + George (1/2/06)
Pierre, Could you put together a timeline that shows your voltage adjustments and the voltage/current response of the cell for a successful experiment? I'm sure that I'm not using the correct voltage profile. You also indicate a delay in beginning the measurements as the current stabilizes. I would like to duplicate this profile if possible.

= 6
Richard --> Pierre + Ludwik (1/25/06)
I thought you might like to look at this data. I'm not sure what it means!! I'm very skeptical of these results. I'm using two methods of measuring input power one is a commercial watt meter that gives a pulse every 2250 joules and the second uses the average voltage and current reading. The graph below is several hours of testing. The yellow line is the electrolyte loss and gain (I added more water).

= 7
Richard --> Pierre + Ludwik (1/25/06)

Pierre, I'm still looking for definitive results. I had some data last weekend that looked promising. I'm just not high enough about the noise level to be positive.

I have a lot of noise in my input power measurement where I'm measuring voltage and current to get power under plasma conditions. The commercial watt meter I'm also using gives a pulse for every 2250 joules delivered. These two methods correspond to within 5% when I'm using an ohmic heater. When I am measuring the plasma input power I see a much larger difference so I'm not sure which is the most accurate. A lot of my data shows COP = 1 +/- 5% regardless of which input power measurement I use.

I'm having trouble maintaining the yellow plasma for a long time. The plasma may start out being yellow but in a short time turns mostly white. The papers seem to indicate that the proper operating point is when you have the yellow plasma for an extended time. Do you agree with this statement? I see all the changes you mentioned as the voltage is raised. I plan on doing a lot more test!!! Hopefully I'll get some definitive results soon.

= 8
Pierre --> Richard + Ludwik (1/25/06)
By the way Richard, where are you in the CFR tests ? I am anxious to know more about your experiment. Friendly yours Pierre. PS: we are trying also to duplicate the experiment of Koldamasov and Yang....

= 9

Richard --> Pierre + Ludwik (1/25/06)
" I ran a dozen experiments tonight all negative. I . . " Thanks for sharing. It seems to me that Richard has reached the point at which the best way to solve the COP puzzle would be to work with Pierre. Both of you indicated willingness to travel and work on the experiment together. Perhaps it is time to organize this; I would be happy to join you. Are you ready? When and where should we meet? Attached is the photo of Pierre

= 10
Ludwik --> Richard (1/27/06)
If going to Paris is a problem for you do not hesitate to suggest that Pierre comes to Boulder. He told me in Japan that this would not difficult for him. I would also prefer to use your setup in Pierre's presence rather than the other way around. We should not miss this opportunity to come to a mutual agreement, one way or another. That could become an interesting report at ICCF13, probably at washington DC next summer (I hope).

= =12
Pierre --> Ludwik (1/26/06):
When back from JAPAN to your home, are you always planning to see your dear aunt in PARIS ? If so, I would be pleased to arrange tests in my lab (CNAM) but also at " les Renardières" with Didier NOËL (EDF), and even with Jean-Louis NAUDIN at GIFNET (Fontainebleau). We will see after all these tests if we have to decide Richard and me to join our efforts somewhere...

= 13
Ludwik --> Pierre + Richard (1/26/06)
Pierre: My participation is much less important than that of Richard. I have not been in touch with Scott Little. Perhaps Richard was. What his attitude toward additional experiments? Since you and I are retired finding time (a week?) for an experiment in Paris is probably not a problem. But Richard has a full time job. So it is he who should suggest when we can possibly travel to France?

= 11
Richard --> Ludwik (1/27/06)
I would like very much to go to France. I had the impression from Pierre's email that he was suggesting I wait until you had review all the test. I did not want to invite myself. I would be able to go the France in late February or early March.

I think it would be better to review his working system than try to make mine work. I could bring my measurement system and we could add it to Pierre's system. This would give us great confidence in the input power measurement.

= =14
Ludwik --> Pierre + Richard (1/27/06)
Dear Pierre,
In my opinion it would be better if you could help us to confirm your results in Richard's lab than for one of us to go and witness your experiment. If you come and help us to demonstrate the COP > 1.2 in Colorado then it would be a second independent setup confirming your findings. It is not the same as one of us saying "I did not see anything wrong with the experiment performed in front of me in Paris." I am not an electrochemist. My testimony would not add much to what has already been described by you. Let Richard perform the experiment, using an independently built replica of your setup. You will watch and tell him what to do and what not to do. I assume he will be successful after a couple of days.

Suppose his results also become 100% reproducible. We would then describe the experiment with sufficient number of details and offer help to anyone who wants to be convinced that excess heat (at least several tens of watts) can easily be generated in a Mizuno-type cell. You would do this in Europe and we would do this in the US. Perhaps we can, after a year or two, convince honest mainstream scientists that the excess heat claims of Mizuno, Naudin, etc. can now be measured by any qualified researcher in any laboratory. That "missionary work" could transform the situation radically. One truly reproducible experiment will change the CMNS from proto-science into recognized science. That would be a fantastic accomplishment.

Are you able to come in February? Tell us at once and we will start talking about practical things. For example, how to minimize costs, etc. One possibility is for two of us to stay in the Youth Hostel in Boulder. That is where Richard's own home laboratory is. Boulder is less then one hour (by bus) from Denver; a major international airport. Any time interval between now and 3/2/06 or after 3/8/06 is OK for me. But we should start planning as soon as possible.

= 15

Richard --> Ludwik (2/2/06)

Have you any word from Pierre about visiting Colorado? Did you get my last email? Below is a copy. I don't want to loose the opportunity to work with Pierre on this experiment! I'm willing to go to Paris if that's what it takes!

= 16

Ludwik --> Pierre (2/2/06)

Assuming the message I sent you about one week ago was lost I am writing again. The more I think about it the more am I convinced that we would accomplish more (in terms of convincing others that COP>1 is real) if your results are reproduced by Richard. Another success with your setup will not add much to what has already been reported by you. I hope that the absence of the reply from you does not mean that you sick, or something else of that kind. Please reply at once, even if you need some time to decide about coming or not coming to Colorado.

Richard, thanks for offering us your house for staying. Where is your lab now? Is it at your home or is it in another location? I will order the airplane ticket as soon as I know that Pierre is coming, and when? To get a cheap ticket I must buy it at least two weeks ahead of time.

= 17

Richard --> Ludwik + Pierre (2/2/06)

This is great news. I'm looking forward to working with you both. My lab is now in my basement. I have a setup that will give us a little over 300 Vdc at 20 Amps on the cell. I'm using a variac, transformer and full wave bridge for rectification. It would be a good idea for Pierre to bring his electrode and anode. I still wonder about the Pt on NB for the anode. This is one common thing about Scott Little and my experiment.

= 18

Pierre - Ludwik + Richard (2/2/06)

After discussing with my friends (Pr Fauvarque, J.P Bibérian and some others), I think I will go to Denver and try to help Richard to succeed with this experiment .First, Ludwik, are you always in Japan for the time being? Do you plan to go home via Paris (France) ? If yes, it will be for us very interesting to show to you our experiment at the CNAM laboratory. Second, I thanks also Richard for offering us his house for staying. I am a retired nuclear physicist and I will go to Denver at my own expenses, so I appreciate very much this Richard's offer. Now for how long and when.? I must ask for a visa from the American Consulate and it may take a few weeks, as our french passports are not yet in the new required shape. I will try to do my best by the end of this week.

I will also see air companies for their best fares, and I think that one week of stay in the USA is required in this case. I suppose that this will be a sufficient time for our experiment, as Richard must have already the necessary equipment. I think that the possible period could be for me between March the 6th to the end of March. Tell me please, both of you, if this proposal seems reasonable and, of course, as soon as possible. As you can see, I believe in cold fusion....

= 19

Ludwik --> Pierre + Richard (2/2/06)

I returned home about ten days ago. And only now is my biological clock more or less normal. I am glad that you are able to come to Boulder. If you are a skier take what you need and I would then do the same. But this is not as important as our experiment. I did not know that French citizens need visas to visit the USA; is this something new? Richard will probably tell us when is the best time to come, considering his regular work. Any time after March 8 is OK with me.

Can you bring your Pt anode; this would eliminate one possible uncertainty ("anodes are not identical")? Also one or two French tungsten rods, just in case this makes a difference. We should probably start discussing everything that can help us to succeed. My mind was away from this topic for while but I will review what I knew.

= =

Richard --> Ludwik + Pierre (2/2/06)
This is great news. I'm looking forward to working with you both. My lab is now in my basement. I have a setup that will give us a little over 300 Vdc at 20 Amps on the cell. I'm using a variac, transformer and full wave bridge for rectification. It would be a good idea for Pierre to bring his electrode and anode. I still wonder about the Pt on NB for the anode. This is one common thing about Scott Little and my experiment.

= =

Pierre --> Ludwik + Richard (2/3/06)
You were right, Ludwik ! I have no problem with my passport, quite new, and I don't even need a visa. So now, we have to agree for the week at Boulder. Are you OK, Richard and Ludwik, for the week starting from March the 6th? Thanks in advance for a quick reply. Friendly yours........PS: of course, I will bring with me anode, cathodes and wattmeters…and maybe clothes for skiing!

= =

Ludwik --> Pierre + Richard (2/3/06)
I can come on Wednesday, March 8, or later. I suspect that Richard would probably prefer us to arrive on Friday because he has a regular job. . . Richard wrote "I will bring with me anode, cathodes and wattmeters. ..and maybe clothes for skiing!" That is good. What else would be worth bringing, Richard? You wrote that the highest voltage of your homemade power supply is 300 V. Is this enough? The COP was 1.35 at 350 V, and much less at 300 V. We certainly do not need 20 A. But going up to 370 V would very desirable. (Possible systematic and random errors of ~5% could prevent us from accurate measurements of COP below 1.10 or so.) What limits the voltage of your power supply? Can the limit be pushed up if we sacrifice the amperage? I am thinking about going down to below 4 A, as in many Naudin's setups. What about adding another front-end variac?
.

= =

Richard --> Pierre + Ludwik (2/3/06):
The week of the 6 is ideal for me. One of my sisters will be skiing a Breckenridge starting the 11. She has a condo and we could stay one night there and ski a couple days. Ludwik I think you can ski free since you are over 70. I have additional family coming in starting March 15. Since Ludwik can't come until the 8th lets plan to run the experiment from the 8th to the 15th. If you need to come a day earlier or leave a day later that's OK. My basement is not really a lab but I have all the equipment we should need. I have plenty of K2C03 500g. I've been using just distilled H20 I've thought maybe we should use de-ionized distilled H20? I have 6 mm tungsten rod 0.3 meters long. It is very pure tungsten rod. I was burning so many of the 2-4 welding rods I purchased some larger diameter rod.

= =

Ludwik --> Pierre + Richard (2/4/06)
(3) I just spoke with Richard and he said that the power supply goes to 450V, not only 300V, as he indicated below. That is good, Pierre's COP at 300V was small but it was ~ 1.3 at 350V.
(5) I am very happy that we will be working together in about a month.
(6) Attached is a file with our recent correspondence. Please give me permission to attach it as an appendix to unit #271. That unit will be devoted to our upcoming experiments.
(7) Let us hope it will go to a museum (Palais de la Decouverte in Paris?) one day. But the precondition for this is to produce a protocol that can be used by any qualified researcher to demonstrate reality of excess heat anywhere in the world. That would certainly change our proto-science into science.
(8) We know what we wish to accomplish. But, hopefully, this will not prevent us from being objective. Let us hope for the best.
(9) We will have a lot to do after excess heat results become reproducible. The next step, both in Paris, Texas and

Colorado, will be to optimize excess heat, one parameter at a time. Right?

= =

Richard --> Ludwik (2/9/06):
Looks like Scott doesn't think it will work. [He wrote]: “Thanks for the invitation, Richard. Frankly, I just don't think the chances of any change in the outcome of that experiment outweigh the expense and time of the trip, despite the favorable location you have. Of course, if you guys do get o-u results with Clauzon's assistance, I would be honored to have the opportunity to perform the first independent replication of those results. Our apparatus is all still in one place and could be resurrected quickly and easily. Good luck. Stick to your principles and demand good measurements.”

= =

Ludwik --> Richard + Scott (2/10/06):
I am not surprised by Scott's reply. He has spent much more time on trying to confirm excess heat from Mizuno-type cells than we did. And each time the excess heat was nearly zero. In his place I would probably feel the same way. But I am glad that Scott remains open-minded. Let us hope that our results will be different. I am glad that he is ready to try again, if we succeed.

Pierre (and his friend Paul Biberian) think that our failure to succeed was due to insufficient preparatory loading. Paul is an electrochemist. My reaction to this (during a dinner in Japan) was “but we followed your protocol. If loading (by increasing the current gradually) is so important then why was it not even mentioned in your paper?” They smiled and said that such things should be obvious. Our description of the protocol, if the COP>1 is confirmed, should be much more detailed.

= =

Richard --> Ludwik + Pierre (2/9/06)
Ludwik, I found out today that there is a way to run the Pinnacle on 220 single phase power. I’m going to borrow another Pinnacle so that if we are successful with the variac system we will be able to use the Pinnacle and confirm our results. This will also let us go to much higher voltages. I think now that there was something wrong with our first experiments.

Pierre,The Pinnacle is a programmable power supply that can deliver 0-800 Vdc in single volt increments. The supply can be programmed to regulate the voltage current or power. The supply is designed to deliver continuously 20 kW yes 20,000 Watts. In our case we will be limited to about 4 kW. It also reports joules deliver to the output. We had some difficulties with it during our first experiment but I’ve learned a lot since then.
Richard

= =

Richard -->Ludwik (2/10/06):
This is just between you and me. Tonight for the first time I saw the current drop when it’s suppose to and the reaction inside the beaker became more placid. These are thing that have been described by other researcher but I’ve never seen. I’m very optimistic about the upcoming experiment. Lets all have very positive thoughts. This is going to be a lot of fun.

= =

Ludwik --> Pierre + Richard (2/10/06)
I think that it is not too early to discuss the strategy we would follow if the COP>1 were definitely confirmed in our Boulder experiment. Presenting our results over the Internet, and at the ICCF13, is worth the effort but this is definitely not enough. I am thinking about many good reports that have been published in that way but had very little impact on the overall situation.

What should we do to convince mainstream scientists that a truly reproducible experiment now exists to explore a puzzling “excess heat” phenomenon? Our weakest point would be the inability to rule out a possibility that a chemical fuel might be responsible. Reviewers will not fail to notice that non of us is a chemist. I suggest that we ask Fauvarque, or another recognized electrochemist, to write a detailed appendix entitles “Excess heat cannot be of

chemical origin." He can probably do this now, on the basis of what has been done in Paris. Our paper would be stronger with an author who is an electrochemist. Samples of materials we used (pieces of electrodes, salt and water) should be preserved for future examination, if necessary. The paper should be sent to a mainstream journal. But it should not be a journal known for its unfair attitude toward CMNS. Any suggestion? Our paper should not mention cold fusion; it should refer to a "puzzling 100% reproducible, and simple to demonstrate" phenomenon. What else can we do to produce favorable attitude of mainstream scientists toward our findings?

= =

Richard --> Ludwik + Pierre (2/11/06):
When we have positive results that are reproducible I'm sure that we can get the help of several people at Fermi Lab to help publish this in the manner that will get the attention it deserves. My sister Jean Slaughter will be here later in March. If we can show her positive results she will be a big help at Fermi Lab. I've had emails from several others at Fermi that show real interest in CF.

= =

Pierre --> Ludwik + Richard +his colleagues: (2/13/06)
A message from Naudin is shown and Mizuno's ICCF12 paper is attached. Naudin wrote: "Pour info, regarde en PJ, le compte-rendu complet de Mizuno sur l'explosion de son CFR... C'est très intéressant, je pense qu'il a eu une nano-explosion nucléaire sur la pointe de son CFR... Soyez donc prudent dans vos manip à Denver..."

= =

Ludwik --> Pierre + Richard (2/13/06):
1) Thanks for the attached file (Mizuno). Very interesting. I do not recall him presenting this at ICCF12; perhaps I was too tired to pay attention.

2) Here is my description of Mizuno's protocol, based on this ICCF12 report:

Mizuno's Protocol (ICCF12 paper) K2CO3 at 0.2 M (700 cc in 1000 cc beaker).

a) Wait 3 minutes at V=0 (to show that cell temp=constant=30C
b) At t=180 sec start increasing V for about 30 sec. At t=210 s the voltage becomes 40 V.
The current during that 30 s time interval goes up with voltage and becomes 1.9 A.
The cell temperature is essentially constant 30 C.
c) Keep the voltage constant (40 V) till t=300 s. The current remains 1.9 A. The cell temperature goes up to ~31 C.
d) Sudden change of voltage to 65 V at t=450 s. The current starts growing rapidly, up to about 3.5 A.
e) Another sudden change of voltage (to 65 V) at t=550 s. The current becomes 4.7 A and then it starts going down rapidly. At t=700 s the current is 3 A; at t=2000 s I=2 A. The voltage is still 65 V at t=2000 s. The cell temperature at t=2000s is about 65C. This is far below boiling.
f) At t=2000 s the voltage is suddenly changed to 100 V. It remains 100 V till t=2500 s. The current also drops suddenly from 2 A to 1.6 A and then continues to decrease slowly. The cell temperature stabilizes at about 70 C. It never goes much higher.
g) Between t=2500 s and t=4500 s the voltage is changed, in eight small sudden steps, up to 250 V. Each step is by about 20 V, Once the voltage is changed it remains constant for about 6 minutes. The current keeps going down till t=3000 s; then it remains nearly constant, about 0.7 A.
h) At t=4500 s the current starts growing and the voltage is turned down. That is the end of one experiment.

3) This protocol is not good for us because only very small (hard to measure) amount of water will evaporate at 70 C, even if we wait for 2 hrs. Non-evaporative heat losses (conduction and convection), instead of being small, will become dominant.

4) I suggest that before coming to Colorado Pierre describes the boiling water protocol, more or less as Mizuno did (two graphs describing time dependence of three parameters). Also all qualitative observations, such as color and size of the plasma region at different times, relative strength of light emitted (going up, going down, remains about the same, etc.) We are going to replicate your boiling water experiment, not Mizuno's experiment with two calorimeters.

Protocol details will be of great help to us. Unless you already have them, I think that repeating the experiment (to collect as much information as possible), say at 350 V, is worth the effort.

5) What do you two think about my suggestion (in another message) to have a reputable electrochemist, for example, Fauvarque, on our team? He does not have to be present during the experiment. But he will write a detailed appendix about the upper limit of chemical energy that might possibly be in the excess heat we measure.

= =

Richard --> Ludwik + Pierre (2/13/06):

Your right the protocol is not good for our test setup. It is confirming what I've noticed recently that I've been rushing the test. Up until a few days ago I thought that each test would only take fifteen to twenty minutes the time it takes to boil off 30-40 g. Recently I've be giving the test a much longer soaking period at lower voltages. This changes the appearance of the plasma at the higher voltages.

I'm looking forward to trying the Pinnacle again. It will let me program the exact function described below. If we can setup a repeatable function that produces excess heat that will be a great help. Pierre if you could provide a similar step description then I can have the Pinnacle programmed before you arrive. The other advantage of the Pinnacle is that it is designed to maintain plasma in gasses. It has a feature that suppresses arc when they are generated in the plasma.

= =

Ludwik --> Pierre + Richard (2/14/06):

Plotting Mizuno's protocol as amperage (vertical axis) versus voltage (horizontal axis) one gets an interesting curve. Up to about 70 V the current grows with voltage, up to 4.7 A and after 70 V it decreases with voltage, down to 0.7A at ~200 V. How can this be explained? At low voltages the electrolyte is like a resistor (about 20 ohms). But R becomes much larger when a column of gas is formed around the cathode. At higher V the column becomes thicker and R goes up accordingly. That is the glow discharge mode. Above 250 V the current starts to go up because the arcing mode starts to develop.

I see no reason why what happens at 70 C should not happen at 100 C. The only difference is that the removal of the electrically generated heat at 70 C is done by cooling water (of their flow calorimeter) while at 100C this is done via rapid evaporation (boiling). Our last summer protocols were very different from the one described by Mizuno. That is why I am optimistic about the next experiment.

= =

Pierre --> Richard + Ludwik (2/15/06):

I did receive your recent e-mails about Mizuno experiments, but I have to think more about that ... During the two last months, the Fauvarque lab was very busy with works to do for external contracts and my friend Gérard was not free to work with me ... But, yesterday, in the course to prepare my Boulder trip, we operate again our CFR experiment. We have to confirm the results obtained, but I am very glad to tell you that at 300 volts we got a COP value of 1.13 and at 350 volts a COP value between 1.35 to 1.40...(as in our YOKOHAMA paper)

Of course, the real problem is the validity of the measurement of the inlet energy. To morrow, we will try to have in front of all the experimental set up a second wattmeter in order to confirm the value of the measured watt-hours ... One point important, a good calibration with the auxiliary heater. Richard, do you have two electrical supplies? We think that the continuous water feeding does not work very well. So, now we do not use it any more and we just readjust the water level between two following tests ... I will bring with me cathodes, anode, the wattmeter used, ... OK, Ludwik, I will ask Pr Fauvarque for the appendix we need concerning the chemical energy reactions .. See in picture joined my friend Gérard preparing our experiment with me...

= =

Ludwik --> Pierre + Richard + Gerard (2/15/06):

1) Thanks for the picture of Gerard. I am glad that he and you are performing confirming experiments. Please send us details of the protocol -- for example in the form of a table with three columns (time, volts and amps). Also additional

details about the plasma column (color, intensity, etc.). As you certainly know, many details are usually forgotten later. The best time to describe is immediately after experiments. This will allow us to comment on your observations.

2) One way to be certain the your input energy measurements are reliable is to deviate from the protocol drastically. Try to use pure water. At ~10 volts you will see a lot of bubbles; this is ordinary electrolysis. They will probably be ionized at high voltages and plasma will be formed (perhaps a different color?). If this produces the COP=1 then the electric energy is measured properly. Another way to drastically deviate from the successful protocol would be to change polarity (making Pt negative and W positive). P.S. I see that Richard (in a message that just arrived) also suggests deviating from the protocol.

= =

Richard --> Pierre + Ludwik + Gerard (2/15/06):
Yes I have two electrical supplies. I've been doing my calibration using an ohmic heater and the same supply I used to drive the cell. The ohmic heater is a 250 Volt 400 Watt device. I get the electrolyte boiling as vigorously as possible and measure the evaporated loss and input power. The non-evaporated loss always seems to be about 11 percent of the evaporated loss. Using the 11 percent in my calculations always gives me COP=1.0 +/- 0.03. Occasionally I've had anomalies where the COP has not been 1. The COP results have been both above and below 1. Until I rule out other explanation for the results I can't claim excess heat. I'm encourage by my latest data. I also tried the continuous water feed and gave up. I felt I could not keep track of the temperature of the extra water.

= =

Ludwik --> Pierre + Gerard + Richard (2/16/06):
Hi again. Another thought on your electric energy measurement. The fact that your COP is voltage-dependent seems to a reasonably good argument against a systematic error. Why would an instrument have a voltage-dependent systematic error? Why would the COP be 1.0 below 200 volts only? But, considering very high standards imposed on CMNS researchers (extraordinary claims need extraordinary evidence), a demonstration that the COP=1 at 350 V, when pure water and two Pt wires are used, would be extremely useful.

Our goal, at this stage, is to publish a paper in a mainstream refereed journal. We should anticipate all possible accusations and address them before they address them. That seems to be the only way to win. So far we identified two "weak point" (a) chemical origin of excess heat and (b) a systematic error in measuring electric energy. What else should we address?

= =

Pierre --> Richard + Ludwik + Gerard (2/18/06):
I send you a figure giving you the abstract of our 4 last CFR measurements made in order to prepare my trip. (Ludwik, trying to please to you, I put the power now in abcisses) . As you can see, our tests give good results, values going from COP = 1.14 (300v) to COP = 1.46 (350v)... I am planning to write down our experimental protocol and I hope to send it to you once corrected by Gérard by next monday or tuesday. Richard, as you can see, once over about 300 watts, the thermal losses are constant and we get a straight line parallel to the line with thermal losses equal to zero (2260j per G). I do not understand your results giving thermal losses equal to 11% of the power, whatever the value of the power. An explanation for not finding COP>1.0 ? As the matter of fact, once all temperatures being at equilibrium, the thermal losses must be constant and the slope of the line gives you the value: 2260 j/G. Please do not hesitate to give me your comments... I may be mistaken of course!
[The attached graph shows that four new measurements were made with the following results:

= =

Ludwik --> Pierre + Richard + Gerard (2/18/06):
1) I am glad that Pierre's new results are consistent with what was shown at ICCF12.
2) And I like to see the 2260 J/g label (no cold water is added during an experiment)
3) It would be easier to make comments if tables with raw data were presented. Here is a suggested format:

Table 1 (Ohmic heater:)

Volts Amps (seconds) evaporated (grams)
25 ....
37 ....
51 ....
62 ....
78 ....

Note that I am using font "courier" to create a table. It usually helps. Just cut and paste each table and replace dots with numbers

Table 2 (electrolysis:)

Volts Amps (seconds) evaporated (grams)
300 ....
300 ....
330 ....
350 ....

If Pierre's protocol is similar to that of Mizuno [see the appendix below] then neither volts nor amps remain constant during an electrolysis experiment. In that case Table 2 would refer to mean values. I would like to see a table with v(t) and i(t) for each of your four experiments. That would be a complete set of raw data.

3) I do not know how to answer the question about the 11%.

4) One thing should perhaps be added. If what was actually measured was electric wattage, P, (not current) then the wattage should be specified in the columns with raw data. And the protocol should be V(t) and P(t). If the protocol was similar to that used by Mizuno then P was probably not changing very much during each experiment. That is because i(t) was going down when v(t) was going up. But the P(t) curve is needed, unless P was exactly constant, which is very unlikely. The best is to measure all three things independently v(t), i(t) and P(t). That what we should try to do in Boulder; do not forget to bring the wattmeter, Pierre.

= =

Gerard --> Ludwik + Richard (2/20/06):

CNAM CFR EXPERIMENTAL PROTOCOL:

First, we take care of the electrodes, essentially the cathode. We verify that the bottom of the tungsten cathode not covered by the ceramic tube is about 1.5 to 2.0 cm long. The ceramic tube must go at the other end out of the electrolyte level by 3 to 5 cm.

In our case of a beaker of 2 liters volume, the electrolyte level corresponds to about 1200 cubic cm . (0.2 M of K2CO3)

Then, we begin the abacus of the thermal response by operating the ohmic heater. When temperatures equilibrium are achieved , we plot the answer on a graph, 100 watts of electrical power by 100. We send you an example few days ago.

Then, the beaker remaining at about 100°C due to the previous calibration, we put the electrical supplier on. We increase slowly the voltage. We observe pink sparks usually at about 100 v, but when the cathode is brand new the sparks begin at higher voltages (120 v to 150 v).

Then we increase smoothly the voltage and observe the mean current intensity :

150 v 1.6 A
170 v 2 A

200 v 2 to 2.2 A

The light of the cathode is uniformly orange. Then we continue to raise the voltage :

200 v 2 A to 2.8 A

Light becomes milky orange and you can see that the intensity seems to reach a kind of asymptote…

<u>Picture of the setup (showing the orange glow around the cathode) was included.</u>

Then when we arrive to about 300 v, the intensity in A usually begins to decrease . The light is between yellow and orange. Some small explosions can occur and we verify then if there are not short cuts. We verify too if our grid anode is able to control the movements of the electrolyte. If not, we must dispose some Teflon grids in order to calm the electrolyte waves. We verify also if there are not too much droplets out of the beaker…

Once a value of voltage is chosen, we wait for a while to see if everything look stabilized. Then we begin our measurements by 5 minutes runs. Usually, we disregard the first one and we keep the two or three following runs if they give about the same results.

Then we go on for other voltages after verifying the cathode length….

The measurements consist only to get the values of watt-hours used and the weight of the missing water . The watt-hours gives us the mean electric power and the missing water the thermal power… That's all folks

= =

Ludwik --> Gerard + Richard + Pierre (2/20/06):

Thanks for the protocol description, Gerard.

1) According to Google, "Unigore 390," is a digital instrument to measure ac and dc wattage. Your p(t), i(t) and v(t) keep changing during each experiment. I suppose you record samples of these three parameters. Right?

(a) Is it correct to assume that the averaging of samples is done electronically inside the instrument? In that case each recording is already a mean value from many samples. How many samples per recording?

(b) How often do you record mean values of p, i and v? I suppose that averaging of mean values is performed manually, after each experiment. By am not sure. Perhaps only p(t) is averaged.

c) What do you do to keep the voltage constant, for example 350 V, during an experiment?

2) What do you think about my suggestion to demonstrate that the COP=1.0 at 350V when pure water is used? I am assuming that our Boulder experiment will focus on your 350 V result (because of the large COP).

3) Richard, are you OK? You have been salient for several days. I hope to hear from you after you come home from work today. That would be about 20:00 by New York time. Pierre and Gerard will probably be in beds. I think that discussing details can be useful to all of us. Three weeks from today we will be in the middle of our attempt to succeed.

= =

Ludwik --> Pierre + Gerard + Richard (2/20/06):

Hi folks: Suppose our Boulder experiments confirm, without doubt, that the COP at 350 V can be as large as in Paris. What will we do with such success?

1) Should I assume that, at this stage, our main goal would be scientific and not commercial? Commercial attitude

usually means secrecy while scientific attitude implies openness. My suggestion is to remain scientific. The goal should be to reverse the current unhealthy attitude of mainstream science toward CMNS. Do we have the same attitude about this?

2) I am not against being involved in attempts to become practical. It would be nice to find a sponsor with "deep pockets" willing to built a large and well equipped lab. Than a systematic investigation of materials and parameters can be organized in order to scale up the COP. But this should come naturally later. Let them come to us when our undeniable success is recognized by mainstream science. How to achieve such success? That is a big question. Having a 100% reproducible demos, one in Paris, one in Boulder and one in Texas, would be our first step.

3) And what should we do next? That is what I would like to start discussing.

(a) How to succeed in publishing a paper in a mainstream referee journal?
b) What "public relation" steps should be undertaken?

I have some ideas about these things. But first I want to know what three of you think about being completely open at this stage of the game. Nothing will be hidden from those who want to replicate our findings. One thing we should not do. You probably guess what I am thinking about. A press release would be highly undesirable. But going to as many scientific conferences, with working demos, would be OK. Nobody will object if an experiment is performed in front of scientists. Demos coordinated with handouts, and with good web pages, can be very effective. And we will be addressing experts, not journalists. In fact we will be inviting them to either confirm or to refute our findings experimentally. Nobody will accuse us of sensationalism, or of bypassing "normal ways" of reporting new findings.

= =

Richard --> Ludwik + Gerard + Pierre (2/20/06):
Hi All, I'm fine. I've been working mainly to make sure all the equipment is working correctly. I'm also trying to set up a second cell so we can run two experiments at once. Ludwik you mention earlier that you had a triple beam balance. Could you bring that along? I'm watching EBay for a second electronic balance so I can record the data to my computer like we did before. I've also been checking my calibration based on your protocol Pierre. I see some differences from one calibration to the next. It is just measurement accuracy but I would like it to be closer.

What do you think of the idea of getting 5 or 6 publish scientist, that are not part of the CF community, to sign a letter stating that they have examined our methods and data and think the paper should be published. The letter would be written in such a way that they don't have to agree with results only that the methods and procedures are valid and that the paper deserves to be published. We might have to demonstrate our experiment to get their cooperation. The letter would be part of what is submitted for publication. I agree that our paper must not mention CF or make any suggestion as what is happening. We stick closely only to the claim of over unity output to input. Your suggestion of getting an Electro-Chemist to state that it is unlikely to be chemical in nature is a good idea. I'm just afraid that anything submitted that hints of CF, free energy over unity etc. will just be rejected without some traditional scientific support. We might submit the paper to several journals stating clearing that this is what we are doing. If done right we might create just enough competition that the journal feel obligated to publish.

= =

Ludwik --> Richard + Gerard + Pierre (2/20/06):
Richard: (1) The idea of submitting our paper with a signed letter of recommendation is good. In fact we may send this letter ahead of time and explain why we decided to do so. Then we would ask if the editor wants us to formally submit the manuscript to be reviewed. (2) You forgot to answer my question about being scientific or being commercial. (3) I will bring the triple balance; it will give us the mass lost +/- 0.2 grams.

= =

Richard -->Ludwik + Pierre + Gerard (2/23/06):
Once again thanks for the protocol. I feel like I'm learning to ride a bike. Each session of running the experiment I feel like I'm getting better results. I still haven't seen the rates in your paper but the data is improving.

= =

Ludwik --> Richard + Gerard + Pierre (2/24/06):
Hi Folks: How is everybody? I am recovering from a little cold. Better now at home than later in Boulder. Attached is a file that I want to post on my website today. It will open in a browser. Do you want me to say something more about our upcoming experiment?

= =

Pierre --> Ludwik (2/24/06):
Bonjour Ludwik,

J'espère que vous avez retrouvé une bonne santé et que nous nous retrouverons tous à Boulder en pleine forme... A propos de votre récente question, personnellement, je préfèrerais attendre que nous ayons terminé nos expériences avant d'en parler. Mais ensuite, bien sûr, il faudra en parler, qu'elles soient négatives ou positives. Une annonce faite avant risque de nous mettre sous pression ... et perturber ainsi les expérimentateurs.

Vous savez que la mesure de l'énergie d'entrée est un des points qui fait l'objet d'interrogations... J'ai lancé une expérience décrite ci-dessous qui est censée ne pas faire appel à des considérations électriques pour fournir une réponse..
Dîtes moi ce que vous en pensez... Bien sûr, je vous transmettrai lundi ou mardi les résultats (et en anglais pour Richard !). Excusez-moi de vous envoyer ce mail en français pour gagner du temps. Amicalement Pierre

= =

Pierre --> Ludwik (2/24/06):
Bonjour, Pour tenter de valider les indications de notre wattmètre, nous avons lancé hier après-midi une expérience avec Gérard en mettant en série la résistance de préchauffage (R=45 ohms) avec le CFR... L'expérience a très bien fonctionné et pour 300 v aux bornes du CFR, nous avions comme prévu 80 v aux bornes de la résistance... Ainsi, la résistance était soumise à une intensité très hachée de type CFR...

Seule variation notée : si nous avions bien au total 380 v constant, les 300 v CFR et les 80 v résistance étaient variables... Il fallait s'en douter ! Pas de difficultés majeures cependant pour comparer l'échauffement de la résistance avec les watt-heures mesurés aux bornes de la résistance dans cette expérience. Les premiers résultats ont montré une bonne cohérence, mais il nous faut confirmer avec un plus grand luxe de précautions pour obtenir une bonne précision... Ci-joint le schéma du montage utilisé. Amitiés PPC

= =

Ludwik --> Pierre (2/24/06):
I agree. References to our work will be omitted. I like your very clever approach.

= =

Ludwik --> Richard + Pierre + Gerard (2/24/06):
1) Responding to my message Pierre suggested that we should not advertise our upcoming experiment (as I did in the draft of unit #281). I agree that this would put us under unnecessary pressure. Therefor I remove references to our upcoming work.

2) After the experiment we will share the results widely, either positive or negative. In other words, it is a science project and nothing will be kept secret.

3) Pierre's message is in French. They are performing a very clever experiment whose purpose is to show that the wattmeter can be trusted, even when the current is highly irregular. The detailed description of results will be sent to us (in English) either on Monday or Tuesday.

4) Here is my understanding of what Pierre and Gerard are doing right now. The plasma cell is connected in series with a beaker that contains the ohmic resistor (45 ohms) in water. The power supply voltage is increased to produce the glow discharge in the cell. The only purpose of the the plasma cell is to produce the irregular current through the

ohmic resistor.

5) The beaker containing the ohmic resistor is on the scale and the rate at which water is being evaporated is measured. The wattmeter measures the rate at which electric energy is received by the ohmic resistor. Let us hope that the electric wattage and the thermal wattage will be identical.

6) What is not clear to me is which potential difference should be 350 V, on the plasma cell or on the ohmic resistor. I think that it should be on the ohmic resistor, because that is where the wattmeter is. They are calibrating the wattmeter. The only reason to have 350 V on the plasma cell as well is to be sure that the current waveforms are essentially the same as during the excess heat experiment. Ideally each beaker should be at 350 V. Another possible approach would be to replace the plasma cell by a vibrating contact, for example, from an old doorbell or from a Tesla coil.

7) I still do not know how the wattmeter data are recorded. Do they just read the numbers, for example, every 5 seconds, or do they record numbers electronically at much higher rate.

8) I suppose the distribution of the power-supply voltage between the two beakers is controlled by changing the resistance of the ohmic heater (nichrome wires of different lengths, for example, from an old home heater or from a student laboratory rheostat).

300 V, P_el = 403 W, P_th=459 W) COP=1.14 I=P/V=1.34 A
350 V, P_el = 730 W, P_th=1070 W) COP=1.46 .I=P/V=2.09 A
300 V, P_el = 379 W, P_th=462 W) COP=1.22 I=P/V=1.26 A
330 V, P_el = 439 W, P_th=572 W) COP=1.30 I=P/V=1.33 A

These results are consistent with what was reported by Pierre at ICCF12.]

= =
Richard--> Ludwik + Pierre + Gerard (2/24/06):
Pierre's suggestion not to advertise is good. I like Pierre' check of the watt meter. I've been using two methods of measuring input power since beginning of January. One is an AC Watt meter just after the Variac. The second is measuring V(dt) and I(dt) at the cell. These two methods have agreed within +/- 3%. I have strong confidence that the plasma current is random about a mean so errors are unlikely. Essentially I've been using the watt meter with highest reading as my input power. During calibration I get very consistent results. During the experiment if every thing runs smoothly the two watt meters agree. The AC Watt meter gives a DC pulse every 2250 Joules. At high power rates it's easy to miss a pulse this leads to some discrepancies. This is one of the items I've been working on to improve.

= =
Richard--> Ludwik (2/25/06):
I've been using 2260 joules/g for the vaporization of water. This is for sea level. Water boils in Denver at 97.3 degrees. Don't we need to use a slightly lower value for the Colorado experiment? Unfortunately the amount of excess heat I'm seeing is about 10%, if I have the right conditions. This is just to close to experimental error. I've been rechecking my calibration.

= =
Ludwik --> Richard (2/25/06):
I am happy that you measured the excess heat of 10%. Was this at 350 V? I do not think that difference between your ~10% and the ~35% in Paris is due to the pressure difference. But this is worth investigating. I do not know how L depends on the pressure and temperature. But I know that L does go down when the temperature goes up; it becomes zero at the critical point (374.1 C and 218.3 atmospheres). So at 97 C L is probably only very slightly larger than 2260 J/g.

Viscosity, like L is an indication of how strongly molecules attract each others. That is why I suspect that the temperature dependence of L for water is about the same as of its coefficient of viscosity. Here is a table for the viscosity coefficients:

degr C coeff
==========
0 1.787
10 1.307
20 1.002
30 0.7975
.....
80 0.3547
90 0.3147
95 0.2975
96 0.2942
97 0.2911
98 0.2879
99 0.2848
100 0.2898

As you can see, it is only 1% between 100 C and 97 C.

= =

From Pierre --> Richard + Ludwik + Gerard (3/1/05):
We made with Gérard the planned experiments with a resistance of 98 ohms on this Monday. The results obtained are quite encouraging. The deviation between thermal power of the resistance (measured with boiling) and the electric power as measured by our wattmeter was in most cases smaller than 2% and in one case equal to 3.7%. The current was the same than the CFR current... with a COP of about 1.12 to 1.14 (voltage on the CFR = 250 volts and total voltage, CFR + R, equal to 407 volts). We try 300 volts with the CFR but we got 460 volts for the total (CFR + R) and then it was too much for the power supply which caused some trouble to the wattmeter (intempestive stops). I will bring with me our technical paper on this subject. I ask again about my passport and both the air company and a travel agency told me that no visa was required for my passport... So I hope that I will have no trouble to go to DENVER...See you soon at Boulder...

= =

Ludwik --> Pierre + Richard + Gerard (3/1/06):
Pierre: Thanks for good news. I suggest you bring the 98 ohms resistor to Colorado. Richard's Pinnacle power supply will probably have no trouble to extend the calibration of the wattmeter to 350 V. In my opinion we should focus on electrolysis at 350 V because the COP is large and small errors (up to 5%) can be tolerated.

= =

Ludwik -- Scott (3/5/06):
. . . P.S. I am going to Colorado next Wednesday. Pierre, who is going to work with us, does not want to advertise our work because it will create unnecessary pressure. But he agree that results, either positive or negative, will be published after our work is completed. Hopefully this will be done in one week. Too bad that you are not able to come. We will be staying in Richard's home; his shop is in the basement. I will be happy to bring an additional sleeping bag. I wish you could be part of this combined effort to solve the controversy, one way or another.

Pierre will bring his wattmeter; it has been recently calibrated for the rapidly oscillating current. To accomplish this he used two cells in series. The purpose of one cell (plasma electrolysis) was to produce randomly oscillating current. The current was flowing through the ohmic resistor in the second cell. The rate of water evaporation from the second cell was giving them the thermal wattage. It was essentially the same as the input wattage from the wattmeter. Two weeks ago they measured the COPs again, at several voltages up to 350 V. This confirmed their results reported in Japan (COP =1.35 at 350 V).

= =

Scott --> Ludwik (3/5/06):

Good luck in Colorado. I trust you and Richard will not let Pierre "get away" with any measurement errors. If you do see a COP of 1.35, everything must be checked and double-checked before it can be accepted. In fact, I would say that an excellent test of the validity of such a result would be to repeat the tests in our lab. If WE also get a COP of 1.35 and we cannot find a mistake in the measurements, it will be time to celebrate, no?

= =

Richard --> Ludwik (3/6/06):
What do you think of one of these as a title for our paper. (a) “Does Plasma Experiment Violate First Law of Thermodynamics?” (b) “Help Plasma Experiment Violates First Law of Thermodynamics!, (c) “Plasma Experiment Violates First Law of Thermodynamics.” Just musing.

= =

Ludwik--> Richard (3/6/06):
1) I think that the title should more modest. Otherwise discussion will degenerate away from what we want. A sensational title would hurt us. If we are convinced that a really reproducible protocol has been found then the title should be something like "A simple reproducible protocol for observing the unexplained excess heat." We need independent confirmations, hopefully from many people, that our protocol is truly reproducible.

2) In my opinion we should follow the French protocol at 350 V only. Let not even try lower voltages because this would force us to address the issue of small error. The COP=1.3 or 1.4 would be much easier to "sell," and much easier to confirm by others, that smaller COPs. Pierre will be with us for 5 days only. Let us not try to do too many things at once. We will need many control experiments at 350 V. Also at least ten clean experiments to establish the mean COP and the standard deviation. The last day with Pierre (3/13/06) should be devoted to the draft of the article.

3) Do you still want me to bring the second (not electronic) scale? If so then reply as soon as possible; I am going to the university this evening.

= =

Richard --> Ludwik (3/6/06):
I didn't get a seconds setup running so there is no need for the scale. I suspect you are correct about the title. We want to be taken very seriously. I'm fairly convinced of the presence of excess heat at 350 Vdc. Unfortunately with my setup I only seem able to reproduce about 10% is excess of the input power.

= =

Ludwik --> Richard + Pierre (3/6/06):
My arrival to Denver, at 16:44, is by Continental (flight 728 from Newark, March 8) I will be waiting for Pierre near the fountain at the center of the main terminal. His arrival is at 18:29 (United flight 919 from Paris, March 8) I will turn my cell phone (portable) on at Denver. The number will be (862)-686-5053. See you both on Wednesday evening.

= =

Pierre --> Richard + Ludwik (3/6/06):
I did receive your mail and hope to see you soon. By the way, I send to you enclosed an internal technical paper on our wattmeter tests. (excuse me, Richard, it is in French, but I think it is understandable).I will have also others items to discuss with you. See you both on Wednesday...

= =

Ludwik --> Pierre + Richard (3/6/06):
If it is not too late I would suggest that you also bring some potassium carbonate so that we can use it to prepare the electrolyte. Perhaps it has something that Richard’s salt does not have. Or just bring a bottle with already made electrolyte; perhaps the missing ingredient (Strorms calls it NAE) is in your water. How else can we explain that that at 350 V you have the COP between 1.3 and 1.4 while Richard has only 1.1?

Ideally you should bring the entire setup. But that is probably too heavy. Once we get the COP comparable with what you measured at 350 V then we should try to get the same with the setup prepared by Richard (his salt, his water, his beaker, his electrodes, etc.). You will be in Colorado for only 5 working days. We should use this time as productively as we can. In my opinion we should concentrate on what seems to be the easiest, on 350 V. Working at lower voltages would force us to address difficult issues of small errors while at 350 V the total systematic errors of 5%, or even 7%, would be irrelevant.

Once we confirm your result we will have to measure the COP, at the same voltage, at least ten times. This will allow us to determine the mean value and the standard deviation. Referees of our paper would insist that this is necessary in a paper claiming high reproducibility. Then we must describe the protocol as accurately, and as clearly, as possible and wait for at least several confirmations from mainstream scientists. Turning protoscience into science, by offering a truly reproducible, and simple to implement, CMNS experiment would be the ultimate reward for us.

= =

Ludwik --> Richard + Pierre (3/7/06):I was going to translate to you the description of the wattmeter calibration. But Pierre is correct; you should be able to figure out what they did. I already described to you the general idea; this file provides numerical results. They are in the last table. It compares thermal wattage (column 2) calculated from the number of grams evaporated (column 1) with electrically measure wattage (column 3). As you can see, the maximum difference was 3.7%. The calibration performed at 250 V and ~ 220 W corresponds to the current of 1.1 A. It is hard to imagine how the thermal power and the electric power could become very different. According to Mizuno, the current goes down when the voltage goes up. Therefore going to 350 V might have a small effect on the power. Fortunately, you have a very reliable power measuring system at any voltage, including 350 V.

= =

Pierre --> Ludwik + Richard (3/7/06):
I had thought already to bring our potassium carbonate and all our equipment except our beaker (2l), a little too heavy... and of course the balance and the power supply. I joined a picture, taken at the nuclear power plant or Dampierre-en-Burly. Pr Fauvarque was thinking that the neutrinos may play a role in this Mizuno experiment. Unhappily, we were not able to see any effect...You can see in the picture Gerard Lallevé and myself with our guide from the operating staff of Dampierre, Chistine Léger. A bientôt

= =

Ludwik --> Pierre + Richard (3/7/06):
Great picture Pierre. Let us hope that the EDF (French Electricity Company) will take our results seriously. See you tomorrow.

= =

Appendix -- Mizuno's protocol

In his ICCF12 presentation (it is downloadable from the library at <www.lenr-canr.org>) Mizuno plots the values of the voltage and current versus time. That is his protocol. French protocol was similar. The only essential difference between the two experiment was in the method of measuring the heat. Mizuno's cell was kept at a constant temperature (about 70 C) by cooling if with water circulating in a flow calorimeter. The cell described by Pierre (nearly identical to ours) was allowed to reach the boiling temperature and the amount of heat released was measured by the amount of water that evaporated. I see no reason why what happens at 70 C should not happen at 100 C.

During the first 20 seconds the potential difference between the electrodes was increased gradually to 40 V. In the next 20 seconds it was increased, in several steps, up to about 80 V. It then remained constant for about 30 minutes. For the next hour the voltage was increased, also in small steps, up to 250 V. The current was decreasing progressively at the same time. Then the voltage was turned off. I suppose that most of the excess heat was generated when the current was decreasing from about 4.7 A to about 0.7 A

Plotting Mizuno's protocol as amperage (vertical axis) versus voltage (horizontal axis) one gets an interesting curve. Up to about 70 V the current grows with voltage, up to 4.7 A and after 70 V it decreases with voltage, down to 0.7A at

~200 V. How can this be explained? At low voltages the electrolyte is like a resistor (about 20 ohms). But R becomes much larger when a layer of gas is formed around the cathode. At higher V the layer becomes thicker and R goes up accordingly. That is why the current decreases when the voltage increases. Above 250 V the current starts to go grow with voltage. This is probably an indication that the glow discharge starts to show a tendency to become an ark discharge. Our last summer protocols were very different from the one described by Mizuno. That is why I am optimistic about the next series of Richard's experiments.

286) Colorado-2 in Boulder and over the Internet

Ludwik Kowalski; 3/23/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The first message in the "Mizuno type experiments" was posted on March 15. This was only one week ago. Today my In box has 150 messages with that subject line. That means about 20 messages per day, on the average. I did not have time to read all of these messages very carefully in Boulder. But I will do this now, before deleting them from the Inbox. That might take several days. Being retired I have a lot of time. It is good to know that deleted messages will be preserved in the archive of the CMNS list. The purpose of this unit it collect ideas inspired by these messages.

1) X1 asked "Have you tried other metals e.g. steel wire?" That would be an interesting project after a RoD setup (reproducible results on demand) becomes available. Naudin was able to generate excess heat using anodes and cathodes made from several different metals. Iorio's cathode and anode were tungsten rods.

2) X2 suggested that we preserve the electrolyte for future examinations. We did this. he also wrote; " You might consider purchasing some more of the same production lot and keep them intact in a safe place, in case they contain some particular impurity useful for the reaction." I guess we would do this if our resources were not limited. Platinized mesh is expensive. Tungsten cathodes and potassium carbonate from the same supplier are probably identical enough. We would not start this investigation without what we learned from Naudin, and others, about good reproducibility. They said "do as we did and you should have similar results; they did not say that generation of excess heat depends on impurities. Only good chemists should deal with experiments whose outcomes depend on presence or absence of some contaminants.

3) JR wrote (Jed Rothwell gave me permission to quote anything he posts): "I think you need a more rigorous test to exclude the possibility of droplets, but Mizuno has done countless tests with closed cells from which droplets cannot escape, and he has found copious excess heat, so he has ruled out this possibility." In one case we covered the cell with a fine stainless screen and still observed excess heat. But doing this only once is not sufficient. In future experiments the open container should always be covered with such screen. Only steam should be allowed to escape; liquid drops and droplets should not be allowed to splash out of the cell. Why not? Because this creates illusion of excess heat. Fortunately, under favorable red-orange plasma, the amount of water lost due to splashing was less than 2% of what was lost by evaporation. This can be tolerated when the COPs are larger that 1.2 or so. Test with excessive splashing should be stopped at once because they are indicative of unfavorable plasma.

4) As soon as I finished composing the above, a new message appeared in my Inbox. It was from Jed. Here is a quote from his message; I agree with it 100%. "Much can go wrong with this experiment. You should not declare victory until you have done it many times, using many different calorimeter types and configurations." That is what should be done before we try to publish a paper. Today is 17th anniversary of the famous press release about the discovery of cold fusion. As indicated at the end of unit # 271, we should learn from negative consequences of premature publishing.

5) I am really happy that other researchers help us to identify potential errors and suggest methods to estimate them. The escaping invisible droplets was a good example. A message from Michel Jullian (MJ), that appeared in my Inbox at about the same time, as from JR, is another example. Below is his entire message (quoted with permission):

“Richard: Insulating layer not visible!? That layer I have been ranting about is nothing but the conspicuous floating foam of bubbles I can see on all the photographs, what else? Let me explain again my concern, hopefully more clearly: I suspect that when the liquid surface is calm (no heat-radiating splashes) this floating blanket of electrolytic gas bubbles must be a fairly good thermal insulator, much better in any case than the NON-insulation on the naked liquid surface which happily let radiated/conducted/convected heat escape during ohmic heater calibration (an ohmic heater makes no bubbles).

If you now consider that _most_ of the non-evap heat loss from an uncovered hot water tank is emitted by said liquid surface, there is no doubt that the non-evap heat losses will be significantly affected by a foam layer appearing due to electrolysis. They won't be 60W any more, but may be half of that, maybe less, in any case this error should be evaluated, if only to demonstrate that it can be neglected if such is the case. This is the point of the temperature decay measurement I was suggesting, not _instead_ of ohmic calibration, but _in addition to it_, so the error can be evaluated.

Does it make sense now Richard? (Please don't hesitate to criticize or ask for precessions) M.J.

PS Jed, the droplets question must be addressed indeed (a screen as used in Colorado-2 should be fine, two screens would be totally droplet-proof), but the missing mass due to dissociation is not a problem at all, on the contrary it leads to UNDERestimating the COP, as it is more than compensated by consumed dissociation energy (cf earlier posts in this thread by Scott Little and myself)”

It is a real pleasure to read such messages. They are very helpful. We are lucky to be part of a group of researchers (on a restricted Internet list) who are no less interested in transforming our protoscience into real science.

6) And here is another piece from JR. “Actually, the worst thing that can go wrong with this experiment is when the cell explodes. On the plus side, when Mizuno's cell exploded, it produced at least 411 times more than input energy, and probably several thousand times more energy than any chemical reaction with these materials could produce. It was anomalous -- no question about that! On the minus side . . . you can see why Mizuno has largely abandoned this line of research. If the cell can do this, I suppose there is no reason to think it cannot produce two or three orders of magnitude more energy. If that happens to you, you will, at least, die happy. Your last thought will be: ‘Hey, it worked!’ "

7) Let me summarize what has been stated in several messages today and yesterday. Being a retired teacher I want to do this in the form of a formal lecture.

A) Under ideal situation non-evaporative losses are zero. In that case Pt=Pe, provided there is no excess heat. And Pt>Pe when excess heat is generated. The Pe is the average electric power and the Pt is the average thermal power. The Pe can be calculated from the W*h received during a test and the Pt can be calculated from the amount of water evaporated during that test. Note that 1W*h=3600 J and that Pd=L*m/t, where L is the latent heat of water evaporation (2260 J/g), m is the mass of the evaporated water (grams), and t is the duration of the test (seconds). The COP is defined as the ratio Pt/Pe.

B) In reality the non-evaporative losses might not be negligible, for example, 10% of received energy might be escaping through the walls of the vessel (conduction, Pd), with the rising hot air (convection, Pc, and as the electromagnetic radiation (Pr). In other words, Pt=Pv + Pd +Pc+Pr. The COP is still defined as Pt/Pe but determining the Pv and Pe alone is no longer sufficient to to calculate the COP.

C) The sum of Pd, Pc and Pr is what we call the non-evaporative losses. How do we measure such losses? We do this by using the ohmic heater, for several different values of Pe, such as 400 W, 600 W, 800 W and 1000 W. The ohmic heater is inside our cell with the electrolyte. We know that no excess heat is produced in the ohmic heater. We measure two quantities, Pe and Pv. The always positive difference, between the Pe and Pv, gives us the rate of non-evaporative losses.

D) In a large vessel, and without stirring the electrolyte, the temperature is not uniform; it might be 100 C near the

source (between the electrodes or near the coils of the ohmic heater) and considerably lower neat the walls, for example 75 C or 85 C, depending on the Pe, the size of the cell and other factors. That is why the (Pd+Pc+Pr) should be determined for several Pe. The dependence of (Pd+Pc+Pr) on Pe is called the "calibration curve." In the ideal case, the (Pd+Pc+Pr) is zero for any Pe.

E) Next comes an important ASSUMPTION --> The rate of non-evaporative losses (Pd+Pc+Pr), determined by using the ohmic heater, are the same as the (Pd+Pc+Pr) during the plasma electrolysis. That is where a systematic error can possibly be made in the evaluation of COP. Let me consider several specific situations.

a) In Paris-1 experiments the measured (Pd+Pc+Pr) was the same at each sufficiently large Pe. That indicates that the entire electrolyte was boiling. Boiling provided natural stirring and the temperature of the vessel wall was also 100 C, at any Pe. But was the entire electrolyte boiling during the plasma electrolysis? Pierre told me that it was, at least when their heater was turned on during the electrolysis (correcting for the input heat supplied by the ohmic heater is trivial when the W*h delivered to the heater are measured during a test).

b) And what about cases in which the ohmic heater was off during the electrolysis? The answer depends on the size of the vessel and on thermal isolation around its walls. In our case (a beaker whose capacity was 2 liters) the measured temperature of the electrolyte, near the walls, was below the boiling point, for example, 80C or 90C, depending on the Pe. That is why our (Pd+Pc+Pr) was not the same at each Pe.

c) Pierre also told us that many measurements of COP were made without turning the ohmic heater on. As far as I know, the temperature of the electrolyte, near the walls, was not measured. As in the Colorado-2 experiment the electrolyte was not stirred. I suspect that under such conditions the (Pd+Pc+Pr) was not the same at every Pe. Was the dependence of non-evaporative losses on Pe taken under consideration in calculations of COPs? A good referee is likely to ask such question? My question is slightly different. I know that the average COPs at 300 V and at 350 V were essentially the same as in Colorado-2. In Paris-1, on the other hand, the COPs were found to be voltage-dependent. Can this be due the unjustified assumption that non-evaporative loses are the same at every Pe? This question must be answered before we say that COP increases with the applied voltage, as stated in the Paris-1 paper at ICCF12.

d) One of the question asked by Michel had to do with the Pc (rate of convection losses). Is it possible that, for some reason, the Pc during the ohmic heater calibration is not the same as the Pc during the plasma electrolysis. An error in the determination of Pc would lead to an error in the evaluation of COP. A good referee is likely to ask this question, unless we anticipate it and discuss the possibility.

e) Another question asked by Michel had to do with Pd (rate of conduction losses). Is it possible that, for some reason, Pd during the ohmic calibration is not the same as Pd during the plasma electrolysis. An error in the determination of Pd would lead to an error in the evaluation of COP. A good referee is likely to ask this question, unless we anticipate it and discuss the possibility.

F) In the last case Michel speculated about a possible cause of differences in Pd. Suppose, he said, that a thin invisible layer of gas is formed over the electrolyte during the plasma electrolysis but not during the ohmic heater calibration. That would reduce the Pd (during the electrolysis) and would lead to the overestimation of COPs. What kind of experiment can be performed to rule out possibilities of significant errors postulated in (d) and (e) above? Jed Rothwell suggested that other ways of determining the Pt (average rate of releasing thermal energy) should be used, for example, a flow calorimeter or a bomb calorimeter. I think that using a bomb calorimeter is a better idea. The flow calorimeter calls for a closed vessel (with a heated recombiner etc.) in a constant temperature environment. That seems to be more demanding that a bomb calorimeter used to evaluate caloric contents of foods.

G) Another good suggestion made by Jed was to determine the (Pd+Pc+Pr) from the cooling curve. Consider a brick at 90 C. The temperature decreases exponentially according to the so-called Newton's law of cooling. Suppose its thermal capacity is 50 calories per degree. Also suppose that the temperature goes down at the rate 0.2 deg/s. That would mean that (Pd+Pc+Pr)=50*0.2=10 cal/s = 41.9 watts. At a lower temperature the rate of cooling may be, for example, 0.1 deg/s. That would be an indication that the non-evaporative losses become two times smaller. The

thermal capacity of a vessel can easily be determined by using the ohmic heater. It is simply a matter of delivering a know number of w*h and measuring the resulting increase in the temperature.

Jed suggested measuring several values of (Pd+Pc+Pr) at low temperatures, such as 20 and 30 C, and extrapolating to the actual temperature of the cell's wall. I do not think that this is practical; the extrapolation uncertainty is likely to be unacceptable. But measuring the (Pd+Pc+Pr) at several higher temperatures, for example, between 80 and 90 C will offer a reliable extrapolation toward the wall temperature, such as 95 C. Water, however, is also evaporated below the boiling point and this fact must be accounted for, as I mentioned in an earlier message. Ideally the (Pd+Pc) determined from the cooling curve, and the (Pd+Pc+Pr) determined as in Paris-1 experiments, must be identical. In reality a discrepancy of 1 W, or so, would be acceptable because the (Pd+Pc+Pr) are usually close to 50 W. I am thinking about cases in which COPs are larger than 1.2.

The bomb calorimeter test and the cooling curve test must be performed before we are ready to write the paper. I would not be surprised to learn that such tests are being conducted right now in Paris-2 experiments.

Appended on 4/7/06:

A reader of this unit, David Dow, was confused by the paragraph F above. Here is my reply to him: “Dave, you probably confused the Pd, which stands for the rate at which thermal energy is lost by conduction, with the same symbol for the chemical element. A thin invisible layer of foam, suspected to be formed on top of the the liquid during the electrolysis, might decrease conductive losses. Presumably, no such additional layer is formed when the ohmic heater is used. Under such scenario the COP > 1 might be an illusion. I will now make a little change in the unit #286, to avoid another confusion. In fact I will probably add an appendix to that unit, but not today. Thanks for your help."

287) Social aspects of our controversy

Ludwik Kowalski; 3/30/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Responding to a comment posted by Charles Baudette, at the 17th anniversary of the famous press release about the discovery of cold fusion, **Steven Krivit** wrote:

I just looked at the very first CF news story from the Financial Times just now. What is interesting to me is that they accurately represent F&P's primary basis (excess heat.) "The two scientists are convinced that they have achieved nuclear fusion, rather than a conventional chemical reaction, *because very large amounts of heat are released* and because some of the expected products of fusion - tritium, neutrons and gamma rays - are formed. Even so, it is not clear what fusion processes are taking place."

Well, I guess this, in itself, is not so profound. What I find profound is that this key actually did appear -- at least once -- but everybody else afterwards missed it and got caught up in the "It sure don't look like fusion to me" mess. You've mentioned this before how the books by Huizenga, Close, etc. totally neglected heat. It seems the identical case for the newspapers too: All the subsequent reporters neglected to mention the heat - at least in a way that represented F&P's perspective. Is this your observation and recollection of the popular press too?

2) **Charles Baudette** responded:

. . . All that the outspoken physicists wanted to talk about was "cold fusion."

1. The subject of "excess heat" would require them to develop some proficiency in calorimetry --- an unpleasant prospect.
2. When the engineering group at NSF (along with EPRI) called a meeting in the fall of 1989, their purpose was to bring together those who claimed success at excess heat generation for a comparison of experimental work and discussion of how to improve the experiment. Huizenga led the charge to claim that those who denied the neutronic evidence for "cold fusion" had not been invited. He converted the meeting (for the press) to one about cold D+D fusion.
3. When these physicists went to ICCF meetings (with J. Bishop in tow), they were looking only for reports of neutron (of a certain energy) emissions. When they did not see that, they would report to the press that there was still no progress in the field.
4. When Morrison reported to the newsgroup science/physics/fusion his take on the ICCF8 (2000) meeting, he mentioned my book. He gave it the title "Why cold fusion prevailed." He did not want the physics community to learn that "excess heat" was continuing to be studied, and he did not want the topic to be broadened from "cold fusion" to "cold fusion research." This is typical of the criticisms of our field.

In discussion with physicists and the press, try to get them to study videos of the original press conference so that, in their criticism, they can get started off on the right foot. Most have a distorted notion of what was announced.

2) **My reply**, on the restricted Internet list for the CMNS researchers:

I agree with Charles; excess heat is one thing and ways of explaining it is another thing. Let qualified theoretical people discuss possible explanations of experimental data, after such data are validated. Premature speculations are tempting and exciting -- but they can be dangerous. It would be better if Fleischmann and Pons did not start speculating about nuclear origin of excess heat prematurely.

3) **On another thread I wrote**:

Michel also asked: "is it ok to speculate about explanations between us people already convinced of the reality of the

excess heat?" Why not? I was referring to our anticipated formal publication of experimental data. In that paper we should avoid theoretical speculations. That would divert discussion from the main issue -- the reliability of experimental facts. Interpretation of facts will appear naturally after such facts are recognize as valid. That would already be a big step forward. We should discuss what happens in the kitchen and learn from what more qualified people have to say in the dining room. We badly need an accepted theory to guide future experiments.

In my opinion the history of cold fusion would have been very different if Fleischmann and Pons have had simply said "we observed excess heat but we do not know where it comes from." That what we should say in a publication describing results from recent Mizuno type experiments [Paris-1, Colorado-2, Paris-2, Texas-2 and (?) Colorado-3], provided we all agree that the measured excess heat is not an illusion (caused by experimental errors, or due to well known processes). Results from experiments now in progress, or in preparation, should be decisive. It will probably take at least several weeks before we are ready to start writing a paper.

4) **Scott Chubb**, responding to the message that started this thread, wrote:

I think the hype that the press conference was shameful evolved from two factors:

1. As opposed to looking at the original sources, with time, members of the press relied upon accounts, provided by "purported experts" and other members of the scientific community.

2. Resentment within the scientific community was wide-spread and almost immediate because F&P called the press conference and went public with their results prior to communicating their results (even within their own department) to the scientific community.

A hidden problem, associated with the second factor, resulted from the use of FAX machines. In particular, David Lindley pointed out that their original paper had an obvious error (associated with the energy of the neutrons) that would have been corrected through the review process. But the review process broke down because their paper, de facto, was published in pre-print form (through FAX machines), and this error was not corrected prior to publication. This further compounded a bad situation. In any case, most scientists, at an early point in the debate, got the impression that by calling the press conference, in the first place, F&P had seriously undermined their own credibility and this action, by itself, was viewed as being shameful.

5) **Jed Rothwell** wrote:

This was outrageous hypocrisy, especially on the part of the plasma fusion researchers. Back then and still today, those people routinely call a press conference after a major experimental run. They ballyhoo their results and declare a breakthrough months before they even write a paper, or publish one. They even go the Congress and demand more funding on the strength of unpublished experiments. As I recall,
some years ago Members of Congress got fed up with this practice and told them to stop it.

Researchers in every field do science by press conference. They always have, and they always will. This is another case of demanding cold fusion meet a standard that no other area of research has ever been called upon to meet. "Skeptics" demand 100% reproducibility, even though that is absurd and no practically other breakthrough has ever been so reproducible (except perhaps the x-ray). They demand commercial products before they accept the reality of the phenomenon. They demand a theoretical explanation, even though nearly every important breakthrough in history has been important precisely because it did not have an explanation. It is all stuff & nonsense.

6) **Scott Chubb** added:

I agree. Complicating the issue, however, was the confusion that resulted because at the time Jones's group "seemed" to be doing the same kind of experiment when (as we know, now), this was not the case at all.

7) **Jed Rothwell** added:

The problem did not begin on May 1, or after the press conference. The problem was inevitable. Martin Fleischmann knew full well that he and Pons would be booted out of the establishment. He knew this long before he made the announcement. See the letter from him quoted in Beaudette's book, page 147:

After the press conference, [Arrhenius's granddaughter] Dr. Caldwell came up to us and said, "Well, when my grandfather proposed electrolytic disassociation he was dismissed from the University. At least that won't happen to you." I said
to her, "But you are entirely mistaken. We shall be dismissed as well."

Scientists have always rejected radical discoveries. The problem has grown worse since the Manhattan Project, which politicized basic research, and put it under the control by Washington. The postwar peer review system has also corrupted the process. The skeptics were pathological all along, and if the press conference or the May 1 meeting had not occurred, they would have seized upon some other event or excuse to reject the findings.

People sometimes blame the name "cold fusion" for the opposition, saying it is was a misrepresentation. Of all the nonsensical objections to cold fusion, this is the most absurd, as any linguist or philosopher knows. There is such a thing as confusing terminology, and technical words are sometimes revised to avoid confusion or standardize vocabulary. But fundamentally, the notion that a word can "misrepresent" something goes back to the bronze age, when people believed language has magical power, and a word embodies the thing it represents. All words in all languages are approximations. Words are tokens. They are often based upon some faulty notion that was current when the thing was discovered. Everyone knows that weather is not caused by meteors but we still call it "meteorology." "Manufacturing" is not work done by hand (manus = hand). It now means just the opposite: work done by machine. But these terms are not inaccurate. "Meteorology" and "manufacturing" mean what we say they mean, and nothing else. Words are nearly always obsolescent, because we have no term when something is first discovered, and we must reach back to our older stock of words. Horses no longer dash in front of the "dashboard," and it is not a wooden board, but we still call it that. We say that computer files are "collected" in "folders" even though nothing folds, and nothing is physically collected.

8) **Scott Chubb:**
Scientists frequently reject radical discoveries, but there are also counter-examples; in particular, in 1987, a radical discovery (High Tc superconductivity) was made, where the system functioned. I would argue that the peer-review process is prone to mistakes in situations involving radical changes. But a major reason for this is Postwar funding (as opposed to the peer review system).

In the case of Cold Fusion, there were many factors that entered that corrupted the process. A subtlety in all of this (that was brought out in the Accountability in Research collection of articles--which, as you know is available at <www.lenr-canr.org>) was
the role of information era technology in disrupting the review process. This (not the postwar review system) was at the heart of the underlying problem. Martin might or might not appreciate this. It was only through talking to Lindley face-to-face and by looking in detail at Dave Nagel's and David Goodstein's contributions to the collection that I realized this.

Dave Nagel's contribution (which I highly recommend) pinpoints, nicely,
the key aspects of the communication process that subsequently broke down (after the press conference and after the 1 May 1989 session). David Goodstein's contribution identifies the turning point (the 1 May session), beyond which the scientific process was doomed to failure. It can be argued that the breakdown was inevitable. But these two articles (by Goodstein and Nagel), and the interview I conducted with Lindley, provide significant evidence that until 1 May 1989, there was a reasonable chance that the process could have continued to function.

An important point to keep in mind is that scientific conferences can seriously help or impair communication. Communication can be seriously impaired especially when information is presented in an unstructured way and the appropriate individuals are not present. This is precisely what happened in the 1 May 1989 session. At that time, although Pons and Fleischmann were not even in attendance, they were accused of carelessness and sloppy work by Lewis, in particular, (as well as by others) at a mass gathering of physicists. This took place in a hostile setting, and neither Pons or Fleischmann had the opportunity to respond. In many respects, the associated ritual can be likened to a

"spiritual event", in which physicists became convinced, as a result of serious broaches in scientific protocol, that purported "experts" (like Lewis), who actually knew basically nothing, had demonstrated that Cold Fusion was bogus.

In fact, the real problem pre-dated both the Press Conference and the APS session. It occurred because of the review process that was adopted by Ryszard Gajewski to evaluate the grant proposal that P&F had submitted to DoE. In particular, Gajewski sent the proposal to Jones to be reviewed. Then, as opposed to forcing Jones and P&F to work together, competition between the two groups resulted. This triggered the Press Conference.

[Jed Wrote:] The skeptics were pathological all along, and if the press conference or the May 1 meeting had not occurred, they would have seized upon some other event or excuse to reject the findings.

I disagree. This is speculation.

[Jed wrote:] People sometimes blame the name "cold fusion" for the opposition, saying it is was a misrepresentation. Of all the nonsensical objections to cold fusion, this is the most absurd, as any linguist or philosopher knows.

Jed, you have not talked to mainstream physicists about this. It may seem absurd, but it is a fact that the name has caused a problem. For them, cold fusion had a meaning, that the effect was the result of a colder form of conventional fusion. Along with this meaning came the assumption that high energy particles, and the conventional products of fusion, would be present. Complicating the fact that this name has caused many physicists to have these preconceptions, in fact, Jones may have very well discovered the kind of "colder version" of fusion that physicists thought was required.

[Jed wrote:] There is such a thing as confusing terminology, and technical words are sometimes revised to avoid confusion or standardize vocabulary.

This is what has happened with cold fusion. I would suggest that the terminology "Condensed Matter Nuclear Science" is considerably more appropriate. I have found that using this terminology has been quite useful in alerting physicists to the fact that they may have been wrong in their assumptions about cold fusion. Technically, Jones's work is closest to the definition that physicists would associate with cold fusion. Pons and Fleischmann's work should also be associated with cold fusion. But I believe that the terminology has been applied inappropriately when it has been used in conjunction with the transmutation work. In particular, I do not believe a single effect is at work in many of these effects and to lump all of them into a single category, called cold fusion, seriously misrepresents the physics behind the underlying phenomena.

[Jed wrote:] But fundamentally, the notion that a word can "misrepresent" something goes back to the bronze age, when people believed language has magical power, and a word embodies the thing it represents. All words in all languages are approximations. Words are tokens. They are often based upon some faulty notion that was current when the thing was discovered. Everyone knows that weather is not caused by meteors but we still call it "meteorology." "Manufacturing" is not work done by hand (manus = hand). It now means just the opposite: work done by machine. But these terms are not inaccurate. "Meteorology" and "manufacturing" mean what we say they mean, and nothing else. Words are nearly always obsolescent, because we have no term when something is first discovered, and we must reach back to our older stock of words. Horses no longer dash in front of the "dashboard," and it is not a wooden board, but we still call it that. We say that computer files are "collected" in "folders" even though nothing folds, and nothing is physically collected.

These are all interesting points. Eventually, the terminology "cold fusion" might stick. For now, I think it should be abandoned, and the terminology "Condensed Matter Nuclear Science" should be used, at least in situations involving mainstream scientists.

9) **Jed Rothwell**:

One of the lessons of history is that when extremists make threats, denounce people, and when they call you a fraud and a criminal, you should take them seriously. They mean what they say. Such people do not kid, and they seldom

exaggerate for effect. The Nazis really did intend to exterminate the Jews. The extreme Islamic fascists really do want to impose Sharia law on the US and all other nations. They flew airplanes into buildings, they killed Salman Rushdie's Japanese translator, and given half a chance they would kill the Danish cartoonists. The professors who brought legal proceedings against Taleyarkhan intend to shred his reputation and crush his research. They will stop at nothing. They do not consider themselves unethical. They see themselves as the defenders of science against the rabble. They would be happy to see Taleyarkhan serve time in jail, if it came to that. They will make any accusation that sticks, including larceny. Similar people tried to destroy Bockris with these tactics. If they could, they would put cold fusion researchers in jail too. They have told me this and I have no reason to doubt they mean it.

Some people have suggested that Robert Park may be softening his stand. This is nonsense. It is dangerous nonsense if you fall for it, or lower your guard against him. Here is what Park wrote in 1996, in a Washington Post review of Close's book: "Close asks in the first chapter, 'Was this a delusion, an error, or a fraud?' By the end of the book, it is clear that cold fusion progressed through all three. What began as wishful interpretations of sloppy and incomplete experiments ended with altered data, suppression of contradictory evidence and deliberate obfuscation.

After a while, the objective seems to have been just to prolong the inevitable--but Fleischmann and Pons were no longer alone. Inept scientists whose reputations would be tarnished, greedy administrators who had involved their institutions, gullible politicians who had squandered the taxpayers' dollars, lazy journalists who had accepted every press release at face value--all now had an interest in making it appear that the issue had not been settled. Their easy corruption was one of the most chilling aspects of this sad comedy. To be sure, there are true believers among the cold-fusion acolytes, just as there are sincere scientists who believe in psychokinesis, flying saucers, creationism andthe Chicago Cubs. The lesson from "Too Hot to Handle" is that a PhD in science is not an inoculation againstfoolishness--or mendacity."

He repeated the gist of these comments in 2002. I have not read a single word by him that hints he has had a second thought or a moment's doubt. If you wonder about this, ask him. If he bothers to respond he will probably tell you that he sticks to every word. He has never been reticent about expressing his views.

I know of only one hard-core, anti-cold fusion campaigner who does not frankly own up to his views, and does not respond to such inquiries: Steve Jones. As you saw the other day when I asked him whether he really believes the excess heat results, he cuts and runs. He evades the issue. I suppose he is trying to play both sides and build up support among cold fusion researchers, as well among the people who despise cold fusion. I cannot imagine why he thinks he needs help from us, since we have no political power, funding or influence. Based on all of his published papers and on countless conversations with him, I am certain he does not believe the heat is beyond the limits of chemistry (anomalous). He may want to give the impression that he is willing to examine that idea and take it seriously, but I am sure he cannot bring himself to do that. For one thing, he has not published a single word admitting that might be the case. For another, if he were to confront the truth he would have to admit that Fleischmann and Pons were right from the beginning, and he was wrong, and this has been obvious all along. I doubt he is capable of admitting he made such a drastic mistake.

10) **Ludwik Kowalski** (not posted):
Jed has been trained in humanities and in linguistics. But he is very knowledgeable in many areas of CMNS (condensed matter nuclear science is the new name for what used to be known under the name of cold fusion). Scott, on the other hand, is a theoretical physicist . Each of them believes in reality of excess heat and in its nuclear origin. I suspect the the friendly exchanges of points of view between Jed and Scott will continue. But I have to stop somewhere. There were one more message from Jed, one more from Scott and an additional one from Jed. All of them are interesting. But my goal, in composing this unit, was to show what some CMNS researchers think about social aspect of the 17-years controversy.

11) More from **Jed Rothwell:**

The people who oppose cold fusion went on record within days of the announcement. At MIT they held a party to "celebrate the death of cold fusion." Professors called for the arrest and imprisonment of Fleischmann and Pons for fraud. The US secretary of energy said he could tell cold fusion is wrong because he saw Fleischmann on television, and

"Fleischmann looked stupid." These people never gave cold fusion two seconds of consideration. To this day, they have never looked at any evidence. They are not shy about their views. The editor of the Scientific American brags that he has never looked at a paper.

Whenever anyone mentions cold fusion they assert with unshakable confidence that all cold fusion researchers are frauds or lunatics, all are a disgrace to academia, and should all be hounded, ridiculed and fired -- tenure are not. They are as sure we are wrong as I am sure the Flat Earth society is wrong. Perhaps they do not say this to you in person but that is what they say elsewhere, and their actions prove that is what they think. They are not mincing words, kidding, or exaggerating their own views, so you should believe them. There was never any question that these people are bitterly opposed and they will fight to the end.

12) More from **Scott Chubb**:
It is sad to say that people do pay attention to stature and background. So, I don't doubt that in many cases, particular editors might say one thing to you and something else to me, simply because I am a mainstream scientist and you are not.

[Jed wrote:] There was never any question that these
people are bitterly opposed and they will fight to the end.

Many people have become bitterly opposed to the subject. But in most cases, this is because they either have not formed their own opinions (and have based their opinions on the opinions of "experts"), or they have not bothered to learn the facts.

13) Another quote from **Jed Rothwell**:

Scott, I think you gravely underestimate the opposition. You do not understand the severity of the problem. You seem to think these are reasonable people who mainly "fail to understand." Perhaps they are polite to you when you meet at a conference. I have met Huizenga, Park and and Morrison, and I was polite to them as a matter of course. I would consider it beneath my dignity to insult them in public. I would not want them to think they have got my goat.

These are not nice people who have made some sort of miscalculation or forgot to read a paper. It is not as if they have been meaning to do some fact checking but it has slipped their mind every month for the past 17 years. They have made their goals and their intentions crystal clear, time after time, in statements to the press and to me
and to others. They despise you. They do not believe a word you say. They think you are a crazy, lying, criminal fraud. They do not give a fig about academic standards or freedom or fairness -- they say such standards do not apply to lunatics. Their goal is to destroy you and they will stop at nothing to accomplish this goal.

If you do not think these people hate you, ask yourself: Why do they keep shouting that they hate you?!? Why do they take legal action against Taleyarkhan? What more will it take to convince you? Do they have to come and burn your house down?

Seriously, you might as well doubt the intentions of Bin Laden. You might as well wonder whether he hates you and wants to do you harm. Yes, he does. People are not all sensible, kind and reasonable. Our dispute with Bin Laden is not caused by a failure to communicate, or by good intentions gone awry. Bin Laden is communicating loud and clear, and there is no doubt what he wants to do. He has repeatedly declared that his goal is to use a nuclear bomb against a U.S. city. For months he has been asking the leading Muslim radical imams for a fatwa (permission) to proceed. They say fine, go ahead, as long as he kills fewer than 10 million people per attack. (According the ex-CIA section chief who wrote "Imperial Hubris.") So if a stolen Russian bomb goes off, will you be surprised?

Our professional journalist, **Steve Krivit**, who triggered this thread wrote:

Jed and Scott, You are both have logical and correct-sounding viewpoints. It seems that you're just looking at it from different perspectives. And insightful ones, each.

288) CMNS researchers discuss chemistry

Ludwik Kowalski; 3/29/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) This evening I posted this message: "Dear Francesco [Celani]: Suppose a Pt cathode produces the COP=1.00 while a W cathode produces the COP=1.30, in a Muzino type cell, at the same voltage. Would this not be a sufficient proof that the excess energy is real when a W cathode is used? I think that this would be a valid argument against your suspicion that the inductance of the capacitor might be causing an error in the COP measurements.

It seems that the chemical origin of excess heat, in Mizuno type cells, becomes the central issue. I hope somebody can summarize what has been posted about that topic so far. The K2CO3 disappears when the salt is dissolved in water; it is replaced by + and - ions. An experiment begins when the electrolyte temperature reaches a constant temperature ~100 C. The K2CO3 no longer exists; it cannot be a fuel. If there is a fuel then it consists of ions. Which reactions are dominate and how many joules of energy can these reactions possibly deliver, per gram of the initially dissolved potassium carbonate? Significance of Paris-1 and Colorado-2 results depends on how is this question answered by chemists."

Fauvarque is an electrochemist and I expect that he will write an appendix to our anticipated publication (see unit #271). Pierre, who works in his lab, took back a bottle with the electrolyte we used in the Colorado-2 experiment. Let me gather messages that people wrote about the possibility of chemical origin of excess heat. Even Jed Rothwell admitted that the excess heat in Mizuno type experiments (plasma electrolysis) might have chemical origin. Several days ago he wrote: ". . . but this open cell glow discharge is quite different, and one cannot as easily rule out conventional explanations." In other words it is possible that some chemical reactions are responsible for what was interpreted, prematurely, (by Mizuno, Naudin, Fauvarque and Iorio as liberation of nuclear energy. High voltage plasma electrolysis is very different from the low voltage electrolysis used by most CMNS researchers.

2) On Michel Jullian asked:

"The mass loss corresponding to this large quantity of liberated O2 and H2 is attributed wrongly to evaporation isn't it? Has anybody worked out how significant this effect is, and which way (under or overestimation?) it affects output energy estimation? Responses would be appreciated."
P.S. I forgot to include an earlier important observation made by X1. He wrote: I suggest that exothermic chemical reactions involving the electrolyte salt or its ions could be releasing heat in glow discharge experiments, on the bases that it is the only possible chemical reactant present in sufficient quantity (tens of grams) to explain observed excess heat, and that the color of the plasma "flame" depends on the nature of salt used.

3) The immediate reply from X2 was:
"First, the report of 80 times Faradaic efficiency for dissociation of H2O comes, I believe, only from Mizuno et al. The literature on Contact Glow Discharge Electrolysis (i.e. a section in the big multi-volume electrochemistry compendium edited by Bockris) says that up to 8 times has been reported. In our own experiments (http://www.earthtech.org/experiments/Inc-W/2ndtry/run6.html) we have observed only 2.5 times the Faradaic efficiency. I will use our observation in the calculations below.

Ignoring the fact that some mass is lost due to dissociation of H2O into H2 and O2 results in an underestimation of the heat energy produced by the cell. The error is around 1% for the cells I have run. Consider a cell running at 300 volts and 1 amp. Pin = 300 watts. The fraction of this power that goes into electrolysis is 1.48 volts (the thermoneutral dissociation potential) * 1 amp * 2.5, the latter factor from our own observations. So Pdissoc = 3.7 watts. That leaves 296.3 watts for boiling the water. Assuming no excess heat, if you measured the mass loss correctly and came up with 296.3 watts of heat power, then compared it to the input power of 300 watts, you would conclude that the process is only 98.8% efficient.

If the Faradaic efficiency did go as high as 80, things would be very different. Then Pdissoc would be 118.4 watts, leaving only 181.6 watts for boiling. Using mass-loss calorimetry the process would appear only 60.5% efficient." Let my mention that, according to Mizuno, the amount of H2 produced in plasma electrolysis is often much higher than what is expected by the Faraday's law of electrolysis, for example, 80 times higher. Hydrogen is fuel and its excess must be counted as excess energy.

4) Ludwik Kowalski wrote:
Here is a little rough calculation worth sharing. In our typical 5 minutes test (input electric energy = 400 W * 0.0833 h = 33.3 Wh) the amount of excess heat is about 6.5 w*h (if the COP=1.2). This translates into 1.46*10^23 eV. The estimated mass of tungsten lost during the same time is about 0.5 grams. That translates into 1.63*10^21 atoms. Thus the excess heat per atom of tungsten seems to be close to 100 eV. That is about two orders of magnitude larger than what I associate with common fuels.

What happens to our spent tungsten? Part of it probably melts and then solidifies in the electrolyte. If so then pure tungsten must be found in the cell (in the deposits we see at the bottom, after some waiting). Suppose that 50 % melts and the rest combines with other atoms or ions. Not being a chemist I might be allowed to postulate that all possible chemical reactions are equivalent to one representative exothermic reaction. Suppose that our excess heat is due to that reaction. What would the Q value of the representative reaction be? It would be 178 eV. That is a lot !

The Q value would be two times larger if only 25 % of tungsten was used in chemical reactions while the rest was simply melted. This shows that Q increases when more tungsten is melted. At the other extreme the Q value would be 89 eV if nothing was melted (all consumed in exothermic chemical reactions). Even this number is unusually high. Did I make a wrong assumption, or a numerical mistake, somewhere? . . . Tungsten electrodes should be weighted before and after individual tests. Fortunately, a possible 50% error (in the estimated mass lost) would still support the conclusion -- too much energy per atom of tungsten.

I wish our real chemists, such as R. O. or Mike McKubre. and his team, were performing Mizuno type experiments. Confirmations made by them would be much more significant than by amateurs, like myself. I would be in a much better position to argue about nuclear particles and nuclear detectors than I am in arguing about chemical reactions. That is because I was trained as a nuclear physicist.

5) M. Jullian asked:
" Dissolving solid K2CO3 in water is an endothermic reaction isn't it? (absorbs heat)

6) X2 responded:
My old 1948 "rubber bible" says it is exothermic. ....6.5 kcal is released when 1 mole of K2CO3 is dissolved in 400 moles of water.

7) X6 wrote:
Whilst it is perfectly true that atomic hydrogen can give off lots of heat on reforming H2 (precisely 4.5 eV per molecule) this same energy is required to form it in the first place. Consequently any such reaction would produce no net energy.

8) M. Jullian wrote:
[Somebody asked] "As for hypothetical reactions with the electrolyte, what could they be?" I don't know. Whatever the high temperatures and the active species in the plasma can do to it. If you bring material past a plasma, like the

electrolyte is brought past the plasma sheath around the cathode in a Mizuno cell, it will be processed happily and non reversibly. This phenomenon is called plasma processing, used to e.g. oxidize the material to be processed, exhaust gases, plastic film etc.

In any case it is beyond doubt that the electrolyte intervenes in the plasma reactions, have a look at all the beautiful different plasma colors one can get by trying different electrolytes

<:http://www.geocities.com/spfaile/plasma/Plasma.html>

Note that the above excellent experiment report (couldn't find authors names in LENR-CANR library) also confirms that initiating a plasma is a matter of electric field, not of voltage. They managed to generate plasmas with only 50V, using fine enough cathodes (thin wires, or sword shaped sharp plates). It was pointed out by Jed recently that Mizuno obtained the right kind of plasma at lower voltages than the 200-400V used in recent experiments, I submit that is because the lower radii of curvature of Mizuno's thin W plates' edges induced the required electric field for a lower voltage than with the relatively thick welding rods used in recent experiments.

Back to chemistry, my suspicion as a non-chemist familiar with only the _physical_ aspects of plasmas, is that the field effect ionization effect giving birth to the plasma, combined with the >3500°C temperature of melting tungsten, may be able to break the electrolyte into more active potassium species able to react exothermically with oxygen and/or water with a positive net energy balance.

But there is no need to know exactly what such reactions could be for now or if they are plausible, let's first check the hypothesis experimentally as discussed with Ludwik: is the electrolyte consumed at all in a _successful_ run? If not we can happily eliminate the electrolyte as a possible chemical fuel. Will remain your solvent hypothesis :)

9) Mike McKubre responded:
I have seen this thread bouncing around and hoped that there was a subtle meaning that I was not getting. I may have missed the point but let me address the obvious. Potassium in the electrolyte is in the oxidized state (K+) while oxygen is in its reduced state (O--). If by some means potassium becomes reduced to K and oxygen oxidized to O2, and they somehow are allowed to react, the results is oxidized K and reduced O --- exactly as we started with. Thermodynamics has the wonderful virtue of being promiscuous --- it is completely insensitive to pathway. If the initial and final states are the same --- then no energy is absorbed or released. I am hoping that this is not the theme of this thread. If it is, then let this answer be an end.

10) John Coviello wrote:
. . . Of course I agree with your obvious assessment but would like to include consideration of the possibility that the cell ingredients would undergo reactions that would result in different final compounds. For example, the plasma might stimulate the reaction

$K_2CO_3 + H_2O \rightarrow 2KOH + CO_2$

The CO_2 would leave the cell as a gas. Adding up the heats of formation and solution of these compounds, this looks like a slightly endothermic reaction..... about 25 kcal per mole of K_2CO_3 converted. Compare this to 275 kcal/mole for the formation of K_2CO_3 from its elements. I suppose it is safe to assume that any "rearranging" reaction, i.e. one that leaves the metals oxidized and the oxidizers reduced will not have a great energy production or consumption.

Regarding the W cathode, I have examined this reaction:

$W + 4H_2O \rightarrow H_2WO_4 + 3H_2$

for which we presented evidence in this report:

http://www.earthtech.org/experiments/Inc-W/2ndtry/run6.html

and found it to be almost non-thermic. The energy required to dissociate 4 moles of H2O is about 274 kcal and the energy released when the H2WO4 is formed is 280 kcal. Plus, the total mass of W consumed in a typical run is quite small. In conclusion, it appears that there is no possibility that chemical energy could be the source of the apparent excess heat from the W-K2CO3-H2O system.

11) My own reply to Mike McKubre
Thanks, your comments, concerning the ongoing Mizuno type experiments, are highly desirable. Most of us performing, or planing to perform, these experiments, are not even chemists. The only way to compensate for this handicap would be to receive critical input, and help, from real electrochemists, like yourself, E. Storms, R. Oriani, S. Szpak, etc. Please help us to confirm reality of excess heat from plasma electrolysis cells.

12) Michael McKubre responding to X2:
The first reaction is endothermic as you state. In fact it is the bane of electrochemists running KOH electrolytes as it spontaneously reacts with CO2 from the air to form carbonate. I did not look up the numbers but your assessment of the W + H2O reaction seems right, and I agree with your general conclusion. For non chemists the heats of formation of all these materials are easily looked up and added up. You can answer these questions yourself, easily. In fact, thermodynamics is trivial - like nuclear physics. A few simple rules and a lookup table.

13) M. Jullian wrote:
Thanks M.McKubre Assuming the first reaction proposed by X2 occurs in a significant manner, we will have a significant mass loss via CO2 won't we? Since this mass loss will be wrongly attributed to evaporation, we will have to make sure each gram lost this way takes away as much heat, or more heat, than a gram of evaporated water. Haven't time to do the computation right now, maybe someone will beat me to it.

Ok so X2's first reaction K2CO3 + H2O + heat -> 2KOH + CO2 (well
spotted X2 BTW, you made me look less foolish with my speculation of electrolyte chemistry ;) is endothermic, requiring about 25 kcal per mole of K2CO3. That's 25 kcal per mole of escaped CO2, i.e.25000*4.186 = 105000 J for 12+16*2 = 44 g of lost mass.

This works out as 2380 J/g, which seems to be slightly higher than H2O evaporation heat 2260J/g, but it would be worth double-checking the exact figure for the reaction heat (anywhere online where the formation heats you mentioned can be looked up?)

Pending confirmation of the figure, as far as this reaction is concerned we can happily keep counting all lost mass as evaporated water as this amounts to underestimating the output energy and the COP (it would have been bad if it had overestimated it!). But this result needed to be justified didn't it?

Since the outcome of the calculation had no particular reason to be favorable, I still think it would be a good idea to analyze the electrolyte after a successful run, to check that no other unexpected chemical reaction involving the electrolyte has occurred to mess up our results one way or another.

Note such analysis can be tricky though, as for example the above reaction could not be detected if the electrolyte was left to cool down in ambient air long enough: as Michael taught us the KOH would reabsorb the CO2 from the atmosphere and return to its initial K2CO3 composition. . . . .

Er... group, how about this new silly speculation about chemical heat from the electrolyte? (very basic this time, would probably also escape post-run chemical analysis depending on how the electrolyte is collected) Dissolving solid K2CO3 in water is an endothermic reaction isn't it? (absorbs heat)

So some electrolyte drying up on the cell walls after some splashing, the reverse reaction, would generate heat wouldn't it? Real heat this time, not an artifact of the measurement method. This effect could be far from negligible but it's getting quite late over here so I'll go to bed and ask a charitable soul to do the homework this time: - How many joules of excess heat per gram of dried-up salt on the cell walls? - How many grams end up this way, experimenters? - Couldn't this also affect P&F cells to a lesser extent?

14) X2 wrote:
You asked "Dissolving solid K2CO3 in water is an endothermic reaction isn't it?" My old 1948 "rubber bible" says it is exothermic..... 6.5 kcal is released when 1 mole of K2CO3 is dissolved in 400 moles of water.

15) M. Jullian wrote:
Thanks X2, my mistake, and a very good news: again the outcome is favorable! I submit that a thorough paper on the subject would mention all the chemical reactions that have been thought of, and why they can only underestimate the COP or make it much lower than measured: - Faraday and thermal dissociation of water (underestimates COP) - reactions involving the tungsten (100 times not enough mass to explain the COP) - KOH and CO2 formation from K2CO3 (underestimates COP) - dried up electrolyte (underestimates COP) - ???

Other reactions with the electrolyte might be possible, is there any way at all to predict all possible chemical reactions that can occur in a given system? Analyzing the electrolyte before and after a successful run may reveal reactions we might have missed, and hopefully will give more consistence to the far from obvious claim that excess heat is not chemical in Mizuno experiments.

Such chemical analysis would also quantify the lost droplets/mist phenomenon as has been discussed: just saying it is negligible because some filtering means is used, or because no mist is seen at the surface of the covered cell on the photo (if we "see" water vapor in a covered cell it is not water vapor but means there is some nebulization occurring) may not be sufficient proof.

In any case the dream I had of a simple cell demonstrating reality of cold fusion to any skeptic in a few minutes is getting more remote every time a new artifact is found and ruled out. There is stronger and stronger hope that a simple cell (insulated and covered Fauvarque) could be sufficient proof, but it will also take a lot of reading!!! Unless of course it produces significant excess heat for days and months, but we are not there yet.

16) M. Jullian also responding to what I wrote in (1):
X has just responded (he may be right about ceramic being better than plastic). My own rantings are not about the reality of electric power measurements either (like all or most people here I now have a high level of confidence that they are valid) but about their indisputability from the point of view of a reviewer.

About the COP depending on the cathode material, it would be an interesting result in itself and would certainly increase the level of confidence of the measurement, but would not yield indisputability, why should it?

As I have been stressing, no electrical measurement made in a high EMI environment will ever be indisputable. Please let us never forget that skeptic or even neutral reviewers will need EXTRAORDINARY PROOF for our extraordinary claims. Any reason to doubt, especially a good one such as abundant EMI, will be jumped upon to dismiss the whole stuff, and HAS BEEN actually. Simplicity, transparency, indisputability, should be maximized if we want to stop being considered as self deluding wishful thinkers, agreed?

Talking about EMI, it occurred to me that it might be a good idea if the anode itself, which could easily be made to surround entirely the discharge area (including top and bottom), could be used as a Faraday cage. This would mean connecting it to ground and having the cathode float below ground, Scott Francesco and all what is your opinion on such an arrangement?

P.S. About the chemical effects discussion, I would find it outrageous if the real chemists here did not get more actively involved in this, leaving amateurs such as Scott or myself do their homework as they have effectively done up to now:

1/ What are the possible reactions apart from the ones discovered (by chance more or less) by Scott and by myself?

2/ What can happen or not happen chemically speaking in the plasma at temperatures ranging at least from 100°C (outside of plasma sheath) to melting tungsten temperature (inside), and at high electric fields? Any missing

parameters to answer this question? Why does the plasma color depend on the electrolyte? Real chemists please ENLIGHTEN US (if you have any clue that is).

17) Peter Gluck, who is a chemist, wrote:
. . . From the point of view of engineering, we need first of all, complete ENERGY and MATERIAL BALANCES. Has somebody a complete material balance for all the phases? Otherwise unknown data plus hidden parameters put any positive results in doubt; there more unknowns than equations of balance.

SOLID- e.g. W electrode at start + ? --> electrode at finish + solid precipitate (composition?) I have told that my guess is that W is destroyed by spark erosion (as does Zr in the Cincinnati Cell) i.e. it does not react. This need a bit of analytical chemistry, however a simple balance: initial weight of the electrode vs final weight of electrode plus the **washed and dried** precipitate can tell something about the fate of W- is it broken, is it eroded, is it reduced, is it burn?

LIQUID- initial K2CO3 vs final K2CO3 plus KOH, K balance, CO3 minus 2 balance alternatively dissolved carbon can be measured

GAS- the most difficult part and the most critical, I dare to say! Energy is consumed in order to get gases; Gases are coming out the cell and add to the weight loss;
Extremely hot gases are bubbling through the liquid that is already close to the boiling point and get saturated (supersaturated?) with water vapors. Was the volume/weight & composition of gases plus the weight of the water after condensation and separation measured?

By the way is there a connection between the depth of immersion of the electrodes and COP? This is only an ad-hoc sketch of the chemical aspects of the material balance in these experiment.

18) John Coviello added:
. . . I don't think anyone would find anything exciting about what is going on in these cells if the heat measurements fell within the ranges of chemical reactions.

19) Ludwik Kowalski observed:
I am surprised that neither Mizuno nor Fauvarque, who are electrochemists, presented a complete discussion outlined by Peter Gluck. Why didn't they do this? I am less surprised by the absence of such discussion on Naudin's website; as far as I know he is not a chemist. Naming his device CFR (cold fusion reactor) he showed what he believes in nuclear origin of excess heat in Mizuno type cells. We have no evidence that the amount of "nuclear ashes," discovered by Mizuno, matches the amount of excess energy, as it seems to the case in some Fleischmann type cells. Fauvarque et al, by the way, also refer to their setup as CFR.

20) M. Jullian responded:
Ludwik: the possibility of such chemical reactions may have escaped Mizuno or Fauvarque. X4 you wrote: "Isn't that exactly what Ed Storms and Mike McKubre have been doing on other threads regarding the Colorado replications regarding questions raised about the amount of heat produced via chemical reactions?" The short answer is no. Mike first implied that no chemical reaction with the K2CO3 electrolyte can affect excess heat. Then two effects with the K2CO3 which do affect excess heat or it's measurement by evaporated mass were found by non-chemists, one by X2 and one by myself, fortunately it was worked out that they can only lead to underestimating excess heat, and only slightly, which is not a problem.

My questions were about the possible reactions . . . Of course Mizuno excess heat would not be exciting if it could have a chemical origin, and the fact that two hitherto unthought of reactions REDUCING apparent excess heat have suddenly sprung up suggests that there might be more waiting to be discovered, and there is no guarantee they won't CONTRIBUTE to excess heat. It's awfully hot in the plasma, and it contains hydrogen, oxygen, carbon, and potassium, in various combinations, probably all ionized by high electric fields and temperature and in highly reactive forms. Can we be sure no reaction affecting excess heat can occur in this furnace, other than the ones mentioned? We count on chemists to suggest a detailed protocol to ascertain this.

21) J. Coviello wrote:
I agree with the spirit of your inquiry. There is no reason why we should just accept the excess heat measurements without considering all the possible causes for the observed excess heat and the potential that the excess heat measurements are the result of error. It is correct to explore alternative explanations and only when those have been exhausted to entertain the idea that the excess heat is of nuclear origin.

People like Mike McKubre and Ed Storms have been working on cold fusion for over a decade (or longer) and they have certainly considered at times whether the heat is of chemical origin or not. The arguments I've read against the heat being of chemical origin is the simple fact that the observed excess heat is just too high to be the result of chemical reactions. If a chemical reaction has the potential to cause a 5 milliwatt increase in heat in a cell and the observations are in the 20 to 50 milliwatt range for excess heat, then the chemical explanation quickly falls by the wayside. I believe you are reinventing the wheel here, as the chemical explanation has been considered and dismissed many times over.

The one thing cold fusion research really needs at this point is a larger experimental setup, one capable of outputting heat in the watt range consistently. That would put chemical explanations and error questions to rest forever. I'm not sure what exactly is preventing scaling up cold fusion cells, besides perhaps simple economics, there isn't all that much money for cold fusion research. Whatever money has been available, such as the SRI work funded by EPRI that Mr. McKubre performed, was spent on basic research just to determine if the cold fusion phenomenon is real and is worth pursuing. Now that it has been established as real, we need massive funding for research efforts that determine the optimum operating environment to produce the cold fusion reaction and to scale the reaction up to levels that might be useful for energy production.

22) Ludwik Kowalski wrote:
X4 wrote: "People like Mike McKubre and Ed Storms have been working on cold fusion for over a decade (or longer) and they have certainly considered at times whether the heat is of chemical origin or not."
That is true. But I do not remember them analyzing chemical reactions in Mizuno type cells (along the lines suggested by Peter Gluck). These cells are very different from Fleischmann type cells that were used by most CF researchers. But Mike, Ed, P. Boss, S. Szpak and R. Oriani are electrochemists; their opinion would mean much more than opinion of numerous amateurs. I suspect that our experts have had reservations about Mizuno type cells but preferred to remain salient. Was it because the chemical environment is too complex or because they decided not to create a conflict in our own "army?"

23) P. Gluck wrote:
Dear X1, Excuse me please for adding that some physical effects have to be also considered. An example: The solution has a concentration of 0.2m K2CO3 i.e. also 0.2 m in CO2. If the CO2 is released in the very hot reaction zone as CO2 gas, that is 4.5 liters in normal conditions (1 mol is 22.41 liters). The conditions are far from normal, it is very hot there! If CO2 is released as a very hot gas, it mixes with the also hot hydrogen and oxygen, the gases are bubbling through hot water and get charged (saturated or not, it is a problem of kinetics) with water vapor -- and this leads to extra weight losses. Therefore such problems as: -- is K2CO3 decarbonated during the tests? -- what is the total volume of gases during an experiment and can it be correlated with COP? have to be considered too.

24) Richard Slaughter wrote:
The reason I decided to try the Glow Discharge experiment was that it did produce excess heat in the 10 to 100 watt range or 10 to 30% of input power. [That is much more than fractions of watt, as in many experiments involving the Fleischmann type cells.] I'm not a chemist but it seems to me that we should be trying to figure out what remains chemical after a successful experiment.

I can think of several test we should be doing. I'm sure the chemist can add several more. Find out if there has been a change of mass in the system. If all we are doing is evaporating H20 the total mass should be constant. Find out what amount of K2C03 still remains. Find out how much pure W is still the beaker and how much has gone into solution. Find out what compound is holding the W in solution

If we answer these question don't we have a complete picture of the energy balance of the system? Do we really need

to know the complex multistage relations that might have happen to reach this point? With this data can't we now calculate energy production per/atom and show that this production is outside normal chemical reactions and a potential energy source? Chemist, is there an inexpensive way to answer these questions?

25) Ludwik Kowalski wrote:
I think that this is good way to begin a discussion of "Mizuno cell chemistry for dummies." Suppose the water of used electrolyte is totally evaporated after an experiment. Then the recreated K2CO3 should be extracted from the deposit. No, I am not going to this; I do not know how to separate the K2CO3 from the remaining solid deposit. But a chemist can do this; I am sure Richard will be happy to send used electrolyte to a chemist willing to help us. Suppose that nearly 100% of the initial K2CO3 is recovered. This would show that no mass was lost in the form of the escaping CO2. The other extreme would be total absence of K2CO3 in the deposit. That would mean that concentration of the electrolyte was not constant in our experiments. Does this suggestion makes sense? I do not know which ions are formed when pure K2CO3 is initially dissolved in distilled water.

26) M. Jullian responded:
You wrote “no mass was lost in the form of the escaping CO2.” Not necessarily, as I explained in a recent post: “Note such analysis can be tricky though, as for example the above reaction could not be detected if the electrolyte was left to cool down in ambient air long enough: as Michael taught us the KOH would reabsorb the CO2 from the atmosphere and return to its initial K2CO3 composition."

27) Jed Rothwell wrote:
Ohmori and Mizuno are electrochemists, and they have done very thorough investigations of the cell chemistry.

28) Ludwik Kowalski wrote:
I do not recall anything of that kind in their papers downloaded from our <www.lenr-canr.org> library. It would be very useful if somebody who has access to Japanese papers, and who knows Japanese, could translate for us their analysis of the bulk chemistry in the hot plasma environment. In the context of this debate the bulk chemistry seems to more important than chemical impurities that might be confused with products of transmutations.

27) Mike McKubre wrote:
. . . My position is that the magnitude of the excess energy reported in this thread (and elsewhere) from this class of experiment (as others) is far too large to be chemical in origin. Actually I have been saying this for nearly 17 years. This is a matter of eV vs. MeV. It is a matter of quantification - something I see too little of in this somewhat airy discussion. . . . The Mizuno effect is of interest to me, but not one of my primary foci. In my view there are also far too many posts. I am a little disturbed by the new tone of Chemist/Physicist specialization. If you are going to do experiments or discuss them in this field you need to develop competence in both areas. They are not so different, or difficult. Do not retreat behind your ignorance or ask others to train you or do your work for you. . .

Appended on 4/1/06

28) Peter Gluck wrote:
I think that material and energy balances based on measurements, chemical analyses and search for cause-effect are necessary in order to distinguish between successful (say, COP>1.20) and failed experiments. Without balances for the solid, liquid and gas phases we will not be able to understand what happens and to know if the effect is real - and adequate for intensification and scale-up. The problem is that we have a **metastable system --** plasma, extremely hot gases, boiling water, great temperature gradients etc., and in these systems very small changes can have disproportionately great effects -e.g. fast evaporation, loss of mass. We have to establish if the difference between the successful and failed experiments is: - **thermodynamic** i.e. a real heat effect/excess - **kinetic** - in this case we need further investigation to decide if the effect is real.

29) Peter van Noorden wrote:
I want to stress that it is very important to look for the amount of non evaporated water/ evaporated water during the contact glow discharge experiments, because I think this can have a big influence the energy calculations of the cell.

As I earlier mentioned I did a lot of experiments with a system which has a long vertical condensor (about 1 meter). I used thallium chloride as an electrolyte to study remediation of radioactivity. I did not expect to see any electrolyte in the condensor flask but when I used radioactive thallium 201 I measured about 15-20% of the original activity in the condensor solution. This was very surprising so I assumed that 15-20% of the solution is carried away by (non evaporated) droplets. Further I noticed that during gentle electrolysis the thallium concentrated on the kathode surface (which is ofcourse normal), but as soon as the glow discharge started ,the thallium was rapidly expelled from the electrode and could be found at the bottom of the cell attached to the W debris. Probably this was the result of fast corrosion of the W electrode.

30) Ludwik Kowalski (not posted):
That is a very significant contribution. The COP close to 1.2, that we measured in Colorado-2 experiment would have to be reduced to 1.0 if only 80% of the water were known to be lost via vaporization and 20% in the form of tiny drops.

31) Johnny Coviello wrote:
I came across this critique [by Alexi Tekhasski] of the Mizuno evaporation measurements (see below) . The writer is saying that Mizuno and others who have found positive excess heat results from his experimental design are not accounting for liquid that is lost by the glow discharge cell due to mist created during the boiling process when bubbles violently break the surface of the liquid. The critic is saying that Mizuno and others are assuming that all the missing water has evaporated, and they are not accounting for mist created during the boiling process, which would reduce the amount actually evaporated during the experiment. I assume that Mizuno and others took this variable into consideration in their calculations, but this person says otherwise.

32) M. Jullian wrote:
Indeed. Mist becomes a central question obviously, it will have to be elucidated in a very definitive way, and I don't think an open cell will allow solving the controversy. . . .

33) Peter van Noorden:
This contact glow discharge reaction is very violent at 350V so you have a lot of mist which escapes from the electrolyte surface and is forced through the condensor..... The fact that the radioactivity is transported through the tubing (1 m high) and into the condensor vessel made me conclude that the mist above the electrolyte must be a combination of vapour and droplets

34) M. Jullian wrote:
Yes you are righ, it must be a combination. Indeed there is no way to tell condensing vapor from mist as they are the very same thing: liquid droplets. . . .

35) Peter Gluck wrote:
. . . The Peter's experiment shows you that the very hot gases are very fast too and they carry microdoplets of solution at relatively great distances in fragments of a second..... I made Mizuno type experiments - very preliminary, with stainless steel electrodes (in Gene Mallove's lab in 1998) and have observed that above the plasma zone there is splashing and it is very hot. But have not measured HOW hot and this is an important unknown parameter. We also do not have the slightest idea now, if potassium carbonate is converted in hydroxide and in which extent.That is we have CO2 too.

I am an engineer (chemical, bien sur) and I am not very fond of experiments in which the electrodes are destroyed so fast. (the Cinci Cell has the same fatal flaw), therefore I have not continued this work. The system is not so simple as it seems and therefore the new experiments have to be planned carefully. In case the group needs my know-how, I am glad to help. Please read what I wrote re. the material balance.

36) Jed Rothwell wrote:
Look up "wet steam" and "dry steam" and you will see that engineers have been dealing with the enthalpy of steam and the issue of moisture in steam since the late 18th century. Measuring enthalpy by weight loss alone is a crude

method, as I said here several times. Perhaps it proves there is excess heat but I would not trust it +/- 10%, so the significance of 20% excess is low. The other methods used by Mizuno -- such as bomb calorimetry and flow calorimetry combined with mass spectroscopy -- are much more reliable and convincing. Since there is no jet of steam leaving the cell it is not likely that droplets will be carried a long distance, but it is still better to condense the steam and let the hot water drip back into the cell, the way Mizuno has done. This eliminates the issue altogether.

37) Ludwik Kowalski wrote:
Yes, the COP=1.2 is probably the smallest one can trust by using a simple technique. But, according to Pierre, the COP close to 2.0 are constantly reproducible in Naudin's lab. Was it an exaggeration, Jean Louis? Please describe your most efficient excess heat generator for us. What metals are used as electrodes? Are you also using the 0.2 M K2CO3? What is your average current? At what voltage are you operating? Numerous reports about reproducible experiments with the COP>1.3, coming from students, teachers and amateurs, would have an effect on mainstream scientists. Simple and inexpensive techniques should be encouraged. More sophisticate techniques are for those who can afford them.

38) M. Jullian wrote:
. . . indeed there is no reason to expect the mist's droplets to have a given minimum size, most of it's mass could well be invisible, and it would have no particular reason to be entirely caught by a screen of any arbitrary fineness. . .

39) J. Rothwell wrote:
[The simple evaporated mass method] is wonderfully nice and simple, but not precise, and not very reliable. To make it precise you would have to bring in all kinds of complex instruments and measurement techniques. The same goes for any method of calorimetry, except the Seebeck method. Flow calorimetry is conceptually nice and simple, but Mike McKubre will tell you, beyond the conceptual stage it becomes messy and complicated in real life. The same is true of the evaporated mass method. If you want to make it better than 10% accurate you will have to spend a few thousand bucks and a few months I suppose. Why bother?

There is a reason why I kept saying this "wet steam" issue makes me nervous, and why I have not expressed overwhelming confidence in the results reported here. As I said, if you improve your calorimetry you may well find your excess heat results vanish. There is also a reason why Mizuno stopped using this technique many years ago.

40) Ed Storms wrote:
The plasma method dissipates generated heat mainly by boiling water. In addition, this is how the excess energy will eventually be used, i.e. by making steam. Rather than fighting this condition, why not use it to measure the heat produced? This can be done by surrounding the plasma cell by good insulation (no calorimeter), have water of known temperature delivered to the cell at a rate required to keep the level constant, and allow the steam to exit through another tube. Place a plug of glass wool in the exit tube, within the plasma cell, to trap any droplets. Measure the temperature of the steam as it exits and weigh the condensed water. You can measure the pH of the condensed water to determine if any droplets get through the filter. Of course, some H2, O2 and CO2 will be in the exit gas. The amounts of these gases are easy to determine. The H2 and O2 can be combined back to H2O using a catalyst and the resulting water weighed. Once steady state has been achieved, you have an easy measurement of produced power. In addition, the apparatus can run as long as you wish to show that the output is stable. If significant over unity is indicated, the arrangement would be easy to scale up. Almost all errors will result in a lower value for produced power, hence believable OU if it is claimed. The main challenge would be to make the size of the plasma and the exit pipe compatible to prevent too much pressure buildup in the cell. Eventually, this pressure can be increased to give steam at a higher temperature. Why is this approach not used?

41) Richard Slaughter asked:
Ed, I like your proposed approach. I know there are chemical catalyst to recombine the H2 and O2. I have the impression that these can be dangeroue if the system is not running at the right temperature and there is no visable way to know the catalyst is working. Would it be ill advised to use a spark generator to recombine the H2 and 02? I like the idea of a spark generator because I can tell instantly if it is working. You are proposing a semi-closed cell so I'm concerned about gas build up.

42) M. Jullian wrtote:
In terms of indisputability by a careful reviewer, even if Pt was cheap, a unity COP with Pt as Ed and you suggest wouldn't help in the least because conditions would be too different. Plasma temperature would be different for one thing (different melting temperature). As I suggested before, even a unity COP obtained with a _tungsten_ cathod in a negative run isn't proof that a 1.3 COP in a positive run isn't an artefact (it could be due e.g. to the right regime of discharge nebulizing a particularly large amount of mist).

Group, it occurred to me that the simplest and least expensive method to _quantify accurately_ the mist phenomenon would be to condense each run's exhaust gases as has been suggested, _measure the total salt content_ of the condensates(*), and if not zero use it to correct the run's COP precisely (the maths are easy). This would eliminate altogether the need for a mist filter and would be skeptic-proof I would think. Your opinions welcome.

43) Ed Storms wrote:
a) Wet or dry, the steam leaves as a gas and the droplets join the liquid phase that slowly drips back into the cell. Droplets do not result from the steam or form within the steam, but form as bubbles burst on the electrolyte surface.

b) You wrote: “a way to renew the cathode continuously must be found for this.” This is easy to do by feeding a W rod through a glass tube into the cell. You might need to drain the cell periodically to remove the tungsten, tungsten oxide, and transmutation particles that would accumulate.

c) You asked about the mist filter. As I described above, the steam would push through any liquid in the plug. Because the plug is in the cell, the hot water returns to the cell where it adds its energy to the generation of more steam. Of course, the plug needs to be designed so that steam can leave at a slow rate, to avoid creating additional bubbles, and to allow the water to drain away. Such a design is easy to create.

44) L. Kowalski wrote:
a) Condensing escaping gasses (if practically possible) and vapors, makes sense to me. Please elaborate. (see the P.S. comment below).
b) Using a bomb calorimeter, as suggested by Jed, also seems appropriate when excess heat is generated at the rates of tens of watts, or more.
c) I wish to see more people performing experiments and reporting results.
d) Exploring the same type of phenomenon, and discussing the results on this list, could be very effective.

P.S. Suppose the mass of the water escaping from the condenser is measured. How do we determin what fraction of that mass is from the vaper and not from tiny drops escaping with it? The fraction must be known to calculate the COP correctly.

45) Ed Storms responded:
I don't understand why this is an issue. Removing the droplets is trivial. A resistively measurement of the condensate would give a good analysis for the amount of electrolyte that was not removed.

46) L.K. (not posted):
I am confused. If tiny droops are removed somehow (sparging ?) then what condenses should be pure water. Ed is referring to the study of the resistively of removed droplets. Obviousely, I did not understand some messages.

47) M. Jullian wrote:
. . . Ludwik I disagree with your objection that the condensate salt contents measurement method I suggested cannot measure escaped mist. Let me explain by using an example: if we find say 5g of salt in the condensate, along with _any_ amount of water, and if the electrolyte concentration is 50g per liter, then we can conclude 0.1 liter of electrolyte has escaped as mist. So 100g should be subtracted from the mass loss to determine evaporated mass, agreed? You also said the scale would not be needed anymore, why is this?

48) Jed Rothwell wrote:
. . . Conventional instruments and experimental techniques work fine. People have doing calorimetry and dealing with wet steam for 220 years. Find out how it is done and stop fretting about it. There are plenty of things that actually go wrong with this experiment, so stop inventing imaginary problems.

49) Ludwik Kowalski responded:
1) I disagree; it is better to anticipate what honest referees might say and to address the issues before submitting a paper. This debate was highly instructive to me. It showed that the issue of tiny droplets should be taken very seriously.

2) My last message showed that I did not understand the essence of Michel's suggestion. Only now do I do understand what he, and Storms, had in mind. It is a very clever method of determining the fraction of water escaping in the form of tiny drops. Yes, the scale would be needed, as in Paris-1 and Colorado-2. Am I the only one who did not understand the original proposal? Probably not. The Marseilles-1 experiment will probably produce more convincing results on reality of excess heat than earlier experiments.

50) M.Jullian wrote:
. . . As a lower cost alternative to a condenser, the mist collector could be an _external closed paper filter_ with a _large surface area_ (for low back pressure), airtightly connected to the cell's vent tube (a large vacuum cleaner bag with it's rubber gasket would do the trick), one numbered filter per run. The filter would be weighed once dried, and its new mass minus initial mass would yield the run's escaped salt mass (a more precise version of Mizuno's paper towels disposed around the cell as described by Jed).

Note the filter once dried and weighed would be reusable e.g. the following day ; successive dry weights, increasing with salt accumulation, could be handwritten on the filter itself vs the run numbers, e.g.:

0 -> 28.1g (initial mass)
1 -> 33.2g (+5.1) (run 1 has expelled 33.2-28.1=5.1g of salt)
19 -> 37.5g (+4.3) (run 19 has expelled 37.5-33.2=4.3g of salt)

IMPORTANT: the mist collector must exert no force on the cell: we mustn't count its weight with the monitored cell weight because at least some of the vapor will condense in the mist collector, which would make the evaporated mass erroneous. If we use a vacuum cleaner bag it must be independently suspended, with its opening on top, and the cell's rigid vent tube bent twice to connect airtightly but with zero vertical force with the bag's soft rubber gasket.

51) Ed Storms commented:
a) I get the impression that you have never seen glass wool and think it looks and acts like cotton. If it acted like cotton, it would not work as a filter because, as you say, it would block steam flow. Glass wool has a very open structure and it does not mat when it gets wet. Before you reject this method, I suggest you look at glass wool. I suggest a tube 2cm in diameter lightly packed, which is connected to a tube 0.5 cm in diameter that exits the cell.

b) Also, the paper filter method will not work. You need to have the filter where it remains hot so that steam will not condense. Otherwise, you will get a lot of water that did not come from droplets.

51) M.Jullian replied:
a) I personally trust your word that it would block all the mist without any back pressure, but this claim would be hard to prove indisputably, especially if the reviewer has never seen glass wool as you say. The only way actually would be to have external capture AS WELL, and then there would be no point in having an internal filter at all. So my point is that external mist collection is all that is needed, and we have plenty of room to do it.

b) You will indeed, but it doesn't matter as only the dry weight matters! As I wrote earlier, and as Ludwik may be the only one to have understood in fact, "if we find say 5g of salt in the condensate, along with _any_ amount of water, and if the electrolyte concentration is 50g per liter, then we can conclude 0.1 liter of electrolyte has escaped as mist. So 100g should be subtracted from the mass loss to determine evaporated mass"

52) L. Kowalski
I posted a long message (see in blue below) to which M. Jullian responded. He quotes my entire message and comments in different places.

53) M. Jullian:
You see I too think that mist is not really a problem, I don't even think chemical heat is a problem, but again what we think doesn't matter in the least, we need hard facts to put to rest any doubt a honest reviewer could have. Mist is one of those doubts, and chemical heat is another.

Hi Ludwik, my comments inserted into your blue text.

Let me try to review the situation, as i see it. Please correct me, if necessary. The goal is to reach an agreement on what is the best way to proceed. The bomb calorimeter, suggested by Jed, seems to be a good approach. But like in everything else, the devil is in details. I hope somebody will use a bomb calorimeter to confirm reality of OU ("over unity" COPs). Here I want to focus on the boiloff cell as used in Paris-1 and Colorado-2.

1) Use of the thermos is desirable but not essential because a large fraction of heat seems to be lost via convection above the open cell.
2) Layers of foam outside the cell walls are desirable (to keep the nonevaporative losses low).

I would think 1/ is better than 2/, both as a thermal insulator, and in terms of optical transparency (I suggest we use a transparent Dewar flask).

3) The cell should not be too large. In that way the electrolyte will boil and its temperature will be uniformly ~100 C, even when the wattage is low.

Agreed. It just has to be large enough to hold the electrodes and the heater.

4) A small ohmic heater (say 200 W) should be inside the electrolyte all the time. It should have its own W*h meter. In that way one should be able to turn it on and off at any time (to keep the electrolyte boiling, when plasma current is too low for this.

Agreed.

5) The COP is calculated as:

COP == Et / Ee (thermal energy released/electric energy received)

The electric energy is the sum of W*h (or joules) recorded by electric instruments (including the ohmic heater W*h measuring device) during a test. There are nuances in measuring the Ee, for randomly oscillating currents, but this is not our main problem. The thermal energy is:

Et = Ev + Ed + Ec + Er = Ev + En

It is the energy used to evaporate water (v) plus the energy escaping by conduction (d), escaping by convection (c) and escaping by radiation (r). The nonevaporative loss En, is simply the sum (Ed + Ec + Er). The method of measuring En with an ohmic heater, used in Paris-1, Texas-1 and Colorado-2 experiments is highly appropriate. Next we come to the

main problem. The Ev was calculated as 2260*dm1, where 2260 J/g is the latent heat of evaporation while dm1 is the mass of water evaporated during an experiment. Unfortunately, what we measure with a scale is not the dm1 but the dm=dm1+dm2, where dm2 is the mass lost in the form of tiny droplets. Up to now we assumed that dm2<<dm1. But, as indicated in the discussion, this assumption must be experimentally validated. If the assumption is not valid then Ev must be calculated as 2260*(dm-dm2), where dm is that we measure with a scale and dm2 is the amount of water escaping in the form of tiny drops. Ignoring the dm2 we overestimate the COP.

Ejection of large (visible) drops can be practically eliminated by covering the cell with a fine wire mesh. Large drops are stopped be the mesh and fall back into the cell. Under favorable plasma conditions large drops are rare and they contribute to a small fraction of En (which we measured). The main problem is how to measure the dm2, or how to show that it is indeed negligible in comparison with the dm1?

Michel first solution was to collect all water escaping from the cell and to condense it. Suppose that the scale tells us that dm=10 grams while the mass of condensed water is 7 grams. It means that ~30 % was not condensed. It is important to know the percentage. Michel suggested that condensed water must be evaporated in order to collect solid deposits. The water that was evaporated did not contribute to that deposit. Only the tiny drops bring the dissolved chemicals with them.

We know how much deposit is produced when we evaporate one cubic centimeter of the electrolyte (taken from the cell). Suppose it is 0.3 grams. If the amount of deposit per cc of condensed water is 0.003 grams we can say that dm2 is indeed negligible (when the accuracy of 5% is sufficient). But what would we say if the measured amount of the solid deposit, per cubic centimeter of condensed water, turned out to be 0.1 grams. We would say that about one half of water lost was due to the dm2. Why one half? Because not 100% of lost water was condensed. This shows that the value of dm2 can be determined. Once determined it could be used in the calculation of COP.

Condensers, cooled by tap water, are routinely used by chemists. My guess is that the cost could be about $250. Please correct me if you can; I do not have any catalogues at home. What is not clear to me is a method to catch the escaping water (dm1 and dm2) into the condenser.

A thin rubber diaphragm connecting the cell output tube to the condenser input as I suggested should do the trick (think of the vacuum bag gasket if you have ever seen one of those ;)

Vertical leads to the anode and the cathode, in our cell, would interfere with efficient capturing of the escaping water into the condenser.

We need airtight seals for the leads and everything that goes across the lid. The lid itself must rest on top of the Dewar via a rubber gasket. The inverted U shaped output tube should be sealed to the lid.

So much for a condenser idea, as I understood it yesterday. Simple in principle but not easy to implement in practice, unless one is well equipped for custom-made devices.

6) I am not sure I understand your glass wool filtering method, Ed. How does it help us to determine the dm2? I can visualize a layer of glass wool above the cell, for example between two plastic screens (used on window). The screens have holes to insert electrodes. Suppose the scale tells that 10 grams of water was lost during an experiment. What else do you have to measure to determine the dm2?

7) Michel's method is conceptually clear to me. But it might indeed lead to a large underestimation of Ev (energy used to evaporate water), as indicated by Ed.

No! Wrong, as I have explained to Ed, and I thought you had understood! Dry mass of condensate is all that matters. Again: "if we find say 5g of salt in the condensate, along with _any_ amount of water, and if the electrolyte concentration is 50g per liter, then we can conclude 0.1 liter of electrolyte has escaped as mist. . . .

Underestimation, however, is not as bad as overestimation; it would mean, for example, that what is calculated as

COP=1.2 might actually be 1.5 or more. But we want accurate determinations of COPs (to get the mean value and the standard deviation). I do not understand Ed's objection that the ionic composition of the electrolyte must be known.

Ed's objection could be valid maybe if a large mass of escaped salt is found, which we hope won't be the case.

A filter can always be calibrated by using the electrolyte taken from the cell. We can place 1 cc of the electrolyte on the filter, allow the water to evaporate and measure the amount of the remaining solid deposit. Then determinations of dm2 can be made, at least approximately, in consecutive tests. It would be important to often add 100 C water to the cell to keep the concentration of the electrolyte constant, more or less.

Yes.

My hope is that dm2 will be found negligible. A submitted paper stating that this was indeed the case would be much more difficult to reject than the paper in which the negligibility of dm2 is assumed.

Yes!

P.S. (next day): Now I realize I missed your point (and Ed's). You referred to the external paper filter solution, and assumed that the wet filter was on the scale along with the cell hence affecting it's weight, which indeed would lead to a large underestimation of Ev due to re-condensation of some of the vapor in the filter.

The answer is still "No! Wrong", and the explanation was in my proposal:

IMPORTANT: the mist collector must exert no force on the cell: we mustn't count its weight with the monitored cell weight because at least some of the vapor will condense in the mist collector, which would make the evaporated mass erroneous. If we use a vacuum cleaner bag it must be independently suspended, with its opening on top, and the cell's rigid vent tube bent twice to connect airtightly but with zero vertical force with the bag's soft rubber gasket.

In case your vacuum cleaner bags don't look the same as mine, mine feature a thin soft rubber membrane with a circular hole in them, which connects airtightly to a slightly conical rigid tube at the end of the cleaner hose by a push-on action when installing the bag in the cleaner. This kind of airtight coupling does not exert any significant force perpendicularly to the membrane plane, so if this plane is horizontal there is no vertical force which could affect the cell's weight. So there would be no underestimation of Ev at all. Same kind of no-vertical-force coupling should be used in the condenser solution IMHO. A bellows type airtight coupling would work too (probably better actually).

The corollary of this absence of vertical force between the cell and the output capture device is that the latter must be suspended independently of the cell of course.

Let me know if the above was still unclear, as this point is important: it's ok to underestimate the COP, but not grossly!

54) L. Kowalski again:
J.M. wrote “Mist is one of those doubts, and chemical heat is another.” According to private messages, Paris-2 results will allow us to rule out the anticipated "chemical heat" objection. I hope that new information will soon be published here. Then we can discuss significance of numerical data.

We want to know much water is lost as vapor (dm1), and how much water is lost as tiny droplets, (dm2). A separate experiment, not the one whose purpose is to measure the COP, can be conducted. Michel's idea is to capture a sample of what is escaping. This can be done by using glass wool (also used as thermal insulation) or by using a paper-like filter (also used in common vacuum cleaners). In each case the sample is weighted twice, first as wet and second as dried (after water is allowed to evaporate. The difference was tell us how much water was in the sample, the second mass will tell us how much deposits. A lot of deposit would indicated that dm2 was large, very little deposits would indicate that dm2 was very little.

Knowing the volume of water in the sample, and the amount of salt in it, we are able to calculate the salt concentration

(for example, in mg/cc = grams/liter). Suppose the sample had 0.27 mg of solid deposit per one cubic centimeter of evaporated water. We then take some electrolyte from the cell and repeat the procedure. Suppose we find 27 mg of solid per cubic centimeter. Would it be appropriate to say that dm2, mass lost in the form of tiny drops, is 1% of the total mass lost? I think so. Note that the vapor escaping from the cell consist of pure water while the droplets escaping from the cell contain the salt. Consider the extremes. If 100% of the liquid was lost in the form of tiny drops then our sample would have the same concentration of salt as in the electrolyte taken the cell. And if 100% of the electrolyte was lost in the form of vapor then the concentration in the sample would be zero.

Did I describe your suggestions correctly, Michel (paper filter) and Ed (glass wool)?

Here is another way to accomplish the same thing. Suppose a large funnel is placed above an open plasma electrolysis cell. The leads to the electrodes, in this control experiment, can be on the side of an open plastic cell. The narrow exit tube of the funnel is plugged in and sticks up, like a blocked chimney. The wide end of the funnel is only several centimeters above the cell. A bag with ice can be used to keep the funnel cold. The diameter of the funnel should be larger than the diameter of the cell. Under such conditions what comes out of the cell will condense on the inner surface of the funnel and drip down into a large plate (on which the cell is standing). We can collect the liquid, measure its volume, and remove the water by evaporation. This again will give us concentration of the salt in the sample, for example, 0.27 mg/cc, as above.

I suggest that an estimation of dm2 should be made in Paris-2. Any one of these three approaches is likely to tell us the fraction of the liquid lost in the form of tiny droplets. If dm2<<dm1, for example, 1%, then the reported COP are fine. Otherwise, the COPs should be recalculated by taking the dm2 into account. Note that in Colorado2 COPs were calculated under the assumption that the dm2 is negligible. Will the Paris-2 data justify that assumption? That remains to be seen.
P.S.
Actually three mass measurements must be performed with each sample, not two. First before catching the liquid, second when the catcher is wet, and third after the catcher and remaining solid in it, are dry.

P.P.S.
On Apr 2, 2006, at 3:34 PM, Michel Jullian wrote:

You see I too think that mist is not really a problem, I don't even think chemical heat is a problem, but again what we think doesn't matter in the least, we need hard facts to put to rest any doubt a honest reviewer could have. **Mist is one of those doubts, and chemical heat is another.**

1) According to private messages, Paris-2 results will allow us to rule out the anticipated "chemical heat" objection. I hope that new information will soon be published here. Then we can discuss significance of numerical data.

2) Go to Google type "distillation," in the search box, and click SEARCH. Then type on "images," above the search box. You will see standard glassware used in laboratories. Before deciding what is the best we must know what we want. How much water is lost as vapor dm1, and how much water is lost as tiny droplets, dm2. A separate experiment, not the one whose purpose is to measure the COP, can be conducted. Michel's idea is to capture a sample of what is escaping. This can be done by using glass wool (also used as thermal insulation) or by using a paper-like filter (also used in common vacuum cleaners). The difference was tell us how much water was in the sample, the second mass will tell us how much deposits. A lot of deposit would indicated that dm2 was large, very little deposits would indicate that dm2 was very little.

55) J. Rothwel:
The ice would probably cool down the cell and interfere with calorimetry. Keep ice away from these experiments. I have seen some really dreadful experiments involving ice and calorimeters (and one impressive one). Mizuno used a much better condenser. The flow calorimetry cooling water condensed the steam and the water returned to the cell. See: <http://lenr-canr.org/acrobat/MizunoTconfirmatib.pdf>.

I do not understand why you want to use such complex and unusual methods, when simple, direct, foolproof methods are available. "Wet steam" is only a problem when you do take steps to prevent droplets from leaving the cell or to measure the total enthalpy of the effluent gas. Such steps are trivial, as Storms pointed out, and once you take them you need not worry about the problem again. You do not need to invent six different ways to address this. Simply select the most convenient method from the ones already suggested by Mizuno, Storms and me. (I suggest sparging and measuring the temperature rise of the water column.) It does not matter which method you use.

56) L. Kowalski:
Yes, ice should be kept away while measuring the COP. My suggestion is to conduct a control experiment whose only purpose is to determine the fraction of mass escaping in the form of tiny drops. Once know, for a given electric power, and given geometry, it can be used in experiments whose purpose is to measure the COPs.

Any method is OK for me. The funnel method was just an improvisation. The glass wool catcher seems to be the easier. But to avoid possible consequences associated with glass-wool needles I would use paper towels, napkins, or toilet paper instead. Keeping such collectors above the running plasma cell would accumulate escaping liquids at the rates of grams per minute (?). What can be more simple than this? Measuring the percentage of the liquid lost as droplets, in a separate control experiment, should be done by anybody performing Mizuno type experiments. Perhaps Richard will do this. Then we will know by how much our Colorado-2 COPs must be corrected.

57) M. Jullian:
I submit on the contrary that mist measurement, or any control measurement, must be done on the very runs for which we measure the COP. Otherwise we prove nothing at all, because the ODD overunity runs could be thought by an honest reviewer to be due to the PECULIAR, hard to get, right kind of discharge generating equally PECULIAR ARTEFACTS, like for example: - nebulizing a particularly large amount of mist (e.g. by this discharge generating ultrasounds of the same frequency as used in an ultrasound nebulizer). (a)- plasma reacting exothermically with the salt. (b) - generating an insulating foam layer (c) - or anything which may give the false appearance of excess heat and hasn't been thought about yet.

58) Jed Rothwell:
Michel Jullian wrote: “Hi Ludwik! I submit on the contrary that mist measurement, or any control measurement, must be done on the very runs for which we measure the COP.” Yes. This is essential. Also you should use the simplest and most conventional method possible. Never invent a new or unusual technique if there is already a standard, widely accepted one.

59) L. Kowalski:
Then the ohmic heater should not be used; the nonevaporative losses of thermal energy should be made without it. How can this be accomplished? Let the perfect not be the enemy of the good. I would also prefer a setup in which all measurements are made during one operation. What I am suggesting is a simple costs-nothing test that should make the overunity COPs more credible.

60) Chemistry facts (not posted):
a) What is formed when the K_2CO_3 is dissolved in H_2O? It is K^+, CO^{--}, HCO_3^- and some H_2CO_3. How much of each depends on the temperature. The CO_2 is lost to air because the H_2CO_3 breaks into H_2O+CO_2. The amount of CO_2 going into air increases with temperature. After the electrolyte cool the CO_2 may be taken back from the air but this is a slow process (hours or days) of recreating the H_2CO_3.

b) Can the K_2CO_3 be restored, for example, when the electrolyte was not used for many days and then allowed to evaporate, forming a solid residual deposit? That would create an illusion that no potasium carbonate was spent during the plasma electrolysis. The fact is that all K_2CO_3 disappears quickly when the electrolyte is made.

$HCO_3^- + OH^- \dashrightarrow \dashleftarrow CO_3^{--} + H_2O$

Some KOH might be formed in the electrolyte (from K^+ and OH^-). It is a complex, temperature-dependent kinetics.

61) Peter Gluck, who is a chemist, wrote:
Perhaps it would be useful- for understanding how the Mizuno system works- to perform some qualitative tests, before deciding re. the new experimental setup. It seems we have a system in which a solution of a K salt in water at ~ 100 C is in contact with a plasma flame at (?) 3000 C. A huge temperature gradient. Unnatural combination. It would useful to:

(a) measure the temperature above the plasma zone - a bit above the water level;

(b) to put a baffle - e.g. a sheet of shiny stainless steel in the same zone in order to collect the microdroplets and to see if what's released from the cell is K2CO3 or KOH (pH will tell, or you put a bit of acid and see if gas-CO2 is released or not)

(c) if it is KOH mainly, then to establish if the initial K2CO3 is transformed in KOH- that means CO2 is added to the gases, the material balance has to be made for the ion K+

(d) if this is the case, to see what happens - in the actual system if the carbonate is replaced with KOH from the start- is plasma formed? the COP is O/U? etc.

(e) to see if the W precipitate has the the structure I expect i.e. a core of salt covered by molten and frozen metal (formed by spark erosion) - a simple microscope is needed.

62) L. Kowalski:
Jed wrote: “I submit on the contrary that mist measurement, or any control measurement, must be done on the very runs for which we measure the COP. ”The paper-towel test (PTT), suggested yesterday, can be performed in that way. A typical Colorado-2 experiment lasted 12 minutes; after that we had white flashes indicating that the sticking end of the cathode was essentially consumed. Suppose the time from t~0 to t~2 min is used to perform one PTT and the time from t~8 to t~10 min is used to perform another PTT test. The COP can then be measured in 8 or 9 minutes between these two tests.

63) Michel Jullian:
Your paper towel test proposal consists in covering the top opening of the cell with paper towels to collect escaped salt. I don't see how you could perform a COP measurement while doing this test, as some amount of evaporated water will recondenses in the towels, wronging the evaporated mass measurement . . .

64) L. Kowalski:
I believe that the paper towel test is the same test you suggested (keeping the vacuum cleaner bag above the open cell). The only difference is that your bag is above the cell the entire time interval during which the plasma electrolysis is going on, for example 11 minutes while I would collect two small samples of the escaping liquid, one during the first minute and another near the end. The COP is measured between the sampling. Nothing is turned off or changed. In that way the COP measurement is performed under the same conditions as when the two samples are collected.

Yes, you can question "the same conditions" assumption but, as stated by Jed, that would not be reasonable, especially if the two samples give about the same % of mass lost in the form of droplets. Neither time nor mass lost by the cell have to be monitored when a paper towel (or toilet paper, or a handkerchief) is kept (by hands) about 5 cm above the open cell for about one minutes. That test might not answer all the questions but it is so simple that one must perform it. I hope that Pierre and Richard will perform such tests and share the results with us. We do expect the percentage to be small. That results should be reported in our anticipated paper.

65) J. Rothwell:
I doubt this test would prove anything. First of all, the method is crude. Some water vapor would condense on the towel (false positive). On the other hand if there are droplets in wet steam, many would miss the towel and drift away

in the air (false negative). It is impossible to tell which is more likely. Second, there would only be 5 or 6 g of droplets over 1 minute, and you have no idea what fraction of this you can capture with a towel. In your message of 3/15/2006, you said that over a 20 minute run, the weight of the cell drops from 3052 down to 2801 g. That is 13 g per minute. You said the apparent COP was ~1.4, and a null run was around ~0.8. So about 4/10 of the lost water would be in droplets to explain away this excess heat.

I think you should stop dreaming up crude and unusual ways to address this problem, and simply use industry standard methods. Also, by the way, if you do this experiment again, I strongly recommend you use a computer, multiple thermocouples, digital cameras, and other modern instruments to record the event in detail, and a magnetic stirrer and other gadgets to improve accuracy. There is no point to going to all this trouble to do the experiment if you are going to use primitive 19th-century instruments.

66) Michel Jullian:
Ludwik I hadn't realized you meant to hold the paper towel _by hand_! But in this case as Jed just pointed out the steam and mist won't be forced through the paper as was the case with my airtightly connected vacuum bag suggestion, so you will only capture a tiny fraction of the mist because it will just go round the obstacle, so you'll overestimate the COP. It's a very sloppy solution, and it just won't work.

67) L.Kowalski:
Suspecting that the debate about a reliable estimate of the % of the liquid lost in the form of tiny droplets reached the point at which most people are no longer interested, I suggest that Michel, Jed and myself discuss this topic in private, at least for a while. My reply to the last message from Michel will go to him and to Jed only. But I will be happy to add names of those who might also be willing to participate. Write to at <kowalskil@mail.montclair.edu>.

68) L. Kowalski:
PRIVATE
1) Michel, please write again the latest version of your method. I suspect I am missing something important. Please attached a crude picture. Then I will comment.

2) Jed, you wrote: "First of all, the method is crude. Some water vapor would condense on the towel (false positive). On the other hand if there are droplets in wet steam, many would miss the towel and drift away in the air (false negative). It is impossible to tell which is more likely." I agree, that is a serious issue. I do not want to catch all that comes out, a large enough sample is sufficient. But it is true that the percentage of tiny droplets I catch might decrease when the paper towel is kept higher. Perhaps Michel's method will not suffer from this. I will wait for his picture plus detailed description.

69) Michel Julian:
Hi Ludwik, the vacuum cleaner bag solution was an earlier more complicated proposal, forget about it. As I said no accessory is needed in the current proposal. So I guess it's now time to address the more refined proposal, which allows for CO2 emission.

It is based on potassium mass loss (which can only occur through mist emission), rather than on total salt mass loss (which is affected not only by mist emission but also by gaseous CO2 emission as Peter Gluck pointed out). So basically we just replace "salt" by "potassium" in the method:

1/ weigh the cell's potassium before the run (when preparing the fresh electrolyte ; mass of potassium can be deduced easily from salt mass and salt formula) 2/ weigh the cell's potassium after the run (e.g. measure by precise chemical analysis K+ concentration in g/l, which any medical lab can do for you, and multiply by precisely measured volume)
3/ subtract to get escaped potassium mass
4/ infer escaped droplets mass from escaped potassium mass, based on
salt concentration and formula. Does it still make sense?

70) Jed Rothwell wrote:
We beat that horse to death days ago. Ed & I suggested several ways to solve this problem. If you do not like our

suggestions, do it your own way. I am fed up with repeating these suggestions and I will not say another word about it. In fact, I am fed up with this whole discussion!

71) L. Kowalski wrote:
Too bad that you decided not to share me with what you know about old ways of measuring the percentage of droplets escaping with steam. I do not think our university library has book about this. But I will look for them. Perhaps measuring the temperature gradient in a pipe above the cell, as you hinted, will become clear to me. I know how to measure the gradient of temperature but I do not how to use this information to get what we need. Do not give up on me; I would be glad to endorse your recommendation after understanding it, and after playing with some realistic numbers.

72) J. Rothwell wrote:
Don't be tiresome Ludwik. Review the message archive here and look at the literature. I spelled it out several times and so did Ed Storms. I will reiterate the methods one last time.

Pons: reflux calorimeter. For more, enter the search term "reflux" into the Google search box at LENR-CANR.org.

Mizuno: flow calorimetry, where the cooling fluid goes through a condenser first. http://www.lenr-canr.org/acrobat/MizunoTconfirmatib.pdf

Storms: glass wool in effluent gas tube.

Rothwell: sparge effluent gas tube through a water column. I suggest you insulate the water column and measure the temperature rise. Storms suggests you measure the pH of the water column, or condense the steam by some other method and measure the pH of the condensate. Storms: use a large, closed Seebeck calorimeter. (I agree this method is the best by far.)

73) J. Rothwell wrote:
Here is my suggested method of doing the Ohmori-Mizuno glow discharge experiment while accurately accounting for wet steam. This is based upon many observations I made of both Ohmori and Mizuno at work in their labs, and it is also based upon suggestions made by Storms in this forum recently.

If the run is going to be short, 10 or 15 minutes, I suggest you use a well-insulated cell. (What I have designated "bomb calorimetry.") Seebeck calorimetry is preferred but it is more expensive.

Cover the cell with an airtight lid with various orifices in it to accommodate the anode and cathode lead wires, thermocouples and so on, plus an exhaust tube to capture all effluent gas. You might want to include an emergency valve in the lid. This can be as simple as a drinking straw bent into a "U" shape and stuffed into two holes.

Stuff glass wool into the end of the exhaust tube that goes into the cell. This will stop most of the moisture from leaving the cell.

1) WHAT IS MOISTURE? PROBABLY DROPS OF WATER, NOT VAPOR. THE INTERCEPTED DROPS WILL DRIP DOWN TO THE CELL, AS DESIRED. RIGHT?

Prepare a condensation water column. This is a well-insulated, tall beaker. Weigh it, fill it with ~200 mL of distilled water, and weigh it again to determine the exact mass of water. Measure the pH of the water.

--> Right. Liquid water entrained in the steam will drip back into the cell.

Put the other end of the exhaust tube at the bottom of the water column so that all effluent gas bubbles out through the column and the steam condenses. Also insert a thermocouple into the water and record the temperature.

2) THAT PART IS NOT CLEAR TO ME. HOW IS THE TOP OF THE EXHAUST TUBE (ABOVE THE GLASS

WOOL) CONNECTED TO THE WATER COLUMN ABOVE? ON THE PICTURE I AM MAKING THE WATER IN YOUR CONDENSATION COLUMN WOULD RUN DOWN INTO THE CELL (THROUGH THE GLASS WOOL). WHAT AM I MISSING.

--> It is very simple, [see the drawing below]: That drawing shows that the water column is not above the cell, as i assumed. It is a beaker standing on the same table that the scale supporting the cell. The U-shaped tube containing the glass wool bends twice above the lead of the cell. It provides the only possible escape from the cell. In other words, the lid above the cell must be tight.

The part of the escape tube containing the glass wool is vertical. Thus the intercepted drops can fall down by gravity. Then the tube bends to become horizontal. After that it bends again and becomes nearly vertical. That is how it enters the beaker with water where the vapor is expected to condense. The right-side ending of the tube is situated near the bottom of the that beaker, deep below the surface of water, about as low as the glowing cathode in the cell. The O2 and H2 bubbles come out from the escape tube, rise in the condenser and disappear in the air above the open beaker. Yes, a simple picture is better than many words.

The cell should be equipped with at least three thermocouples separated vertically and horizontally. It should be mounted on a magnetic stirrer. The vibrations from the stirrer make it impossible to measure the weight of the cell during the experiment accurately, but mixing the fluid is more important than measuring the weight precisely. This is not important; you can measure the weight precisely before you turn on the stirrer, and after the experiment when the stirrer is turned off.

Record the appearance of the plasma with a video camera, and a digital still camera. You can probably set the digital still camera to take pictures automatically every 15 seconds or so, by connecting it to a computer. Be sure you turn on the video camera and still-camera date-time-stamp, but keep the date-time-stamp away from the important parts of the picture, such as the cathode. This will help you performed the experiment from a safe distance.

During the run, record all temperatures frequently, such as once per second, rather than every 10 seconds. If the cell explodes you will want a record of this -- assuming you survive. (If you think I am joking about this, you have not been paying attention and you should not be doing this experiment.) The video record may also be helpful in the event of an explosion. You should also record the water column temperature, ambient temperature, input power, weight scale reading, and all other relevant parameters in the same computer, in simultaneous time stamped records. This should be obvious but I suppose some people might record them in separate devices and then try to reconcile them manually.

Immediately after the run, momentarily turn off the magnetic stirrer to record the exact mass of the cell. Then turned back on and let it run until the cell cools to room temperature, which should take about an hour. Continue recording all parameters during this period.

Also immediately after the run, stir the water column (unless you also have a magnetic mixer for it), to be sure you have recorded the correct temperature. If the temperature has risen less than 1°C, you started with too much water in the column. If it rises more than 10°C you need to increase the starting volume of water. Measure the pH of the water column to estimate how much of the unboiled water has passed through the glass wool trap.

3) MY UNDERSTANDING WAS THAT ONLY THE VAPOR PASSES THE TRAP? THAT IS NOT THE UNBOILED WATER.

--> Mostly vapor, but a small amount of liquid water is bound to get through. Probably a tiny amount that does not matter.

4) I WOULD NOT KNOW HOW TO CALCULATE THE AMOUNT OF UNBOILED WATER PASSING THROUGH THE TRAP ON THE BASIS OF PH . . . A LITTLE NUMERICAL ILLUSTRATION WOULD HELP.

--> Neither would I but I am sure it would be easy to find out.

When the cell cools down, turn off the magnetic stirrer and record the exact mass one more time to account for any additional losses to evaporation, and measure the mass of the water column beaker.

That should do it. This should give you enough data to accurately account for heat lost to evaporation and radiation from the cell.

5) I SEE THAT THE OHMIC HEATER IS NOT MENTIONED. HOW IS IT USED?

--> It should be included to calibrate. I neglected to mention it, because it is obvious.

It should greatly reduce wet steam, and even if there is any wet steam, all of the enthalpy from it will be captured in the water column so it will not matter.

6) BY WET STEAM YOU PROBABLY MEAN VAPOR MIXED WITH TINY DROPLETS. IS THIS CORRECT?

--> Yes

Note that mass lost from the cell and not accounted for in the water column is mainly free hydrogen and oxygen. You can estimate whether this exceeds normal Faradaic levels, which would indicate that some hydrogen and oxygen was generated by pyrolysis.

7) THE ABOVE TWO SENTENCES ARE NOT CLEAR TO ME. MY UNDERSTANDING WAS THAT THE WATER COLUMN IS OPEN FROM ABOVE. UP TO THIS POINT I THOUGHT THAT THE COLUMN WAS OPEN, ALLOWING THE H2 AND O2 TO ESCAPE INTO THE AIR. WHAT DID I MISS?

--> You missed nothing. The mass lost from the cell is in three phases:

Liquid -- collected in water column
Vapor -- condensed in water column
Gas H2 and O2 -- escapes from column

You can estimate very roughly how much gas escapes by change in mass in the cell minus change in mass of column.

I leave the details of the heat balance computation up to you.

General advice: Do not stint on instruments or materials. Do not use haphazard methods, unusual methods, half-measures or unreliable equipment. If you are going to devote several weeks or months of your life to this work -- and perhaps even risk your life and health to accident -- you should either *do this right* or *do not do it at all*. I cannot over emphasize that. As Storms pointed out, this field has seen too many half-baked experiments already.

If the results show a positive heat balance I recommend you publish a paper along with every scrap of data and every single still photo on a web page, such as LENR-CANR.org. Do not hold back or summarize data; let those who would critique your results see every detail.

General advice to all researchers, everywhere: Read the last message written by Wilbur Wright, a few weeks before his untimely death. Wright was one of the most gifted experimental researchers who ever lived, and he survived hundreds of tests far more dangerous than a glow discharge experiment. His message is on page 11 of this document:

http://lenr-canr.org/acrobat/RothwellJthewrightb.pdf

Every word of Wright's message applies to cold fusion, in spades. Most research has failed because people ignored the precepts he outlines. I would post his text here, but I encourage you to read the whole document.

P.S.
I wrote:

You might want to include an emergency valve in the lid. This can be as simple as a drinking straw bent into a "U" shape and stuffed into two holes.

Cancel that. The exhaust tube is good enough. If there a buildup of steam too quick for that tube to vent, the drinking straw valve will also fail. The top will fly off and the cell will shatter. This happened to X. Zhang *et al.* three times, as I noted in a revised version of chapter 12 in my book, uploaded yesterday. See:

Zhang, X., et al. *On the Explosion in a Deuterium/Palladium Electrolytic System*. in *Third International Conference on Cold Fusion, "Frontiers of Cold Fusion"*. 1992. Nagoya Japan: Universal Academy Press, Inc., Tokyo, Japan.

Message: Do not stand too close to these cells. Do not sit there with your eye a few centimeters away from the cathode the whole time, watching the glow discharge. Use safety goggles. For Goodness Sake. Have some common sense.

74) L. Kowalski wrote:
In trying something new Richard wants to use a closed cell (with a recombiner). Those who did this used a flow calorimeter. One must learn how to avoid problems with the recombiner, and how to build a reliable flow calorimeter. A bomb calorimeter, mentioned by Jed, probably offers a way to avoid the flow calorimeter.

(a) Considering the high rate at which excess energy is generated in a plasma electrolysis cell, for example 50 W or 100W, the calorimeter can be very simple. In fact, it can be a carton box surrounded by a layer of white packing styrofoam. A small air circulation fan is likely to be neceassary to keep the inner temperature uniform. No scale would be used, as in the water-evaporation calorimeter.

(b) One should be able to open the "door" of the calorimeter and put the working cell inside rapidly. Then it becomes a matter of recording the rising temperature for the duration of a test. Suppose the door is closed at t=0 and the glow discharge current is turned off at t=9 min. Suppose the change of temperature, in the last 5 minutes, is 24 C. How much thermal energy was generated during the test?

(c) The heat capacity of the calorimeter (K in joules per degree) must be known to answer this question. It can be determined by using an ohmic heater, for example, a 60 W light bulb. Suppose the temperature changed by 9 C when the light bulb was on for 10 minutes = 0.1667 hour. The electric energy received would be close to 60*0.1667=10 w*h. I would not trust the 60 W written on the ball; I would measure the w*h with an instrument. The measured 10 w*h translates into 36000 J. Thus K=36000/9=4000 J/C. That is the calibration of my bomb calorimeter. The value of K must be determined when the cell with the electrolyte is inside the calorimeter. This is important because by removing the cell, or by reducing the amount of the electrolyte, one would decrease the value of K.

(d) Now the question asked in (c) can be answered. The formula is Ethermal=K*dT=4000*24=96000 J. That is it. (It terms of power Pth = 96000J / 300s = 320 W).

(e) There is no need to wary about splashing or about tiny droplets being mixed with the vapor. The electric energy, on the other hand, delivered to the cell during the last 5 min, would be measured in the same way as for an open cell. Suppose the Pel turns out to be 240 W (leading to Eel=240*300=72000 J. Then one would say that the COP=96000/72000=1.33. But one thing was neglected. The recombiner has to be heated and this must be taken under consideration before calculating the COP. Suppose the power needed for this is 40 W (?). This leads to 40*300/3600=3.333 w*h = 12000 J. Thus Tth =(96000-12000) = 84000 J and Pel=240-40=200 W. Thus Eel=200*300=60000 J and the COP=84000/60000=1.40. The energy delivered by the electric fan, for example 20 W (?) could also be accounted for.

(e) The nonevaporative losses are likely to be negligible, as I assumed, if the styrofoam is thick and and fits the box tightly. A sticky tape along the rims would help to reduce convectional losses. If losses are not negligible then they can

be measured (see item i below).

(f) Unfortunately, the second big issue -- chemical origin of excess heat -- is not being addressed by switching from one type of calorimeter to another. That is where help from a good chemist would be essential.

g) Would this approach also work for an open cell? Probably yes, if one was willing the dry the calorimeter after each test. I would not try this.

h) I never used a bomb calorimeter. That is why the above description is probably too naive. What else should be taken under consideration?

i) Oh yes, the box should have a small mass, to make the calorimeter more sensitive (small K). Thermal inertia will probably be a factor. I suppose one would have to wait several minutes, after the current is turned off, till the temperature stops rising. Waiting much longer, perhaps several hours, one would see the temperature going down. The rate at which the temperature goes down could be used to calculate thermal losses due to conduction and convection. What else should be anticipated?

75) R. Slaughter wrote:
I'm confused...nothing new... I have two designs in mind. the first is a closed cell with a vent tube as describe by Michel and others in earlier post. We can measure the non-evaporated heat lost of this cell the same way we did with the open breaker cell. Instead of sparging through a condenser column we sparge the vent tube steam through water in a second beaker. The steam condense and adds water to the second beaker. We can even put the second beaker in an ice bath to make sure we condense all the steam. The weight gain of the second beaker is P-evaporated. We calculate COP the same as before. I'm counting on the small size of the vent tube to greatly decrease the possibility of mist and prevent expulsion of K2C03? We can also put glass wool as suggested by others in the vent tube to filter the steam. The liquid in the second beaker should just be distilled water if everything is correct. We can now check the condensed liquid for other chemicals and residues.

The second design is a truly closed cell with a condenser loop. The steam that escapes the vent tube sent to an open air condenser a small pump returns the liquid back to the cell. The trick to this design will be getting a steady liquid flow through the condenser. We measure the input and output temperatures of the condenser and with flow rate we have P-evaporated. We run the same setup using the ohmic heater and we can measure the non-evaporated loses in the cell. We again calculate COP as before.
P.S.
I should have added that both of these approaches would work best if the reaction can be keep going long enough for the system to reach equilibrium. I see a need to be able to feed the cathode to keep the system running for perhaps two hours. In the first design we would need a water reserve to keep the electrolyte level constant so the system could run for hours.

76) L. Kowalski (not posted):
I find

77) M. Julian:
Ok the proposals so far are (BOMs only for now please),

Michel J-1.0
- insulated cell (e.g. transparent Dewar)
- insulating lid, not airtight, vented, sitting on top of the cell ready to
pop off (holds the electrodes and heater)

Richard S-1.1
- Lid should be tight enough so that steam and gas can not escape around the edge. All steam and gas must exit the vent tube.
- Vent tube should be stainless steel. In the shape of a "U".

- Suggestion on the best way to recombine the H2 O2, for safety
concerns!
perhaps a spark plug or glow plug.
- Suggestion on best way to capture and condense the steam? My thoughts
are to run an insulated plastic tube from the vent to a second beaker of water on the balance and sparge the steam through water in the second beaker.

Michel J-1.0 being the simplest so far, let's make it the PUF (proposal under fire)

Michel J-1.0 method to determine mass loss due to mist (inspired by Peter Gluck's comment on potassium not being consumed):

Escaped mist mass = (Potassium mass loss)*K, where K is an easy to determine constant factor (65.71 for 0.2M K2CO3), and potassium mass loss is determined by chemical analysis of final electrolyte, initial potassium mass being known.

I initially thought this required a fresh electrolyte for each run, on second thought that's not necessary, initial potassium of one run being final potassium of the previous one. Small samples of the cell's water could be taken after each run for batch-analysing at the end of the series of runs. If no potassium has disappeared the COPs don't need correcting for mist, otherwise we have an accurate correction. Any potassium loss due to transmutations would be negligible of course.

Sample taking and analyzing is required for chemical heat assessment anyway, so added cost of the method is null.

Questions/comments/critics on this proposal please, let's quickly find it's flaws so we can amend it and move on to another proposal.

78) Peter Gluck:
Strong polycarbonate shield, . . . fire extinguisher, . . .goggles. [Also] an analytical chemist friend who will tell you what on the earth happens with the potassium carbonate and all the other chemical, physical and nuclear (?) players involved in the game. [Also] an open mind - to decide to go along the line: "first understand, then measure again"

79) M. Julian:
Remembering unpublished information I have received from Pierre on preliminary Paris-2 results with their standard (silvered) Dewar, without changing the method for tracking mist and chemical heat I proposed, I would like to further simplify my proposal's BOM as follows:

MJ-1.1
- open insulated cell (e.g. narrow transparent cylindrical Dewar cf attached picture)

(insulating lid is not necessary if the insulated cell has a small enough open area for non-evap losses to be sizeably smaller than observed excess heat, which is the case with the Paris-2 narrow Dewar, where non-evap losses around 30W are only one third of excess heat!)

Electrodes and heater (the latter would probably only be needed for calibration) could be held as in Paris-1 and 2 experiments by a tripod weighed along with the cell, cf photo in http://www.lenr-canr.org/acrobat/FauvarqueJabnormalex.pdf

Periodical replenishing to approximately constant volume (level mark on the container) could be done by adding external boiling water from e.g. a saucepan on slow boil in counted constant doses of e.g. 20ml, or as in Fauvarque setup from an ambient temperature reservoir weighed along with the
cell.

What would then distinguish the MJ-1.1 proposal from Paris-2 Dewar experiment, apart from optional transparency of

the Dewar (which allows for comfortable visual adjustment of the discharge and should not increase non-evap losses by more than a few Watts I would think), would mainly consist in the added method for tracking mist and chemical heat.

80) Ludwik Kowalski wrote:
Even two or three determinations of K1/K2 (see below), under typical conditions, would be sufficient for us at this stage. Do not forget what triggered this discussion. We want to convince potential referees, of our anticipated paper, that the reported values of the COP are not due to the unaccounted for droplets. I am expecting K1/K2 to be close to 1.00. We will not claim a confirmation of the Mizuno-type excess heat if K1/K2 turns out to be significantly smaller. Do you agree, Richard and Pierre? I am assuming that Texas-2, Paris-2 and Colorado-3 results will be similar to those from Paris-1 and Colorado-2 experiments. Otherwise the paper would have to wait till we understand the situation.

Appendix ?

a) Basic assumption:
The K2CO3 dissolved in water turns into ions of different kind. One kind is K+. In this analysis we will assume that what is escaping from the open cell, during a test, is only a mixture of water vapor and tiny droplets of electrolyte. That is an approximation; the mass of the H2 and O2, due to electrolysis, and possibly of other gasses, such as CO2 and CH4, is assumed to be a negligible fraction of the water mass loss. Note potassium ions are removed from the cell by the escaping droplets of the electrolyte; the vapor escaping from the cell does not cary the ions.

b) Conducting the test:
A small amount of the electrolyte is removed from the cell with a pipette, before a test in which the COP is to be measured. That is sample #1. A comparable amount of the electrolyte is removed from the cell after that test. That is sample #2. Both samples are sent to an analytical lab to determine concentrations of K+. Note that professional laboratories perform such measurements routinely on blood and urine. Units of ion concentration can be mg/cc or ions/cc.

c) Discussion:
Suppose that sample #1 shows 100 units of K+ while sample #2 shows only 99.0 such units. That would mean that 1% of the initial K+ was lost. Any arbitrary units can be used, for example, number of ions, micrograms, milligrams, etc.

If only the water vapor is escaping then the concentration of K+ in sample #2 should be practically the same as in sample 1. In that case K2/K1 would be close to 1.00. In a mixture of vapor and drops, however, the concentration of K+ in the sample #2 would be smaller than in the sample #1. The lowest possible value of K2/K1 corresponds to a situation when nothing but liquid droplets contribute to the mass escaping from the cell. In that extreme case (only drops are escaping) the value of the K2/K1 would be (M-dM)/M. That measurable ratio will be represented by the symbol W. If M=1000 g and dM=40 g then W=0.96. It is the lowest possible values of K2/K1 for a given experiment.
.

In a mixture of vapor and droplets the K2/K1 ratio is a number between 1 and W, depending of the composition of the escaping mixture. We want to determine the composition of the escaping mixture on the basis of the actually measured W and K2/K1. Let R be a measure of the mixture composition; it is defined as the mass of tiny droplets divided by the total mass of the escaping mixture. To calculate the COP correctly we need to know R. The COP=1.2, from our Colorado-2 experiment, would be an illusion if R were close to 0.2. Assuming that the relation between R and K2/K1, for any given W, is linear one has:

R= (1 - K2/K1) / (1 - W)

As expected, this formula gives R=0 when K2=K1 (only vapor escapes) and R=1 when K2/K1=W (only droplets escape). If K2/K1 happens to be 0.988 (for W=0.96) then R is 0.3. That would indicate that 30% of the mixture consists of tiny droplets. The table below gives the expected values K2/K1 for different values of R, and vice versa. Note that the assumed W=0.96 is realistic; a typical test lasts about ten minutes and the mass lost during that interval is close to 40 grams.

R 0.010 0.040 0.070 0.100 0.200 0.300 0.500

K2/K1 0.9996 0.9984 0.9972 0.9960 0.9920 0.9880 0.9800

One thing becomes clear, to distinguish small differences in R, for example, between
4% and 7%, the K2/K1 determinations must be very accurate.

Note that the accuracy requirement becomes less severe (only 3 significant digits instead of four, as above) when W is reduced. Suppose that ten short tests, performed one after another. After each test about 40 grams of boiling water is added to the cell to keep the initial M constant. Then all ten tests can be treated as one test during which dM turns out to be close to 400. For that long test W=(1000-400)/1000 = 0.6. The relation between the R and K2/K1, for W=0.6, is tabulated below.

R 0.010 0.040 0.070 0.100 0.200 0.300 0.500

K2/K1 0.996 0.984 0.972 0.960 0.920 0.880 0.800

suppose the K2/K1 happens to be 0.984. That would indicate that R=0.04 -- 4% of the escaping mixture consists of tiny drops of the electrolyte.

d) Plan of action:
The mass of of escaping droplets must be taken under consideration when COPs are calculated. The mean COP=1.24, was calculated (after Colorado-2 experiments) under the assumption that R is very close to zero. That assumption must now be tested experimentally. Will the K2/K1 be very close to 1? I hope so. But that remains to be seen. Honest referees will probably take our claim seriously if the K2/K1 data are used to validate it.

81) Michel Jullian (posting even more simple description, publicly):
Ok so here is a revised version of the maths for the zero-hardware mist
evaluation method I propose.

NOTATIONS
- - - - - -
V Volume of solution in cell
CK concentration of potassium in cell solution
mK mass of potassium in cell
dmK mass of potassium lost (presumably via droplets)
Vd Volume of lost droplets
md mass of lost droplets (correction for droplets
to be subtracted from total mass loss)
StoK Ratio of salt mass to potassium mass
(1.77 for K2CO3 and 1.44 for KOH,
we will use 1.77 for conservatism)

RUN DATA
- - - - - -
1- BEFORE RUN
V1 (L) (will be roughly maintained during the run by adding pure water)
CK1 (g/L) (the same concentration will be assumed in the droplets)

2- AFTER RUN, RINSING OF CELL WALLS ETC WITH PURE WATER, AND MIXING
V2 (L) (a bit larger than V1)
CK2 (g/L)

CALCULATIONS
- - - - - - - -
mK1 = CK1*V1 (g)
mK2 = CK2*V2 (g)
dmK = mK1-mK2 (g)
Vd = dmK/CK1 (L)
md = Vd*1000+dmK*StoK (g)

Comments/corrections/critics welcome.

82) Ludwik Kowalski (after waiting the whole day for a reply to Michel**):**
1) Michel's method of studying wet steam -- a mixture of water vapor and droplets of the electrolyte escaping from an open cell -- seems to be good, at least in principle. It should be an essential part of our COP determinations. Fortunately, it is not too late to make the Paris-2 and the Colorado-2 claims more trustworthy. I hope that Richard and Pierre will confirm that the mass of lost droplets is only a negligible fraction of the liquid lost in a typical COP test. The percentage of the electrolyte droplets in wet steam must be reported in our anticipated paper.

2) My first comment is that the last formula (dm= ...) is not needed. Knowing Vd (volume of escaping droplets) is sufficient. I am assuming that one gram corresponds to nearly one cc for the liquid water or the electrolyte. I am assuming that what is lost during a COP test is essentially pure water vapor and droplets of the electrolyte containing K+ ions. The combined mass of H2, O2, CO2, etc. is presumably negligible. For example, if 40 grams of the liquid was lost during a test (or 40 grams of water added to the cell to keep the same amount of liquid in the cell) then the Vd= 10 grams would indicate that droplets contribute 25% to the escaping mixture. In such case the mean COP=1.24, claimed in Colorado-2, would be an illusion. I hope that the Vd for such tests will be less than 1 gram; that would validate the tentative claim that excess heat was indeed close to 24% of the inputted energy.

3) Suppose we want to distinguish the ideal 0% "mixture" from a mixture containing 2% droplets. How accurate should the determinations of the CK1 and CK2 be? Suppose CK1=4.0000*10^19 ions of K+ per cubic centimeter. This corresponds to 27 grams of the K2CO3 salt dissolved in one liter of water, as in fresh 0.2 M electrolyte. Consider a typical test, lasting 10 minutes, in which 40 grams of mass escaped from the open cell. If the escaping mixture has 2% of tiny drops then the mass of droplets is 0.8 grams (the volume is close to 0.8 cc). This allows us to calculate the CK2. Unfortunately, the CK2 is only slightly smaller than the CK1. Replacing 0.8 grams, of the escaping electrolyte, by fresh water, changes the concentration of K+ ions by (0.8/1000)*100% = 0.08%. In other words the CK2 becomes 3.9968*10^19 ions per cubic centimeter. Measuring the CK1 and CK2 at the accuracy level of five digits is probably possible in a specialized lab. Very accurate determinations of CK2/CK1 (relative concentrations from two samples, one extracted at t=0 and another at t=10 minutes) are likely to be easier than very accurate determinations of individual CK1 and CK2.

4) Michel suggested much longer tests. Suppose that ten consecutive tests are treated as one 100 min test. In such test 400 of the mixture would escape. This corresponds to 8 grams of the electrolyte (instead of 0.8 g). The final CK2 would be 0.8% smaller than the CK1 (3.967*10^19 ions per cc). Under such condition the accuracy of only four significant digits would be sufficient to distinguish the wet steam containing 2% of droplets from the pure vapor.

5) The earlier suggestion of Michel -- capturing the escaping mixture and condensing the two samples (to determine the CK2/CK1 ratio) -- seems to be more attractive. In that case the accuracy at the level of two or three significant digits would be sufficient to distinguish the 2% mixture from the ideal 0% mixture. Measuring the CK2/CK1, in an open Mizuno-type cell, can be decoupled from the COP measurements. I already wrote how I would do this by using a large funnel. Jed's objection to the use of ice (to keep the funnel cold) would be valid if the COP were to be measured. But it is not valid for an experiment whose purpose is evaluate a typical steam wetness. The wetness of a sample, R, is defined as the ratio of the mass of electrolyte droplets and the total mass of wet steam. That is what we need in order to calculate the COP correctly. The description of my cold-funnel condenser can be found in the message #54 above.

Michel wrote that medical laboratories routinely measure concentrations of potassium ions. How accurate are these

measurements? In what units are medical concentrations expressed? Should a typical chemist be expected to know how to measure the CK2/CK1 ratios (at the level of ~3% accuracy) in an improvised lab?

82) Michel Jullian:
. . . The last formula md = Vd*1000+dmK*StoK (g) is needed actually, to convert Vd (in liters) to the mass of escaped droplets (grams) which is what we are after. My conversion accounts not only for the mass of the water but also for the mass of the salt, as it should (even if it doesn't make much difference we might as well use the exact formula since it is quite simple)

Since Vd=dmK/CK1 the final formula can also be written md=dmK*(1000/CK1+StoK), which e.g. for 0.2M K2CO3, i.e. 0.2 mole of K2CO3 per liter, i.e. 0.4 mole of K per liter, i.e. CK1=0.4*39.1 g/L = 15.64g/L, would boil down to: md=dmK*(1000/CK1+StoK)=dmK*(1000/15.64+1.77). As expected we find: md=65.71*dmK (66*dmK will be used to compute accuracy below)

[You asked] "How accurate are these measurements?" We can see by ourselves in our own blood tests. Potassium is an important blood electrolyte, and it's concentration in routine blood tests is given to the hundredth of a millimole per liter (e.g. potassium (mmol/L) 4.47). Since we have about one liter of solution in the cell, we would know potassium mass to the hundredth of a millimole, i.e. to 0.39 mg (molar mass of K being 39g or so). Even if the error on dmK was five times that, it would only be about 2mg, so the error on the total escaped droplets mass would be only about 66*0.002 ~ 0.1g which you will admit is quite accurate!

83) L. Kowalski:
My recent blood report shows 4.2 mmol/L of potassium. The normal range is 3.5 to 4.5. I do not know how accurate the 4.2 result is. Several results (for the blood) would be needed to estimate the standard deviation. My guess is that it could be as large as 0.3, for a routine medical test. That would be 7%. By the way, the unit of concentration should be mmol, not the mmol/L. Do you agree? It could also be grams per liter or number of molecules per liter, or mg/L, or mg/cc, etc.

Suppose that the first sample has no droplets at all, its potassium concentration, CK1, is 0.000 mmol. Suppose the second sample has 100% of droplets. What is the potassium ion concentration, CK2, in the second sample? It is the same as in the original electrolyte. That amounts to 0.4 mol = 400 mmol (27.6 grams of K2CO3 are dissolved in one liter of water to produce a 0.200 M solution of the salt). A wet steam containing 1% of droplets would have 100 times smaller molarity -- 4 mmpl. That is about the same as for my blood. For the third sample, containing 2% of droplets molarity would be 8 mmol, etc. A difference in the potassium concentration resulting from only 1% difference in the steam wetness seems to measurable with automated medical analyzers. That is good news. But such analyzers could not be used when samples of the electrolyte are collected from the cell (before and after an experiment), as illustrated yesterday.

Condensing several grams of wet steam, with a cold funnel test, should not take longer than two or three minutes. That would be sufficient for several samples needed to establish the accuracy at which potassium concentrations are measured. My advice to Peter, Richard and Scott is to perform the cold funnel test, and to interpret it in the context in which the test was originally suggested by Michel. He is now preoccupied by other nuances but this should not delay a simple test described above. Let the perfect not be the enemy of the good.

Appended on 4/13/06:
On Apr 12, 2006, Michel asked:

Do you agree now that 0.025 mmol/L accuracy on CK1 and CK2 yields
about 0.1g accuracy on escaped mist mass if volumes are exactly
known and of the order of 1L?

1) What are we discussing? It is a method of measuring wetness of the steam escaping from an open cell during a Mizuno-type experiment. I agree with Jed (and others) that this problem can be eliminated by using the closed cell method. But that was the method we used. Paris-1 and Colorado-2 experiments were performed with open cells and

we want to know the composition of the lost liquid (a mixture of water vapor and droplets of the electrolyte). The mass of the H2, O2, CO2, etc. was considered to be negligible. That is how the problem was originally formulated by Michel. If droplets of the electrolyte represent ~20% of the escaping mixture then the reported COP~1.20 can be explained as an artifact. On the other hand, if the percentage of droplets is close to zero then the reported COP~1.20 should be taken more seriously.

Two methods of measuring the percentage of droplets have been proposed by Michel. Which of these two methods is more desirable, from the point of view of accuracy? That is the issue.

a) Method 1: compare the concentration of K+ in two samples of the electrolyte, one extracted from the cell before the plasma electrolysis experiment and another extracted after the experiment. If two concentrations are identical then only a negligible fraction of the escaping mixture consists of droplets.

b) Method 2: compare the concentration of K+ in two samples of condensed mixture. One when the ohmic heater is used and another when plasma electrolysis is in progress. If the two two concentrations are identical then only a negligible fraction of the escaping mixture consists of droplets.

2) The numerical example below will show why I am in favor of the method (b). To prepare a 0.2000 M solution of K2CO3 we dissolve 27.000 grams of the salt in 1000.0 grams of water. Five digits of accuracy will be used in my arithmetic. The original concentration of K+, based on known atomic weights of K, C and O, is:

27.000 * (2*39.098 / 138.19) = 15.278 grams of K+ in 1015,3 grams of the electrolyte.

In other words, the original concentration, CK1 is 15.048 units (the units are grams of K+ per 1000 grams of mixture). That is the value CK1 for the method (a). Suppose a test, lasting 10 minutes, was conducted and t50.000 grams of the mixture escaped. To compensate for this we add 50.000 grams of water to the cell and measure the CK2. What is the expected value of CK2 when 20% of the mixture consists of droplets of the electrolyte? The fraction of the K+ removed during the test is (50 / 1015.3) * 100% = 4.9246 %. That amounts to 0.75238 grams of K+. The new mass of K+ is (15.278-0.75238) = 14.526 grams of K+. It is dissolved per 1015.3 grams of the mixture. Thus the CK2= 14.307 units.

4) Now let me compare the CK1 and CK2 for the second method. The CK1=0.0000 because no K+ is expected to be found in condensed "mixture" when droplets represent 0%. And what is the value of CK2 when 20% of the mixture consists of droplets of the electrolyte? We now have 0.75238 grams of K+ in 50 grams of condensed mixture. That gives us CK2=0.015048. Distinguishing 0.0000 from 0.015048 is likely to be much easier than distinguishing 15.048 from 14.307.

5) To summarize let me show a table of expected values CK for different percentages of droplets in the mixture, first for the method (a) and then for the method (b). Units of concentration are g/1000g, as explained above.

drops --> 0% 1% 2% 3% 4% 20%
==========
CK (a) --> 15.048 15.011 14.974 14.937 14.900 14.307
CK (b) --> 0.0000 0.0015 0.0030 0.0045 0.0060 0.0300

The table shows that five digits of accuracy would be needed to measure concentrations from the method (a) and only three digits from the method (b). That is why I wrote that the method (b) is more desirable. It is easier to deal with situations in which what we want to know (% of droplets) is directly proportional to what we actually measure. Note that numbers in the last line double and triple with doubling and tripling of the corresponding numbers in the first line.

6) When Richard and Pierre send me samples (one from condensing the mixture during the ohmic heater boiling and one from condensing the mixture during the plasma electrolysis) then I will try to measure their concentrations on the basis of conductivities. To do this I will build a small cell with two Pt electrodes. The current flowing through the cell is likely to be directly proportional to CK, provided the voltage (such 0.5 V) and temperature (such as 20 C) remain

constant. I will calibrate that cell by using several electrolytes of known concentrations. Should I anticipate problems with this simple approach?

Yes, I know that other ions, if present, would also contribute to the current. The conductivity test is not selective; the current will be proportional to the total concentration of all cations. But suppose the two currents are practically identical for my two samples. In that case it would be possible to say that the contribution of droplets was negligible during our experiments.

84) Michel Jullian wrote:
Another possible chemical fuel which could be supplied indefinitely by the atmosphere: nitrogen (80% of ambient air). As Bill Collis rightly mentioned in the Jules Vernes thread: "Ah but one of the benefits of burning in pure oxygen rather than
air is that you cannot form any polluting nitrogen oxides (NOx)."

My scenario for this other possible Mizuno artefact: **(1)** atmospheric N2 dissolves spontaneously in the electrolyte solution (SCUBA divers know this phenomenon quite well) **(2)** N2 in solution is convected towards the plasma area **(3)** N2 burns in the high temperature plasma where explosive O2+H2 recombination occurs, forming NOx (a good soul with one of those rubber bibles may tell us how much heat this produces per gram of burnt N2 **(4)** GOTO (1) I wonder how this artefact could manage not to happen if the cell is exposed to ambiant air BTW. Another good reason not to let atmosphere interfere with the experiment isn't it?

85) Ludwik Kowalski:
As shown in unit #290, several people think that Colorado 2 experiment was a waste of time. I have no idea how to estimate the amount of excess heat generated by N2 reactions. Why should these reactions produce 24% of excess heat and not, for example, 50% or 500 %?

Not being a chemist I will not be able to address every possible objection. Perhaps it was a mistake to go ahead without a good chemist. The goal was to perform an experiment as in Paris 1. We did this and we got similar results. But this will not be enough for referees. A paper without convincing evidence, against chemical origin of excess heat, presented by a reputable chemist, is likely to be rejected. I would not criticize the editor for this. It is too bad that original results of Mizuno, or results of numerous reports from Naudin, were not discussed, as far as i know, in terms of exothermic chemical reactions. It is too bad that nobody waned me about the issue of safety after units #252and #253 was posted.

86) Michel Jullian:
Group, I was quite glad to find out, thanks to a Google search, that one can do thermochemistry without one of those rubber covered chemistry handbooks and associated expertise and tedious calculations :)

I was able to check the hypothesis in my previous post, and more, with a trial version of CHEMIX ("lab" edition, available at http://home.c2i.net/astandne/), a very helpful tool whose thermochemistry page could be dubbed "thermochemistry for dummies", so simple that even it being in Norwegian language was not an obstacle to using it! (I must have missed the language option at download or install time).

Example of use, you type in the following unbalanced reaction (electrolysis of water):

H2O(l) > H2(g) + O2(g)

it balances it for you (works out the coefficients), works out the enthalpy change, and outputs:

2H2O(l) = 2H2(g) + O2(g) - 571.6kJ

meaning that the reaction is endoenergetic, 1 mole of the elementary reaction requiring 571.6kJ of energy (electrical or thermal or whatever) You can even get it to display the energy for a given mass of either a reactant or a product, e.g. you type: 1gH2O(l) > H2O(g) and it outputs:

H2O(l) = H2O(g) - 2.44237kJ

meaning vaporizing 1 g of liquid water requires 2442J (and not 2260J as we have been using, can anybody explain this discrepancy BTW?)

The various Nox (NO or NO2) forming reactions that I tried turned out to be globally endothermic (absorb heat) so we probably don't have to worry about those.

A more preoccupying reaction is the spontaneous and exothermic (produces heat) reaction between N2 and H2 forming ammonia gas:

N2(g) + 3H2(g) -> 2NH3(g) (+ 15.1795kJ per g of H2)

but fortunately this produces much less energy per g of H2 than was used to produce the same gram of H2 by dissociation of water (e.g. thermal dissociation):

2H2O(g) -> 2H2(g) + O2(g) (- 119.948kJ per g of H2)

so we don't have to worry about this reaction either. However the possibilities of reactions between the various substances in play being quasi infinite it would be very presomptuous to claim none of the reaction paths is globally exothermic.

Whereas preventing the atmosphere and it's unlimited supply of various substances from interfering with the experiment, and still getting over hours/days/months much more excess heat than could possibly be produced chemically by the precisely known limited amount of substances we will have deliberately put into the cell, would make the claim of non-chemical origin of the excess heat much stronger obviously.

About the method 3 I suggested below to achieve this (keeping the solution boiling at all times to maintain an outgoing flow of steam), of course the cell opening would have to sufficiently narrow, and the liquid level sufficiently low, to make sure the outgoing steam constitutes an efficent barrier against atmospheric gases contacting the liquid surface.

87) Michel Jullian:
Hi John. Yes, liquid and gas H2O are at same temperature (100°C). I have found that the discrepancy comes from formation enthalpies variations with temperature being significantly different for liquid and gas between standard temp 25°C and 100°C.

According to
<http://webbook.nist.gov/cgi/cbook.cgi?Formula=H2O&MatchIso=on&NoIon=on&Units=SI&cTG=on&cTC=on>
the standard (25°C) formation enthalpies are:

DH0f H2O(g) -241.83 kJ/mol
DH0f H2O(l) -285.83 kJ/mol

So the standard enthalpy change is +44kJ/mol, which for water's 18.02g/mol is 44/18.02=2442J/g as given by CHEMIX.

But if you now take into account the temperature dependencies, also given in the NIST page, you find the actual enthalpy change at 100°C is only about +41kJ/mol (based on rough interpolations from their tables: gas DH0f increases by about 2.5kJ, whereas liquid DH0f increases by about 5.5kJ, so gas minus liquid decreases by about 3kJ), which is 41/18.02=2275J/g very close to the 2260J/g we have been using. So 2260J/g must be the correct value for 100°C evaporation heat of water indeed.

This shows that the usual approximation that enthalpies do not depend on T can lead to significant inaccuracies in

some cases. What would be needed is a super-CHEMIX which wouldn't make such approximations.

P.S.
Powerful consequences of the proposed "permanent one way steaming" scheme with very long duration runs:

1/ After a while, the only gases that can possibly escape the cell in meaningful amounts are water vapor, hydrogen and oxygen. 2/ The long duration of the run renders the potassium mass loss significant if there is any significant salted mist escaping, which makes it easily measurable.

1/ and 2/ make the mist-corrected evaporated mass calorimetry method simpler, easier and more convincing than ever. For example it is not needed anymore to explain why mass or energy balance of other gases such as CO2 cannot overestimate the COP, since there are no other gases. All there is to explain is that our counting of H2 and O2 escaped mass as evaporated H2O mass only underestimates the COP since it takes much more energy to dissociate 1g of water than to evaporate it.

Of course for the runs to last hours/days the necessary cathode replacements, whether continuous or not, have to be part of the run. If we keep using the easily procured 2.4mm welding sticks we could consider forming them beforehand by operating them in short preliminary dummy runs (e.g. the day before) so they are already suitably pointed and cracked when they are inserted into the experiment, ready to produce the right kind of discharge right away.

Regarding my proposal of an immersed smoothing filter to make input power and energy measurement easier and more convincing by suppressing spiky i and v waveforms and associated EMI, it has occurred to me that only the most dissipative part of it (the resistor) really has to be immersed, as neglecting the comparatively small losses in the capacitor and inductor only underestimates the COP, and only slightly. This simplifies things by allowing the use of the already included ohmic heater as the filter resistor at electrolysis time, and suppressing the need for any additional submersed component: the cap and inductor just have to be located in an EMI-shielded area, e.g. a grounded Faraday cage made of screen which would also enclose the cell.

The pieces of the puzzle seem to all come together nicely, making my dream of a both simplistic and indisputable Mizuno experiment less unrealistic than it was.

Michel Jullian (private message):
I know our common objective is to prove to anyone interested -not just the converted few but also honest scientists and politics- that the Mizuno excess heat is (a) indisputable and (b) indisputably abnormal. This should have been done long ago by Mizuno himself or others but hasn't. To fully realize this objective, we both know that some changes are required wrt existing experiments.

I have proposed yesterday what is probably a minimal (let me know if you agree on this qualifier(*)) set of such changes wrt the nice and simple Fauvarque-ICCF12 version of the experiment run in Paris and Colorado, in my "making the puzzle fit together" post. Note the cell remains _physically open_ in this proposal so it can't turn into a bomb a la Mizuno ICCF12 (no open cell has ever exploded I don't think, correct me if I am wrong)

What this proposal needs now (if it works, and even more if it doesn't so we can quickly find it's flaws and move to a better one without regrets) is commenting and criticizing by the group so an unbiased and argumented consensus can be reached wrt it's fitness to achieve the objective.

88) Richard Slaughter (private):
Ludwik, Good morning hope all is going well. I'm still waiting on getting my boards back so I can't measure the input power correctly. I've designed a new cell that is looking very promising. The new cell is closed except for a 0.5 inch hole in the top to let out the H2 02 gas. I've put a (condenser) coil of tubing just below the lid of the cell. Between the lid and the coil are several layers of stainless steel screen. The screen is in contact with the tubing so it stays the temperature of the tubing.

I've a large ice chest with ice water and I'm running the ice water though the condenser. Using my 0.25 inch tungsten rod I'm able to run the cell for an hour before the tungsten burn away. The water in the ice chest is staying at 1C for duration of the test so I only need to measure the outlet temperature of the condenser and the flow rate to get my output power. The outlet water from the condenser circulates back into the ice chest. I spray it as a fine mist back into the ice chest so it looses a lot of heat to the air.

The temperature of the electrolyte is about the same as before 80C. When I run the test there is very little loss in mass. Looks like input power is going mostly into making steam and the steam is immediately condensing on coil of tubing. Haven't got any real data yet but I'm encouraged. If I can make this type of cell run for several hours at equilibrium with excess heat it should put to rest most of the objections were hearing on CMNS.

89) Michel Jullian:
The changes wrt Fauvarque-ICCF12 in the new proposal (let's call it BM_MJ-2.0, BM for boiloff Mizuno) are really few and simple, I'll summarize them here:

- insulated cell with a not-too-wide and not-too-low opening (e.g. same double walled reactor as in JLN's enhanced CFR, only with a closed airspace in the double wall) - a couple protocol changes to prevent ingress of known (CO2, N2) and unknown reactive atmospheric substances, make the runs long-duration (hours/days so any initial chemical fuel is exhausted), and correct evaporated mass for escaped mist (note long runs make the cell potassium concentration method more accurate)

- plus an _optional_ hardware change which boils down to adding an inductor and an EMI shielding screen and doing some rewiring to make electrical measurements totally convincing, even if done with a dumb AC mains watt-hour meter which anyone can use and read.

Note the cell remains _physically open_ in this proposal so it can't turn into a bomb a la Mizuno ICCF12.

What this "minimal change" proposal needs now (if it works, and even more if it doesn't so we can quickly find it's flaws and move to a better one without regrets) is commenting and criticizing by the group so an unbiased consensus can be reached wrt it's fitness to realize it's objective.

It's objective being what I assume to be a common objective of this group: proving to anyone interested -not just the converted few but also honest scientists and deciders- that the Mizuno excess heat, and hence cold fusion excess heat in general, is (a) indisputable and (b) indisputably abnormal. As I suggested before, simpler solutions should be discussed/eliminated first, because they are more likely to realize the above objective than more complicated solutions. Or am I missing something?

90) Richard Slaughter:
MIchel,
I'm working on a design for a new cell. I'm trying to incorporate as much as I can about what has been said here. I think to have an indisputable experiment we need to do the following. The cell has to be completely closed. A high speed analog measurement of input v(dt)*i(dt) something like the AD835 multipllier chip. The H2-02 needs to be recombine inside the cell. The cells need to run at equlibrium for at least 1 hour producing excess heat.

I think this can all be accomplished and still have as simple a system as used in the Fauvarque experiment. The key is to condense the steam inside the cell at the same rate it is being generated. I propose we put a liquid to air condencer inside the cell. The condencer only has to disapate about 300Watts to bring the system into equlibrium. A constant temperatue ice bath provide cooling water to the condenser. We only need to measure the output temperatue and flow through the condenser to calculate output power. I'm not sure of the best way to recombine the H2-02. I'm thinking of using a spark plug or glow plug. The whole cell can be well insulated so the only heat output is via the condenser.

If flow though the condenser is 0.5 liters/min and we have a temperature rise of 15C that's over 500 watts. This seems reasonable approach.

91) Michel Jullian:
Richard, I will be glad to discuss your new proposal (RS-2.0?). Shall we discuss mine next then?

92) Richard Slaughter:
Michel, Lets dicuss yours first. I concerned that as long as you are trying to do a boil off it will be difficult to keep the system running for hours or days? Replinishing of the lost water greatly adds to the complexity of calculated the heat loss. Can the critics say that fresh water is adding "fuel"? I tried to replinish the water for a while and found, it difficult to maintain the fresh water temperature because of the output steam. I'm sure this problem can be solved. The boil off approach is always going to be suseptable to changing conditions inside the lab such as Temperature, humidty and pressure. I don't see the system ever reaching an equlibrium where COP is constant. If we can devise an experiment where the COP is greater than 1 and constant for hours or days that is going to be very convincing.

You comments on the EMI sheild and computing input power are correct. I think this is just a case of selecting and building the correct hardware. The other problem with all system is how to keep the W rod active for hour or days? I see two approaches to this problem. One is to build a system that auto-feeds the electrode. The other is devise an experiment that can reaches equilibrium quickly and thus doesn"t need as much electrode. My Musing, Richard

93) Michel Jullan:
Richard wrote: Lets dicuss yours first. I concerned that as long as you are trying to do a boil off it will be difficult to keep the system running for hours or days? In any non-automated scheme, boiloff or otherwise, hours will be easy, days will require taking shifts like at the helm of a boat... or more appropriately like at the controls of a power plant :)

Replinishing of the lost water greatly adds to the complexity of calculated the heat loss. Easy, we add water from pre-weighed bottles and weigh the last unfinished
bottle to know how much pure water we have added.

Can the critics say that fresh water is adding "fuel"? No :) Unless we add gasoline or whisky to it to improve our COP ;) Using water as a fuel to produce heat would be quite an achievement anyway.

I tried to replinish the water for a while and found it difficult to maintain the fresh water temperature because of the output steam. I'm sure this problem can be solved. Let's keep the bottles away from the steam.

The boil off approach is always going to be suseptable to changing conditions inside the lab such as Temperature, humidty and pressure. No, lab conditions have no influence whatsoever on this scheme since non-evap losses are small by design (<30W) and therefore can be neglected altogether if we can sustain a COP>1.1 at 300W. This prevents any objection based on bubbles or foam reducing those losses since we already assume they are null!

I don't see the system ever reaching an equlibrium where COP is constant.If we can devise an experiment where the COP is greater than 1 and constant for hours or days that is going to be very convincing. Indeed, it will be very much like a car going on for ever without ever refueling.

You comments on the EMI sheild and computing input power are correct.I think this is just a case of selecting and building the correct hardware. Actually an off-the-shelf residential electricity meter (joule or watt-hour meter) working from 100-400VAC installed between the variac (or insulation transformer) and the rectifier will be perfect with a proper smoothing filter, which only requires adding an inductor to existing setups and doing some rewiring to use the ohmic heater as the filter's resistor at electrolysis time ; flipping a multipole switch to go from electrolysis mode to heating mode will put the heater in the right circuit.

The other problem with all system is how to keep the W rod active for hour or days? I see two approaches to this problem. One is to build a system that auto-feeds the electrode. The other is devise an experiment that can reaches equilibrium quickly and thus doesn"t needas much electrode. As I said in an earlier post we can also keep using the easily procured 2.4mm welding sticks. I suggested to pre-form them (by operating them in a "dummy" glow discharge before the actual run) so they can produce a high COP immediately when inserted into the system. While changing the

cathode, which won't take long with a proper holder/connector, we switch to ohmic heating mode to keep the vapor barrier active, and then flip back to electrolysis mode.

More constructive comments/criticisms please, it seems we haven't succeeded
in ruling out this scheme yet and there are others awaiting discussion so we must validate it or debunk it fast.

94) Ludwik Kowalski:
Colorado2 experiments replicated the COP>1 claim of the Paris-2 team. They showed that by doing the same things we obtain similar results. That was an important step forward. To make Colorado-2 results publishable we must be able to convince honest referees that excess heat cannot be explained in terms of known chemical reactions. That is the main issue. Unfortunately, it has not been addressed by recognized authorities in chemical aspects of high voltage electrolysis. Did Mizuno, or some of his collaborators, publish something along these lines in Japanese?

My understanding was, and still is, that a complete analysis of potentially possible exothermic chemical reactions is now being conducted in Paris. Im I correct? Planning for new setups, ahead of such analysis, does not seem to be productive, at this stage. Writing a paper based on Colorado-2 results also seems to be premature, for the same reason.

But we should compare the conductivity of water (from which the electrolyte was made) with conductivity of condensed liquid escaping from the cells (when the COP was measured). In that way we can estimate the percentage of tiny droplets of the electrolyte in the escaping steam. Several people suggested that the COP>1 might be due to our inability to distinguish between water vapor and droplets of the electrolyte. Yes, this problem would be eliminated in a closed cell, as illustrated by Jed. But Paris-1 and Colorado-2 experiments were performed by using open cells. Our anticipated paper will describe these experiments, and results should be made trustworthy.

95) Richard Slaughter:
Michel, If the goal you've set for your experiment is to make the existence of excess heat "indisputable, and indisputable abnormal". I think that it is essential that your data colection system run continuous for hours or days. You must collect the input and output power measurments at least once a minute and ideally once a second. You must be able to add water to your system and adjust the electrode without disrupting the data stream and keeping the reaction going. In the French 1 and Colorado 2 experiments this was one of the shortcomming. We could only collect continuous data for 5 to 20 minutes so we could only say we had excess heat for a 5 to 10 minutes

I think from an engineering standpoint it will be very difficult in the boil off experiment to maintain the reaction and the continuous data stream. Any disruption in the system seems capable of stopping the production of excess heat. In Colorado we would add hot water to replinish the lost water so our down time was a minimum. Still adding the hot water could stop the reaction. Adding cold water always stops the reaction. Adjusting the electrode required turinng off the input power and killing the reation.

The continuous data stream is essential to the primary goal of being indisputable. If you can show that excess heat continues for hours or days it's hard to argure that it is chemical in nature. It is this practical problem of keeping the reacting going for hours or days that is the biggest downside I see to the boil off experiment. If you have a engineering solution to add water and adjust the electrode so the reaction continues that's great. I don't see a way and keep the experiment simple. That why I'm leaning toward the closed cell approach. Richard

96) Michel Jullian:
Hi Richard, my comments in your text below, feel free to do the same.

If the goal you've set for your experiment is to make the existence of excess heat "indisputable, and indisputable abnormal". I think that it is essential that your data colection system run continuous for hours or days.

Long runs would be nice, highly desirable even, but are not essential in my proposal. Short runs as you have been doing would be still ok in this scheme: provided the vapor barrier is not interrupted in-between, there can be no ingress of potential chemical fuels.

You must collect the input and output power measurments at least once a minute and ideally once a second.

I was thinking of collecting them permanently by integration: measuring cumulated input energy (watt-hours from a simple electricity meter working on the digital multiplier principle, that's how recent meters work it seems) and cumulated output energy (evaporated mass), and reading them as often as we can so we get a smooth curve, but without this being an obligation: if there is no reading for 2mn it doesn't affect the run's global COP.

You must be able to add water to your system and adjust the electrode without disrupting the data stream and keeping the reaction going. In the French 1 and Colorado 2 experiments this was one of the shortcomming. We could only collect continuous data for 5 to 20 minutes so we could only say we had excess heat for a 5 to 10 minutes

I think from an engineering standpoint it will be very difficult in the boil off experiment to maintain the reaction and the continuous data stream. Any disruption in the system seems capable of stopping the production of excess heat. In Colorado we would add hot water to replinish the lost water so our down time was a minimum. Still adding the hot water could stop the reaction. Adding cold water always stops the reaction. Adjusting the electrode required turinng off the input power and killing the reation.

All this is useful information Richard. Why did you have to turn off the input power BTW? The cathode was grounded wasn't it?

The continuous data stream is essential to the primary goal of being indisputable. If you can show that excess heat continues for hours or days it's hard to argure that it is chemical in nature. It is this practical problem of keeping the reacting going for hours or days that is the biggest downside I see to the boil off experiment. If you have a engineering solution to add water and adjust the electrode so the reaction continues that's great.

Replenishing with boiling water is one thing. Weighing it would be trickier but we could use the magnitude of the steps on the scale readings to know precisely how much we have added couldn't we? To adjust the electrode, how about holding/connecting it in a sliding arrangement so it could be tapped gently with some tool to push it down a few mm at a time?

I don't see a way and keep the experiment simple. That why I'm leaning toward the closed cell approach.

I don't follow your reasoning. A closed cell would make things even more difficult wrt the above engineering questions than an open one it seems to me. Also what would be the advantages of the closed cell that the one-way scheme of the vapor barrier doesn't offer? They would have to be worth the risk of explosion...Michel

289) A different claim for excess heat

Ludwik Kowalski; 4/2/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This item is based on what has been reported in 2005 by Sterling D. Allan and Adrian Akau, in Pure Energy Systems News. Here is the URL for this article:

http://pesn.com/2005/06/26/9600116_Naudin_MAHG/

1) The MAHG stands for "Moller's Atomic Hydrogen Generator" that Jean Louis Naudin is experimenting with. Alexander Frolov, from St. Petersburg, is another inventor of this energy producing device. His email message, quoted in the article, states: "I am happy to see independent positive confirmation of my invention. Moller knew nothing about this way but he proposed to work on this topic and he paid 50% of cost. Also we have contract about 50-50 on the topic (including authorship)." Frolov also tells us that testing of the device is planned in Australia.

2) The excess energy, according to Moller, is somehow released when molecular hydrogen is turned into the atomic hydrogen and then back into the molecular hydrogen. Any chemist would say that this is not possible, unless the excess energy comes from another source? What is the source? In the case of CMNS that source is believed to nuclear reactions. Moller seems to thing that empty space supplies "free" energy.

3) As I wrote in another context, it is pointless to speculate about sources of excess heat before reality of that excess is validated. Naudin claims to generate excess heat much more efficiently then those who performed Mizuno type experiments. The article refers to the 526% efficiency. That implies that 5.26 joules of energy appears at the output for every joule that enters the system to sustain the process. Referring to this result the authors write: "This is the first known replication and collaboration of the work done by Nicholas Moller in conjunction with Alexander V. Frolov of Faraday Lab Ltd. of St. Petersburg, Russia in January 2003." Here is how that collaboration is described by N. Moller (February 2004) on Naudin's website <http://jlnlabs.imars.com/mahg/mahg1.htm>

"After having studied in detail, the work on atomic hydrogen that Irving Langmuir performed 80 years ago (see article Irving Langmuir & Atomic Hydrogen), Mr. Nicholas Moller of Spectrum Investments Ltd decided to experiment with Langmuirs findings in greater depth. To this effect Spectrum Investments Ltd. contracted with Faraday Lab Ltd. of St. Petersburg, Russia in January 2003 in order to verify Langmuirs proof of concept. After a constructive co-operation, Mr. Alexander Frolov, Director of Faraday Lab Ltd. confirmed Mr. Moller's assumption that recombination of atomic hydrogen can be used as physical mechanism for the operation of a practical high efficiency heat source/generator.

The main point was to determine what method of the hydrogen dissociation could be efficient. Several different methods (plasma welding, Pd proton-exchange membranes, high-frequency glow discharge and direct heating) were discussed. Agreement was reached on the design of a test bench with a special gas-filled tube, based on a standard design of a powerful vacuum tube. Hydrogen filling of 0.1 atm and dew point -60 C degrees was agreed with sub-contractors and design for the tube was completed (see photo and diagram below)." The diagram of the Moller/Frolov device is shown but my background is not sufficient to understand it. The text below the diagram uses familiar technical terms but it is not clear to me at all. A lot of words and numbers but not enough of the "logical glue" to make the text comprehensive. I wander what more knowledgeable people think about clarity of this description. The link to

“full construction diagrams” produced very impressive drawings but that is not what one needs to understand the device.

4) Fortunately, the article provides a layman-oriented section whose title is “Mechanism.” The device is essentially a flow calorimeter; water removes heat generated in the inner cell. That cell is filled with hydrogen at the pressure of 0.1 atm. Presumably, the inner setup is a glow discharge cell whose cathode is tungsten. The hydrogen is not consumed; it undergoes cyclic conversions from molecular form to atomic form and then back from the atomic form to the molecular form. In the first path the energy is consumed while in the second path the energy is released. The excess heat is the difference between the energy needed to decompose the H2 into two H atoms, and the energy released when two atoms of H form the H2 molecules.

The voltage between the anode and the cathode, about 250 V, must be pulsating at the frequency of 10 MHz and shape of each pulse is said to be important. This reminds me the super waves used by Israeli researchers. “The shape and length of time for the pulse might be the most important part of the experiment”. Why should frequency and shape be important? I suppose it has something to do with natural (resonance) frequency of H2 molecules. But these frequencies, as far as I know, are much higher than 10 MHz. High harmonics are likely to play a significant role in breaking the H2 molecules. The technical term for this process is “dissociation.” Its probability increases rapidly with the temperature, as demonstrated, in 1926 by Langmuir. Practically no molecules dissociate below 2000 K and nearly all molecules dissociate above 8000 K, without super waves.

5) The section entitled “Open source project” is also interesting. It describes what motivates researchers and provides additional information. Here is one quote: “This technology is nearly 70 years old, and is not likely to be patentable. (A patent was obtained by Frolov in Russia, but a source that request to remain anonymous states that it is probably not valid). It appears to be a feasible candidate for the ‘open source’ model of development by interested scientists worldwide.” And here is another quote: “Nicholas Moller, one of two individuals after whom this variant (2.0) device is named, said, ‘The time has come for removing the responsibility of defining the energy policies and structures of the future from the hands of the established energy industries, and place it in the hands of men of science who will work for the preservation of the environment that sustains all life on Earth.’ "

Impressive data from recent Naudin’s experiments are shown in the section entitled MAHG. In one experiment (May 2005) the difference between the output power and the input power incased nearly linearly when the input power. It changed from 50 W at 100 W of input, to 1000 W at 500 W at the input. In other words, the efficiency at the input power of 500 W was 300%. Generating excess heat at the rate of several hundred watts is remarkable. On June 23, 2005 the efficiency was 1153%. The device is referred to as an energy pump. I suppose that this term reflect the believe that energy is being pumped from the world of nothingness to the world of atoms and molecules. The effect of the duty cycle, for square pulses, on efficiency was demonstrated by Naudin. The efficiency increases significantly when 10 MHz pulses become shorter. Note that for shorter pulses (5% of each cycle) the frequency spectrum is wider and more input energy is delivered in the form of high harmonics than for the longer pulses (40% of each cycle).

A fast electronic switch was used by Naudin to control the the duration of pulses from a simple d.c. source. I wander what the efficiency would be if a very sophisticated power supply, such as Pinnacle (see Appendix in the unit #270) were used instead. As far as I know, Pinnacle can be programmed to deliver all kind of superwaves. It is worth mentioning that plasma, in Mizuno type experiments, also acts as an electric switch rapidly modulating the electric power. The modulation is random and the frequency spectrum is very broad. Can this also be significant in terms of what happened near the very hot tip of our tungsten cathode? Karabut, whose experiments are described in the unit #13, also used a pulsating power supply. This is another independent (?) indicator that high frequencies might play a significant role in production of excess energy. I am thinking in terms of resonance frequencies of the oscillating H2 molecules (or groups of molecules) and about moments at which distances between their atoms are somehow reduced.

6) And here is a quote from the last section. “Once others have been able to repeat these results, and the effect fully characterized, explained, and optimized; the big question will be how practical this technology will be as a free energy tapping modality. Solar energy is free energy, but the hardware required to convert photons to electricity is anything but free. Likewise, even though this MAHG technology apparently taps free energy, does not automatically mean that it will solve the world's energy problems. The machine cost and efficiency will be a primary consideration in the

practicality of the technology for commercial application. Preliminary results and extrapolations appear promising for the MAHG. Further studies and development will answer that question more definitively.

In an email granting permission to use the images that appear in this article, Naudin said, ‘I hope that my modest contribution of my researches about this fascinating device will soon give us a clean energy source for the future and will contribute to saving our planet.’ " I hope his expectations will be fulfilled, sooner than later. Those who are interested in Naudin’s investigations of MAHG devices should refer to this website:

http://jlnlabs.imars.com/mahg/index.htm

Also worth reading is Moller’s article entitled “Irving Langmuire and atomic hydrogen.” It is essentially a biography of Irving Langmuire, a Nobel laureate who died in 1957. The article can be found at:

http://jlnlabs.imars.com/mahg/article.htm

The biography ends with speculations about how Langmuire would interpret heat released by atomic hydrogen (when it turns into molecular hydrogen) if he were familiar with the idea of the infinite amount of free energy from the so-called “emptiness.” It is ironic that Langmuir’s name is also associated with criticizing pseudoscience. Would he be declared a pseudoscientist if he decided to confirm Naudin’s findings? I do not think that Langmuir would speculate about free energy before convincing himself, experimentally, that claimed effect is not an illusion (due to experimental errors or well known processes). After convincing himself he would probably focus on convincing others.

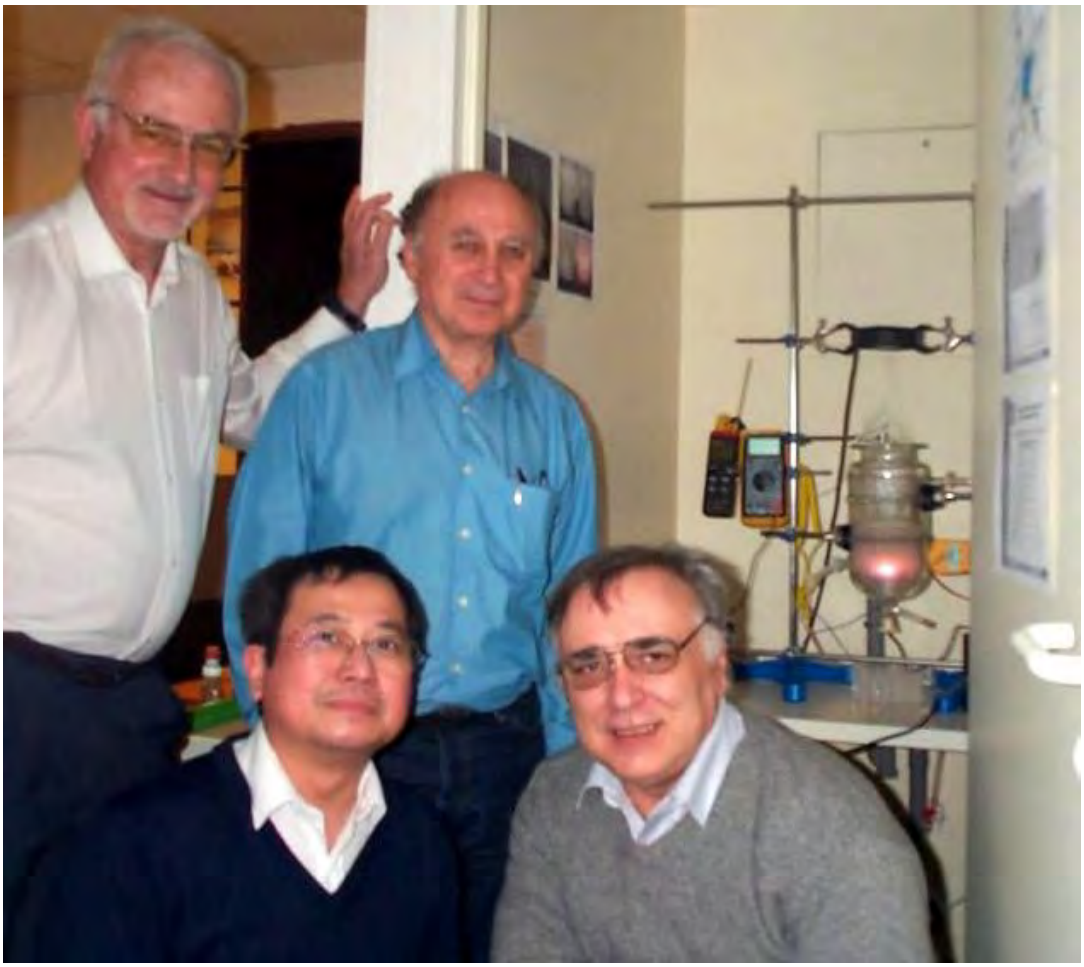
290) Attitudes toward our ongoing project

Ludwik Kowalski; 4/5/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) This morning Pierre sent me a picture which I see think is worth posting. Pictures of other researchers, with whom I had privilege of working on the ongoing CMNS project (Scott Little and Richard Slaughter) have already been posted in unit 270. The picture below shows Pierre Clauzon (upper left) and Gerard Lalleve (lower right). Also shown are Jean Paul Biberian (upper right) and Jean Louis Naudin (lower left). Jean Paul might start a new Mizuno-type experiment in Marseilles soon while Jean Louis is a veteran in the field of plasma cells, as indicated in the unit #289.



Do not miss a Mizuno-type cell on that photo. It is next to Gerard's head. The red-orange spot is the glowing plasma column at the tip of the cathode. The next photo shows Ed Storms (left side) and Fangil Gareev (right side). I took that picture December 2006, at our last conference in Japan (ICCF12). Gareev is from the Nuclear Research Laboratory in Dubna, Russia.

And how could I not show the photo of me with Russian friends? On the right side is Alexander Karabut, then the interpreter Natalia Famina, then myself, and then Irina Savvatimova. Discoveries of Karabut and Savvatimova, described in the unit #13, had profound effect on me. The picture below was taken December 2006, at our last conference in Japan.

A) *

So much about pictures. Now I would like to show the unexpected message that Ed Storm posted on the restricted discussion list for CMNS researchers.

" I want to add emphasis to what Jed said and reiterate what I have been saying in previous e-mails. Trying to do CF experiments on the cheap and with crude equipment is a complete waste of time. Like most people in the field, I started this way and have regretted it ever since. After many years of trial and error, and on the job training, many of us know what works and what does not. It is essential that this experience be used unless you want to spend years getting this experience yourself. The advice is to use standard, well understood methods; use equipment that is reliable; and design the experiment so that it is as simple as possible.

On the other hand, I see that it is hard for some people to take such advice. People seem to be designed to insist on doing an experiment their own way so that they can express their own creativity. Perhaps, making mistakes and learning the lessons are required for everyone. That is why actually running an experiment teaches more than any amount of advice. Only failure gives interest in making a change in the approach."

B) *
And here is my immediate reply to this message. "Ed, instead of arguing in general let me review our specific situation.

1) A claim was made (Paris-1) that a very simple method can be used to demonstrate excess heat. What should be the most natural way to check this? It is to perform the identical experiment and look for results.

2) We did this in Texas-1 and in Colorado-1. Results did not confirm excess heat. Our report at ICCF12 was criticized for not performing the experiment in the same way as in Paris-1. A researcher from the Paris-1 team, Pierre Clauzon, came to help us to replicate their experiment properly. Under his guidance we were able to observe excess heat. We confirmed that identical, more or less, results are obtained under identical conditions.

3) This was a big step forward. In any other field of science we would write a paper and this would probably be

viewed as a small step forward. Other researchers, or ourselves, would then start performing better experiments to explore various aspects of the natural phenomenon, including practical applications.

4) But, as you know very well, it is not easy to publish results of CMNS investigations in a refereed journal. Facing this situation, we do not have the luxury of being satisfied by publishing the results. Our work is unfinished. Starting another project, for example an experiment in a closed cell with a flow calorimeter, would mean that we simply wasted time. We want our results to be known, as they are, not as they might be in another experiment. If we are right then we want to convince others that we are right. If we are wrong then we want to know where we are wrong.

5) I think the methodology chosen for the Paris-1 experiment was appropriate to investigate the COP>1.2; it would not be appropriate for the COP<1.05. The claimed signal is said to be large, and systematic errors of 2% or 3% should not prevent a researcher from identifying it. After all, the energies to measure are in the range between 30 KJ and 100 KJ.

6) We performed about 50 evaluations of the COP and found the results to be reproducible. The mean value was 1.24 and the standard deviation was 0.13. Preliminary Paris-2 and Colorado-3 results (at least ten measurements, as I know from private messages) are consistent with these data.

7) Why should we abandon the methodology which produces credible results? Why should we not continue searching for possible systematic errors? Perhaps there are no large errors; perhaps the true value is somewhere between 1.1 and 1.3. We want to know this for sure.

8) You wrote: 'Trying to do CF experiments on the cheap and with crude equipment is a complete waste of time.' I do not think that we were wasting time. Our instruments are not too crude. You also wrote "The advice is to use standard, well understood methods; use equipment that is reliable; and design the experiment so that it is as simple as possible." That is what we were doing. We measured temperatures with a standard student laboratory thermometer, we measured the mass lost with a standard digital laboratory scale, we measured electric energy by several standard methods and verified that differences between these methods were very small.

9) I suspect that our weak points are in the interpretation, not in measurements. Fortunately, voices on this list helped us to identify two weak points: (a) absence of determination of the amount of liquid lost in the form of tiny droplets and (b) the possibility that the measured excess heat is due to well known chemical reactions.

10) It is always better when such issues are recognized before a paper is submitted. In our situation this is essential. We must address the weak points in the paper before the referees identify them. Unfortunately, we are not chemists. That is why help from chemists and electrochemists is expected. With help we might be able to succeed; without help and encouragement we might fail. Just imagine what might possibly happen after excess heat, in a Mizuno-type experiment, is recognized as real by mainstream scientists, by the DOE, the NSF, and the editors of leading journals. Yes, I know that our paper will not produce spectacular results. But it might be a successful first step toward recognition. Then more sophisticated approaches will be justified. Giving up at this stage would be a big mistake."

C) *
I waited for the reply from Ed but what came instead was a message posted by Jed Rothwel. I wander what Ed Storms thinks about Jed's message. It is shown below. Note that what is attributed to me is in black while what is from Jed is in blue. Rothwell wrote:

Ludwik Kowalski wrote:

1) A claim was made (Paris-1) that a very simple method can be used
to demonstrate excess heat. What should be the most natural way to
check this? It is to perform the identical experiment and look for results.

That is a good first step.

A researcher from the Paris-1 team, Pierre Clauzon, came to help us

to replicate their experiment properly. Under his guidance we were able to observe excess heat. We confirmed that identical, more or less, results are obtained under identical conditions.

Good on you, as they say in Sydney.

3) This was a big step forward.

Well, it is replication #5 or so. Not bad, and it calls for round of applause, but it has not pushed the state-of-the-art or added any knowledge yet.

4) But, as you know very well, it is not easy to publish results of CMNS investigations in a refereed journal.

"Not easy" is incorrect. It is utterly impossible, and if your goal is to publish in a refereed journal you are wasting your time. I think your goal should be to convince qualified people that your results are real, not artifactual.

Facing this situation, we do not have the luxury of being satisfied by publishing the results. Our work is unfinished. Starting another project, for example an experiment in a closed cell with a flow calorimeter, would mean that we simply wasted time.

No, it would mean that you learn the technique and you are ready to begin a more serious experiment.

We want our results to be known, as they are, not as they might be in another experiment.

Why? Ohmori's results are already known. You have not improved upon him or proved anything he did not prove long ago. This is kind of like building an exact replication of the original 1903 Wright Flyer, to prove that airplanes can fly. Why not build a better model? why repeat crude experiments that were performed years ago? Ohmori had no choice -- he had no money and he faced enormous opposition from the University -- but you can use a proper computer, a digital camera to record the appearance of the plasma, multiple thermocouples or a Seebeck calorimeter. Why should you limit yourself to instruments that were available in 1890? I cannot see any logic or any reasons for this.

5) I think the methodology chosen for the Paris-1 experiment was appropriate to investigate the COP larger than 1.2

Okay it is "appropriate to investigate." But if you want to convince large numbers of people, or if you want to learn much more about the reaction, you will use better instruments.

We performed about 50 evaluations of the COP and found the results to be reproducible.

Good. You are about the fifth group to confirm Ohmori, using a method similar to his, albeit with less skill and care than he used. If that is all you want to accomplish than you are finished and you can stop doing the experiments.

6) Why should we abandon the methodology which produces credible results?

Because we already have credible results! Why continue with a methodology that has been tapped out and has taught us all that it can teach? Why repeat old experiments that were already as convincing? There was never any doubt that Ohmori and Mizuno were reporting honestly, and that they did observe apparent excess heat. I saw it myself in their labs on many occasions. Your confirmation does little to buttress their credibility, and it adds nothing to our knowledge of this phenomenon.

Ed wrote that “trying to do CF experiments on the cheap and with crude equipment is a complete waste of time. ”I do not think that we were wasting time. Our instruments are not too crude.”

They are way too crude. Take it from Ed -- and Mizuno, and me for that matter.

Ed wrote “The advice is to use standard, well understood methods; use equipment that is reliable; and design the experiment so that it is as simple as possible.” That is what we were doing.

You are certainly not using well understood methods or reliable equipment. You roached your computer! How reliable can that be? (I mean you burned it up -- in 1960s jargon.) As for simplicity, perhaps Storms should have said, as Einstein did, "as simple as possible, but not too simple."

We measured temperatures with a standard student laboratory thermometer, we measured the mass lost with a standard digital laboratory scale, we measured electric energy by several standard methods and verified that differences between these methods were very small.

Yes, so did Ohmori and Mizuno, many years ago. Why do you think Mizuno stopped doing this long ago? Because the method has many inherent disadvantages and inaccuracies, as I have explained time after time.

D) *
Johnny Coviello wrote:
. . . No reason to continue raising the same objections over and over again, once they are acknowledged by the researchers. Certainly, the researchers reporting this recent excess heat result in Colorado were open to criticism of their experimental methods. Ludwik even said that due to the rather crude nature of calculating excess heat, the experiment results under COPs of 1.20 should be considered suspect. Of course, many of their results were above COP 1.20, so once again the chemical explanation or other error explanations, such as misting due to the violent nature of the reaction, might not be adequate.

Look at it this way. The Colorado experiments are another indication that something unusual is occurring in these cells. If they did not record unusual COPs, then there would be nothing to talk about. All they can do is take the criticisms into account and design another cell that tries to address the pontial error concerns, and see if unusual COPs are once again recorded. Process of elimination. It does appear to me that a reproducible cold fusion experiment might be evolving from the original Muzino work.

E) *
Jed Rothwell wrote (in black):
He was referring to a message from Michel Jullian (see quotations in blue).

Ed, instead of patronizing and stigmatizing . . .

Storms has been doing this for 16 years. Take his advice or leave it, but stop acting childish.

. . . please note that the simple and inexpensive (for wide replication) . . .

Define inexpensive. $50? $500? $2,500? What advantage would there be in saving $2000? I cannot think of any. How widely do you want this to be replicated, anyway? I do not think we should encourage large numbers of people at home to try an experiment that calls for boiling poisonous electrolyte, 3000°C metal, and which has been known to explode violently without warning for no apparent reason. Someone could be seriously hurt or killed doing this. You should think about liability before you go around promoting replications by inexperienced people outside of well-equipped laboratories.

but rigorous (for indisputability)

If you want something indisputable, you will have to use more sophisticated techniques and better instruments that Ohmori did. Frankly, his experiment was better than the one described here. He has skill and decades of experience. As long as you stick with inexpensive 19th-century techniques, you will not improve on what he did, and you will not prove anything he did not prove years ago. That is why Mizuno went on to use more sophisticated techniques.

. . . boiloff Mizuno experiment we are trying to design in this collaborative way has never been done before, so if it can be done at all it will require creativity obviously . .

You have that backward. You are being too creative. To do this experiment properly you need to be less creative and more willing to take advice from experts and do things according to the textbooks.

. . . i.e. lots of many silly complicated proposals which don't work before reaching the clever simple one which will work.

Cleverness is not called for. People do not believe clever results. We have already described techniques that will work. Your best choice would be a large Seebeck and a closed cell (perhaps a reflux cell).

F) *
L. Kowalski:
We can not address all issues . . . Our experiment produced some results and I want to know if the COP=1.24 (st. dev.=0.13) is not an illusion due to an error. I am certainly not going to discourage others from perform better experiments. And I will be extremely happy when they come up with results that are more trustworthy, for example, COP=1.75 (st. dev. 0.03). General problems are worth discussing . . . I hope that your comment on my reply to Ed will generate an interesting discussion. The issue -- why bother with what has already been done? -- is well framed in your message.

G) *
Michel Julian (responding to a message from ED that have not seen):
Ed is quoted in blue, Michel's comments are in blue.

Dear Ed, my comments in your text. (To Jed and JCJ, less verbal violence please)

Dear Michel, I do not mean to be insulting. My comment was a simple observation

No insult taken then. Sorry I misinterpreted your comments. [What follows is from from another message of Michel]:

Group, assuming we all agree on the objective of the simplest possible indisputable boiloff Mizuno experiment design, we could discuss honestly and peacefully the merits of all proposals, giving priority at any given time to the simplest that is currently proposed (which should take the least time to debunk), and working our way progressively up through the more sophisticated ones as and if we find flaws in the simpler ones. The metric for simpler could be that more people can replicate the experiment, based on the bill of materials.

We should try to refrain from any preference based on whether the solution is 19th century or 21st century, nor whether it was invented here or there, nor whether the proposer has been 17 years or 1 month in the field, nor whether he has scientific/technical education or not, nor whether he can shout louder than another. Merits only.

If we don't understand a proposal we should say so rather than ignoring it, and the proponent should explain. Critical sense would be welcome. Flames or patronizing wouldn't. . . .

H) *
Jed Rothwell:
Michel Jullian wrote: "The metric for simpler could be that more people can replicate the experiment, based on the bill of materials."

Why would the bill of materials be the limiting factor? I should think that an easier, safer, more certain method would increase the number of people who can replicate. Whether an experiment cost $1,000 or $5,000, and whether it takes 5 components or 20, seems immaterial.

[He also wrote:] “We should try to refrain from any preference based on whether the solution is 19th century or 21st century . . .”

Indeed, why stop at the 19th century? Let us consider using 18th century techniques to refine our own tungsten from wolframite. I assume the goal of this technological time travel is to make life difficult, create extra labor, and reduce precision, so that when we return to the 21st century with a sigh of relief, we will appreciate computers, thermocouples and the other 'tools of advanced civilization' (what the Japanese call 'bunmei no riki'). It is sort like camping, in other words. I myself spent enough time in the pre-computer world of typewriters, slide-rules, film-cameras and mercury thermometers. Nostalgia aside, I have no desire to reenact it.

[He also wrote:] “ nor whether it was invented here or there, nor whether the proposer has been 17 years or 1 month in the field, nor whether he has scientific/technical education or not . . .” Another interesting suggestion! Ah, but consider -- (a) "Those who cannot learn from history are doomed to repeat it." - George Santayana [and] "Experience is a dear teacher, but a fool will learn at no other." - Benjamin Franklin

G) *

Ed Storms wrote:

Of course a machine shop is required along with a glass blower and a computer programer. Without either the money to hire such people or the personal ability to do the job, you should not be in the business of trying to prove that an unbelievable effect is real. In the good old days when I learned science, everything had to be designed and constructed by the experimenter. Now, a great deal can be bought, but this takes money. Without money, you can still make the required items, but this takes skill. As a result, most people cut corners and jerry rig a Rube Goldberg device that does nothing but entertain the experimenter. This is worthwhile, but it is not science and will not be believed by the world of science no matter how well the arguments are constructed or debated.

I) *

L.Kowalski wrote (but not posted):

Yes, in comparison with Ed Storms and Michael McKubre we are amateurs. By "we" I mean people involved in Colorado-2, Paris-2, and Colorado-3 experimens. Scott Little, in my oinion, belongs to a much higher category of researchers. This jugemen is based on his exceptional technical skills, and on experience he gained on working with calorimeters. He cooperated with Mizuno but was not able to replicate excess heat. I am dissappointed that the Texas-2 experiment must be delayed because they are investigating something else. I would feel much more comforteble about the Colorado-2 results if Scott also obesrved the COPs significantel larger that unity.

For the time being I rely on the data collected in Colorado-2, plus private confirmations from about ten more recent tests (preliminary data from Paris-2 and Colorado-3 experiments). I already responded to the hint Ed made about our “complete wasting of time.” I am not going to repeat this again on the CMNS discussion list. Nothing could be gained from this. We were not “cutting corners” in the Colorado-2 experiment. We did what science teachers and students could do in a school lab (after reading units #252 and #253) . Now we are discussing ways to determine how much liquid is lost in the form of tiny droplets. One of these methods, or more, will be used in subsequent experiments. What is wrong with this? Why should we stop now? We found potential sources of errors and we want to be sure that excess heat is not an illusion. We need help and encouragement. I think that our simple device did a little more than “nothing.” What I am affraid of is that people planning for the Paris-2, Colorado-3, Texas-2 and Marseilles-1 experiment are going to give up because the most senior CMNS researchers are not providing as much help and uncouragement that I expected. I hope this will not happen.

O) *

Jed Rothwell wrote:

You do NOT -- repeat NOT -- want anyone to do this as a science fair project! This experiment should not be done by high school kids or by people who do not have safety equipment at hand, including goggles, a shower and so on. Let me reiterate what I said earlier, with emphasis: This experiment is DANGEROUS. The electrolyte is toxic and it is boiling. The light from the cathode is so intense it will damage your eyes if you look at it too closely for too long. On at least one occasion, a glow discharge cell has exploded violently without warning, releasing over 400 times more

energy than was input into the cell. This is far beyond the limits of chemistry -- there is no doubt the energy release was anomalous. It drove a glass shard about 1 cm into Mizuno's neck, next to the carotid artery, and the noise deafened him and his colleague for several hours.

I spent several days watching both Ohmori and Mizuno performed their versions of this experiment. Both of them are careful, and both have decades of experience doing electrochemistry, but Ohmori's technique was so frightening to Mizuno that Mizuno refused enter the lab. "I will watch from out here, " he said, standing out in the hall. "The way Ohmori does this scares the hell out of me." This was five years before his own cell exploded. . . .

K) *

Ludwik Kowalski wrote:

(1) An explosion due to accumulation of hydrogen is much less likely to occur in an open Mizuno-type cell. (2) Nearly all chemistry experiments performed by students must be supervised by teachers. If I were to supervise an open-cell-Mizuno-type student project I would used the open cell. And I would insist of using a standard laboratory hood, plus protection glasses, etc. . Yes, safety aspects are very important. (3) Do you remember a report from two high school girls who confirmed the COPs >1 in Louisiana two years ago? I do not recall any safety concerns being raised (at our conferences) about open cell experiments by high school students. Why now? I would like to see several student reports about over-unity COPs each year. The fact that these reports do not prove anything new would not bother me. At this stage we need confirmations, the more the better. And think about educational and motivational effects of such projects on students.

L) *

Jed Rothwell:

This explosion [in Mizuno cell] was anomalous. It could not possibly have been caused by hydrogen, or any chemical reaction. I presume it was a runaway cold fusion reaction, like the one that melted or vaporized Fleischmann and Pons' cathode in Feb. 1985. We should not kid ourselves about this issue anymore. I have now seen five credible reports of anomalous explosions, four them clearly beyond the limits of chemistry. I think it has been established that cold fusion can produce runaway reactions and explosions. It is my gut feeling that the glow discharge version is particularly prone to this, because it sometimes produces large energy spikes very rapidly. I only hope cold fusion cannot be used to make a large-scale nuclear bomb, but no one can be sure of that at this stage.

291) Yes, these experiments are dangerous, but . . .

Ludwik Kowalski; 4/9/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Several days ago Jed Rothwell, the author of the book "Cold Fusion and the Future," posted the following message on the restricted list of CMNS researchers. Note that CMNS stands for Condensed Matter Nuclear Science -- a new name for what used to be called Cold Fusion (CF). The CF is a subfield of CMNS in which unexpected nuclear particles are studied. Jed wrote:

I recently updated my book, and I included a list of 4 anomalous cold fusion explosions in chapter 12. I also uploaded some photos of accidents here:

http://lenr-canr.org/Experiments.htm#PhotosAccidents

I just realized there was another anomalous explosion reported at ICCF-3:

Zhang, X., et al. *On the Explosion in a Deuterium/Palladium Electrolytic System*. in *Third International Conference on Cold Fusion, "Frontiers of Cold Fusion"*. 1992. Nagoya Japan: Universal Academy Press, Inc., Tokyo, Japan.

This event occurred in April 1991. I just asked Zhang if he still thinks it was anomalous and if I should include in the list. Glow discharge appears to be the most dangerous and unstable version of cold fusion, but the other types are also hazardous.

This was followed by several messages (shown in the appendix below") in which Jed argued that plasma electrolysis experiments should not be conducted by students and amateurs. This goes against what I wrote in the unit #252. And I still disagree with Rothwell that Mizuno type experiments in an open cell, as described in the unit #286, are much more dangerous than experiments students perform in high schools and universities. Safety issues are important one protection rules, such as using a ventilated hood, protective glasses, etc., must be respected. Furthermore, student experiments must be supervised by science teachers. In replying to one of Jed's messages I wrote:

An explosion due to accumulation of hydrogen is much less likely to occur in an open Mizuno-type cell. Nearly all chemistry experiments performed by students must be supervised by science teachers. If I were to supervise a Mizuno-type student project I would used the open cell. And I would insist of using a standard laboratory hood, plus protection glasses, etc. Yes, safety aspects are very important.

Do you remember a report from two high school girls who confirmed the COPs >1 in Louisiana two years ago? I do not recall any safety concerns being raised (at our conferences) about open cell experiments by high school students. Why now? I would like to see several student reports about over-unity COPs each year. The fact that these reports do not prove anything new would not bother me. At this stage we need confirmations, the more the better. And think about educational and motivational effects of such projects on students.

The topic of risks in research is very broad and interesting. It has recently been discussed in the context of some ongoing medical and agricultural projects. Frederic Joliot Curie addressed that topic in his (1934 ?) Nobel Prize

address. He speculated about a possibility that a nuclear chain reaction can develop in our environment and destroy it at once. That is what Jed is speculating about. I think he is exaggerating. But his comments, like his book, are worth reading.

APPENDIX: Rothwell's messages:

Message #1

You do NOT -- repeat NOT -- want anyone to do this as a science fair project! This experiment should not be done by high school kids or by people who do not have safety equipment at hand, including goggles, a shower and so on. Let me reiterate what I said earlier, with emphasis: This experiment is DANGEROUS. The electrolyte is toxic and it is boiling. The light from the cathode is so intense it will damage your eyes if you look at it too closely for too long.

On at least one occasion, a glow discharge cell has exploded violently without warning, releasing over 400 times more energy than was input into the cell. This is far beyond the limits of chemistry -- there is no doubt the energy release was anomalous. It drove a glass shard about 1 cm into Mizuno's neck, next to the carotid artery, and the noise deafened him and his colleague for several hours. I spent several days watching both Ohmori and Mizuno performed their versions of this experiment. Both of them are careful, and both have decades of experience doing electrochemistry, but Ohmori's technique was so frightening to Mizuno that Mizuno refused enter the lab. "I will watch from out here," he said, standing out in the hall. "The way Ohmori does this scares the hell out of me." This was five years before his own cell exploded.

Let me put this very bluntly. If you go around encouraging unqualified, unprepared, inexperienced people to do this experiment, and one of them is hurt or killed, you will regret it for the rest of your life. You might end up in civil court owing huge sums of money. This is like encouraging people to repair gasoline motors and gas tanks in their garage. I have know two people who burned their house to the ground doing that. One of them also incinerated his 6-year-old son. For you to even suggest this should be done as a "science fair project" is utterly irresponsible and stupid. Furthermore, it would serve no useful purpose. Hundreds of inexperienced people doing this as a science-fair-level project would not convince any scientist, and it would not teach us anything new about the reaction.

Message #2

Ludwik wrote: "An explosion due to accumulation of hydrogen is much less likely to occur in an open Mizuno-type cell." This explosion was anomalous. It could not possibly have been caused by hydrogen, or any chemical reaction. I presume it was a runaway cold fusion reaction, like the one that melted or vaporized

Fleischmann and Pons' cathode in Feb. 1985. We should not kid ourselves about this issue anymore. I have now seen five credible reports of anomalous explosions, four them clearly beyond the limits of chemistry. I think it has been established that cold fusion can produce runaway reactions and explosions. It is my gut feeling that the glow discharge version is particularly prone to this, because it sometimes produces large energy spikes very rapidly. I only hope cold fusion cannot be used to make a large-scale nuclear bomb, but no one can be sure of that at this stage.

Ludwik asked: "Do you remember a report from two high school girls who confirmed the COPs >1 in Louisiana two years ago?" Was that with glow discharge, or ordinary electrochemistry? Glow discharge is much more dangerous at a practical, hands-on level. The electrolyte boils, the cell shakes and rattles, the light is blinding, power levels and temperatures are much higher than other types of cold fusion, and the cells sometimes produce large volumes of free H2 and O2 gas, from pyrolysis.

Message #3

Ludwik Kowalski wrote: "Would you support a moratorium on experiments with Mizuno-type cells anywhere, including national labs, old deep mines etc.?" No, that would be ridiculous. Let me put it this way. Internal combustion gasoline engine technology is 120 years old. It has been developed in national labs and corporations, and people work on gasoline engines in millions of shops and garages across the land. But, even after 120 years these things are still dangerous, and they always will be. As I said, I knew two people who destroyed their houses -- one who killed his son -- because they were monkeying with gasoline engines in their garage, and they did not have the proper tools, training, ventilation and so on.

There are many other dangerous jobs that untrained amateurs should not engage in, such as working with AC electricity house wiring or using heavy duty chain saws. Nobody suggests we should ban the use of AC electricity, even though every baby and toddler in the country is a few meters away from sticking a finger into a socket, and babies do that every day. We must take risks, but we should also take precautions. (You should cover up those sockets with plastic gadgets until the kid turns 3! And don't do it when the kid is watching.)

As I have said and said again, people who do the Mizuno experiment should use proper tools and safety procedures. They should know about these procedures because they should be trained chemists -- or at least they should consult with chemists. They should use a television camera to observe the glow discharge, rather than squinting at it from 50 cm away. They should use other common sense methods of avoiding danger. They should be willing to spend a few thousand dollars extra to ensure safety, if that is what it costs.

Of course if the experiment produces an explosion on the scale of a small nuclear bomb nothing can be done. I would not rule out that possibility completely, but I personally would be willing to observe or participate in these experiments despite that remote possibility. Present-day fossil fuel based systems cause enormous damage, and they kill vast numbers of people. Coal alone kills roughly 20,000 people per year in the US. They are probably causing worldwide global warming which may kill millions of people, wipe out hundreds of thousands of species, and destroy thousands of cities and towns. So although there is a remote possibility that cold fusion might be capable of causing nuclear bomb scale explosions, it is worth taking that risk because the energy systems we have now are causing catastrophic damage.

Message 4:
[X asked for details.], they are here: <http://www.lenr-canr.org/acrobat/MizunoTanomalouse.pdf> [X also asked: "Would this not provide sceptic-zapping proof that LNER are real?" It proves LENR is real, but it will not zap any skeptics because Mizuno cannot make it happen on demand, and no skeptic will believe that it happened in the first place. Mostly it has zapped Mizuno and his colleague. He is no longer doing these experiments because he is frightened, which is understandable. There have been at least 4 anomalous explosions, and probably 3 others count (one at BARC and two reported by W.-S. Zhang). See: <http://www.lenr-canr.org/Experiments.htm#PhotosAccidents>

That book, by the way, is available (free) over the Internet. Jed wrote: "If you would like to print a copy, we suggest you download the high-resolution version:

http://lenr-canr.org/ColdFusionAndTheFuturehires.pdf (15 MB)

Please feel free to print as many copies as you like. Note that it is cheaper to print in black and white. The first two chapters of the book have been translated into Italian and are available on line here: http://www.progettomeg.it/fflibrofreeit.htm "

292) Are we fighting an uphill battle ?

Ludwik Kowalski; 4/12/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The messages below were posted recently on the restricted Internet list for the CMNS researchers. They show what these people think and feel about being discriminated by the establishment of mainstream science.

Message 1;
Jean Paul Biberian, a French electrochemist from Marseilles, wrote:

When I perform an experiment, I have three goals in mind:

1- Most important: convince myself, that the measurements are valid, and make sure that there is no artifact. People who have done calorimetry can tell how easy it is to make mistakes, I have done many myself. Calorimetry needs a lot of practice, and there is nothing more difficult than a simple experiment.

2- Then and only then I can think of a demonstration to convince others, i.e. colleagues of mine interested enough to have a look at the experiment.

3- Try to publish the results. Here things become very difficult, because production of heat alone is not sufficient. The referees will want to have an explanation of where the heat comes from. Even though the total amount of heat might be beyond any chemically possible reaction, doubts may persist. Think of the heat pump which produces several times more heat than the electrical power input. You can never prove that somewhere somehow there is not a hidden energy source. It becomes necessary to come up with an explanation, i.e. for instance the production of energetic particles or helium, tritium, transmutation. ...The point is that no referee will want to spend the time to come to the lab and stay a few days with me to check everything in details. Even if he happens to do it, the editor or another referee will kill the OK of the first referee, because the credibility of the journal is at stakes.

Why are we in such a situation? :
We want to sell Cold Fusion as a scientific reality, and get acceptance from mainstream science. After 17 years, twelve international conferences, thousands of papers and experiments, we are not yet accepted. Why? I think because nobody wants Cold Fusion :

1- Scientists don't like paradigm changes, most are very conservative and do not like to have to change their habits. Lot has already been said about that, no need to develop here.

2- Energy suppliers: oil-gas-coal-nuclear don't need a new competitor, like with the mafia each one has a part of the territory, and they will join to expel a newcomer, even though they fight all the time between themselves. A new energy source will endanger all of them.

3- Environmentalists do not want Cold Fusion, for them this is the worst thing that could happen, if Cold Fusion becomes a major source of unlimited energy, then mankind will destroy the planet.

4- The military don't want us to look at that. There might be military applications, and this might give everyone access

to powerful weapons. Nobody understand some of the explosions that occurred during electrolysis.

We are fighting an uphill battle, we are in a situation where everybody and everything is against us. What is our best hope:

1- An experiment that produces lot of heat, with a large COP, for a long period of time. The calorimetry must be very simple, with no calibration. My opinion is that mass flow calorimetry is the best. Input power should be simple, i.e. DC current so that no correction is needed, The output power is easy to calculate if you can measure the input and output temperatures with a mercury thermometer, and the water flow with a stopwatch.

2- An experiment that produces anomalous isotopes, the Iwamura work is in that direction, but there is not enough material produced to convince skeptics.

3- The best experiment: a stand alone system,with no electric wire attached producing heat or electricity. However, if anyone can do that he doesn't care about publishing, he can probably sell the device!

Conclusion:
I do not have a solution yet, but I think that a convincing Mizuno type experiment should be done with mass flow calorimetry, I am thinking about doing one in Marseilles. Duplicating what has been done several times before will not help.

Massage #2
Ludwik Kowalski
I do not think that an explanation is essential at the very early stage. An experimental claim like "we demonstrated an excess energy that can not be due to a mistake or to an artifact" should be publishable. Pierre Curie had no theory explaining why his radium source was generating heat. That was in 1903. Good luck with Marseilles experiments.

Message 3
Jean Paul Biberian
Pierre Curie, he had found anomalies in the uranium salts, but nobody wanted to believe him. When he and his wife managed to isolate radium, and that at this point it was obvious to everyone that something unusual was happening then and only then radioactivity was accepted. A little bit like having a stand alone system producing heat without any external source...

Message 4:
From Jed Rothwell
Jean-Paul Biberian wrote: “Calorimetry needs a lot of practice, and there is nothing more difficult than a simple experiment. ” Exactly right. Try replicating J. P. Joule's experiments some time and you will see how true this is. [He also wrote] “Then and only then I can think of a demonstration to convince others, i.e. colleagues of mine interested enough to have a look at the experiment. ” Good start!. He also wrote] ”Try to publish the results. Here things become very difficult, because production of heat alone is not sufficient. The referees will want to have an explanation of where the heat comes from. .....” When editors and referees say things like that, you are wasting your time. Forget about trying to convince such people.

We agree that the best way to begin to convince people is with colleagues who are interested in the experiment. After you shall the experiment to your colleagues, who is next? What group of people do you show it to after that? People who attend the ICCF conferences, naturally, but they only meet once a year. However, 5000 people per week gather at LENR-CANR.org and they download 4000 papers. These are mostly researchers and they appear to be serious, open-minded, and willing to read difficult papers. So obviously you should publish at LENR-CANR.org, and also at ISCMNS, and your own web page, and at as many other web pages as you can find. You write papers in order to inform other researchers of your work, and convince them that your results are important. You can accomplish those goals by publishing online.

[Jean Paul also wrote] “Even though the total amount of heat might be beyond any chemically possible reaction,

doubts may persist. Think of the heat pump which produces several times more heat than the electrical power input. You can never prove that somewhere somehow there is not a hidden energy source." That is incorrect. Only a few heat pump types exist and they are readily identifiable. Furthermore, if the excess power is greater than a few watts it is easy to identify where in the heat pump cycle it is coming from. Look for the component that is covered with condensation and cold to the touch. If the Mizuno cell is a heat pump, some part of it would be covered with ice. It would also be one of the most efficient refrigerators ever invented, and a world-class discovery. [He also wrote] "Energy suppliers: oil-gas-coal-nuclear don't need a new competitor . . . " I doubt they are aware of the situation.

[He also wrote] "I do not have a solution yet, but I think that a convincing Mizuno type experiment should be done with mass flow calorimetry, I am thinking about doing one in Marseilles." It will be much better to use Seebeck calorimetry.
[He also wrote] "Duplicating what has been done several times before will not help." Exactly right. Ohmori and Mizuno would agree, I think.

Message 5:
Jed Rothwell wrote:
[X wrote, sarcastically] "Nature does not employ an editorial board of senior scientists, nor is it affiliated to a scientific society or institution, thus its decisions are independent, unbiased by scientific or national prejudices of particular individuals."

<http://www.nature.com/nature/authors/get_published/index.html> "]

That's pretty funny. It reminds me of Sci. Am. editor John Rennie's statements to me, "we aren't scientists, so don't blame us for our opinions. " Sort of the opposite tack after you get past the denial part, but equally loony. Quote:

"The second misconception concerns Scientific American's function. We're journalists here at the magazine, even those of us with scientific credentials. We don't claim to be authorities on physics or any other discipline (for all that there is quite a lot of real expertise built into our staff). For that reason, the scientific points of view we choose to publish are ones that have already been vetted in the technical, peer-reviewed literature and that generally seem to represent a consensus within the scientific community. To do otherwise would mean that we were pretending to be more expert than the actual scientific authorities. That is not what Scientific American's readers want or expect.

(As for whether we're entitled to mock cold fusion...well, sorry if you disagree, but that opinion reflects the consensus of most scientists, too.)

So it really doesn't make a difference to me if LENR-CANR advocates petition me for articles on the subject; I'll put them on the stack of similar requests from the scientific creationists, the global warming deniers the face-on-Mars people, the crypto-archaeologists, and all the others who want publicity and scientific respectability but can't make their case convincingly to the community of scientists. But I'll say this again, too: if LENR-CANR's physicists can convince the mainstream physics community that they've got a credible case and articles to that effect start appearing in major peer-reviewed journals, Scientific American would be glad to write about it." http://lenr-canr.org/AppealandSciAm.pdf

These are strange people. You wonder how they ended up in charge of major scientific journals. (The previous editor, Piel, inherited the job.) ... .

293) Jed Rothwell comments on some accusations

Ludwik Kowalski; 4/19/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Wikipedia is an online encyclopedia where anyone can delete, add or replace anything. The following message, from Jed Rothwell, just appeared on the restricted discussion list for CMNS researchers:

The cold fusion article at Wikipedia has grown too large, so it must be split up. Someone asked me to assist with the sub-article "cold fusion controversy." I should not waste my time on this sort of thing, but I did. The skeptics will soon trash this and erase it, but I had a lot of fun writing it. Have a look before it is gone:

en.wikipedia.org/wiki/Cold_fusion_controversy (The article was deleted in 2006)

I have a copy on my desk, preserved for posterity. I did not set out to make this humorous, although I can never resist. I doubt the skeptics will see it as funny. But I trust the readers here will see the humor in parts such as my deadpan rebuttal of the claim that cold fusion researchers are insane; my description of Hoffman's masterpiece; and the juicy quote from Happer and its source (Taubes).

- Jed

I think that what Jed wrote is worth preserving. Knowing that others will modify his text I pasted it below. It will be interesting to compare the current version with future versions. Be aware that what appears as a link in Wikipedia is nothing but a blue word below.

= =

Cold Fusion Controversy

Originally published in Wikipedia, April 2006, updated 4/20/2007

Ever since the Fleischmann-Pons experiment in March of 1989, the existence of chemically catalyzed cold fusion has remained a controversial issue. This article discusses the major skeptical arguments in the controversy. Experimental evidence for cold fusion can be found in the main article, cold fusion.

==Cold fusion as a violation of theory==

Most leading skeptics dismissed cold fusion because it appeared to violate the laws that govern high energy plasma physics. In a plasma reaction, copious neutrons "commensurate" with helium are produced, whereas with cold fusion the number of neutrons per helium atom is roughly 11 million times smaller. Skeptics say this means cold fusion is impossible. As Prof. H. Feshbach (MIT) put it in 1991: "I have had 50 years of experience in nuclear physics and I know what's possible and what's not........I don't want to see any more evidence! I think it's a bunch of *junk* and I don't want to have anything further to do with it." [1]

The books by F. Close [2] and J. Huizenga [3] are mainly devoted to proving that cold fusion violates theory and is therefore impossible. Huizenga, who was the head of the DoE ERAB panel that dismissed cold fusion in 1989, concluded his book with a 6-point summation. Point number six states that we know *a priori* that all positive cold

fusion excess heat results must be wrong:

> "Furthermore, if the claimed excess heat exceeds that possible by other conventional processes (chemical, mechanical, etc.), one must conclude that an error has been made in measuring the excess heat."

Cold Fusion researchers feel that they subscribe to the traditional view, that experiments are the standard by which all claims must be judged. [4] [25] They believe this is fundamental to the scientific method. When a phenomenon has been replicated many times at a high signal to noise ratio, that proves it does exist, and if theory predicts it cannot exist, the theory must be wrong. Cold fusion theorists believe that cold fusion does not violate conventional theory. The number of neutrons produced by cold fusion is much smaller than plasma fusion because a metal lattice at room temperature is very different from the center of the sun. As cold fusion theorist Julian Schwinger put it, "The defense [of cold fusion] is simply stated: The circumstances of cold fusion are not those of hot fusion". [5]

==Explicit rejection of the experimental method==

Several leading skeptics have stated that cold fusion proves the experimental method itself does not work. In other words, when dozens or hundreds of laboratories report they have replicated a phenomenon, they might all be wrong, and the only way to be sure a finding is correct is to show that it conforms to established theory. [Close, Huizenga ibid.] [6]

A variation of this idea was expressed by R. Ballinger (MIT) and B. Kevles (Yale). They say that Fleischmann and Pons were definitely wrong, but those who later replicated them may be right. Ballinger wrote:

> "It would not matter to me if a thousand other investigations were to subsequently perform experiments that see excess heat. These results may all be correct, but it would be an insult to these investigators to connect them with Pons and Fleischmann. .....Putting the 'Cold Fusion' issue on the same page with Wien, Rayleigh-Jeans, Davison Germer, Einstein, and Planck is analogous to comparing a Dick Tracy comic book story with the Bible." [7]

Kevles [8] accused Fleischmann and Pons of misconduct (fraud) and "scientific misdeeds,", and she said that the later replications of their work prove nothing to the contrary: [9]

> "Eventually, [Fleischmann and Pons] particular claims were refuted as theoretically unfounded and without experimental support. This is the incident I referred to in my article and it has altogether nothing to do with research since in this field." [10]

In all of the "research since" researchers used similar materials and reported similar results, and they cited the original paper by Fleischmann and Pons, so it is difficult to judge what Kevles has in mind.

Cold fusion researchers also assert that incomplete understanding of the process does not invalidate it, often citing the 1898 report by Marie and Pierre Curie that radium was permanently warmer than its surroundings. This report was accepted even though the source of the warmth was not known to science [Beaudette, ibid. p. 3]. Indeed, Nobel laureate Schwinger pointed out that discoveries of processes such as high temperature superconducting are "a prime example of embracing the concept without having to understand the mechanism." [ibid] The comparison is debatable, however. J. Piel, late editor of Scientific American, likened this "incomplete knowledge" claim to Langmuir's criteria for pathological science. [11]

==Cold fusion as pathological science==

Many have dismissed cold fusion as an example of pathological science: in such a science, a scientist, originally conforming to the scientific method, unconsciously veers from that method, and begins a pathological process of wishful data interpretation.

While there are no rigorous criteria for defining a pathological science, the following characteristics were listed by

Irving Langmuir when he invented the term:

* The maximum effect that is observed is produced by a causative agent of barely detectable intensity, and the magnitude of the effect is substantially independent of the intensity of the cause.
* The effect is of a magnitude that remains close to the limit of detectability, or many measurements are necessary because of the very low statistical significance of the results.
* There are claims of great accuracy.
* Fantastic theories contrary to experience are suggested.
* Criticisms are met by ad hoc excuses.
* The ratio of supporters to critics rises and then falls gradually to oblivion.

===The causative agent is almost undetectable===

The causative agent of excess heat in cold fusion experiment, if any, is not certain, but most cold fusion researchers think it is nuclear fusion. Nuclear reactions can only be detected by their effects. Some nuclear reactions have effects that can be easily measured (such as the production of tritium), while others are more difficult to detect (such as the production of helium-4).

Showing a correlation between excess heat and the amount of helium produced is challenging, but cold fusion researchers say it has been done at China Lake, the Italian national laboratories and elsewhere. [12] [13]

Other nuclear evidence, such as tritium, neutrons and gamma rays are far easier to measure. Cold fusion researchers say that these products have been confirmed in thousands of experiments in dozens of different laboratories, at levels far above the limits of detection, in some cases thousands of times above those limits. [14] For example, at the Bhabha Atomic Research Centre (BARC) the reactor safety experts have been measuring tritium for decades with accuracy and confidence. When several experiments at BARC experiment produced tritium, at levels up to 20,000 times above the initial concentration, they had no difficulty whatever detecting or confirming this, and they used several different methods. [15] [16] [17] [18]

===The effect is almost undetectable===

The excess heat has been measured by several different types of calorimeters often at a level that is easily detected, and sometimes impossible to miss. Tritium has been measured at levels ranging from 100 to several million times background. Gamma rays have also been measured far above background. Helium from cold fusion reactions is often close to the limits of detection but in at least one case it exceeded atmospheric concentration. Transmutations have in some cases converted milligram levels of materials, making them easy to detect. [19] [20] [21]

===The causative agent is not commensurate with the effect===

The causative agent of excess heat in cold fusion experiment, if any, is not certain, but every indication is that if they exist it is nuclear fusion. Nuclear reactions can only be detected by their effects. Some nuclear reactions have effects that can be easily measured (eg. neutron emission), while others are more difficult to detect (eg. Helium-4).

Showing a correlation between excess heat and the amount of helium is challenging, but as noted above, researchers at China Lake, the Italian National Nuclear Laboratories, Los Alamos, SRI and other laboratories report success. Tritium and neutrons, which are much easier to detect, have been measured at levels far above the limits of detection in hundreds of laboratories.

===There are claims of great accuracy in the measurement===

Cold fusion researchers do not claim great accuracy. They often use standard, off the shelf instruments within the manufacturer's certified levels of accuracy. Great accuracy is often not called for in any case, since, as noted above, the signal is often quite strong (far above background).

===Proposed explanations===

Critics of cold fusion say there are currently no satisfactory theories of cold fusion. Many cold fusion researchers agree with them. They consider cold fusion an experimental observation that is not derived from or supported by theory at this stage.

Many theories have been proposed to explain cold fusion, and some of these would generally be considered fantastic or fringe theories. However, other theories have been proposed by mainstream physicists such as Julian Schwinger and Peter Hagelstein. Schwinger and Hagelstein believe their theories are valid, and that that they do not conflict with the canon of established physics.

===Initial interest in the topic does not last===

Skeptics say that interest in cold fusion faded rapidly, and that the "vast majority" of scientists do not believe it exists. They do not cite public opinion polls or other hard data to back up this assertion. A poll published in Japan in 1994 indicated that most scientists there believe cold fusion is real, and nearly all support continued research. [22]

The majority of newspapers and news magazine reports on cold fusion published in the U.S. are negative. They usually say that the research was "debunked" and that it was fradulent and/or incompetent. (See below.)

Skeptics [Piel, ibid.] also say that no peer-reviewed journal papers on cold fusion have been published, but this is incorrect. Approximately 1000 have been published in mainstream peer-reviewed journals, [http://lenr-canr.org/DetailOnly.htm] and they continue to be published despite the hostility and opposition to the research expressed by APS officials, the *Washington Post*, some MIT professors and others. (See below)

==Doubts on the quality of the cold fusion scientists==

Cold fusion scientists have been often criticized for lacking credentials. However, many of them were previously considered to be world class experts in their fields. Distinguished Prof. John O'M Bockris, for example, wrote an authoritative and widely used textbook, *Modern Electochemistry*. He is a Fellow of the International Society of Electrochemistry [http://www.ise-online.org/geninfo/fellows_details.php]

Heinz Gerischer was considered a leading electrochemist. He was the Director of the Max Planck Institute for Physical Chemistry in Berlin, and a prize was established in his memory. He concluded that "there is now undoubtedly overwhelming indications that nuclear processes take place in the metal alloys." [24] Nobel laureate Julian Schwinger was considered a leading theoretical physicist and was respected by most scientists, but he reported being denigrated and attacked after he began writing theoretical papers about cold fusion. [ibid.] Dr. P. K. Iyengar conducted and directed cold fusion research while he was director of BARC. [http://lenr-canr.org/acrobat/IyengarPKprefaceand.pdf] He later became the chairman of the Indian Atomic Energy Commission

Profs. Miles, Oriani and Huggins have published textbooks and hundreds of articles, are designated Distinguished Professors and Fellows by universities and the U.S. Navy, and have been honored by the Electrochemical Society, NATO and other prestigious organizations. Other cold fusion researchers include three editors of major plasma fusion and physics journals, a retired member of the French Atomic Energy Commission, and many top researchers from U.S. national laboratories.

===Martin Fleischmann===

Martin Fleischmann is widely considered one of the top electrochemistry|electrochemists in the world. He is a Fellow of the Royal Society and past president of the International Society of Electrochemistry, and he was awarded a medal by the Society. He has published numerous papers in leading journals. On the other hand, he has no credentials in nuclear physics, and his first paper on cold fusion was shown to contain errors in this subject, in neutron detection. However, subsequent research was performed by leading experts in neutrons at Los Alamos, BARC and many other institutions, and these studies confirmed that cold fusion experiments produce neutrons. [Srinivasan, ibid.]

==Claims that experiments have been debunked or that they are fraudulent==

Most newspaper and magazine articles attacking cold fusion say it was debunked, or that it is fraud.

Debunked. The term "debunked" is not defined exactly, but it is usually taken to mean that replications were attempted but they failed. Cold fusion researchers believe these replications failed because the researchers performing them were not skilled in the art and because the experiment is inherently difficult to perform. The most famous three negative experiments performed in 1989 were at MIT, Caltech and Harwell. All three were subsequently shown to be positive. [25] [26] [27] [28]

Some articles have said that cold fusion was debunked because it was shown to be theoretically impossible. As noted above, cold fusion researchers believe this is a violation of the scientific method.

Many skeptics feel that cold fusion should be attacked, ridiculed and actively suppressed. In March 1990, D. Lindley, editor at Nature, wrote: "All cold fusion theories can be demolished one way or another, but it takes some effort.... Would a measure of unrestrained mockery, even a little unqualified vituperation have speeded cold fusion's demise?" [28] Cold fusion researchers feel this is a violation of academic freedom. Schwinger felt that such intemperate views will lead to the "death of science" [Schwinger, ibid.]

Fraud. Dozens of articles have said this. Writers in the *Washington Post* have been notably vehement. In 2006 Prof. B. Kevles (Yale) described cold fusion a "scientific misdeed." [Kevles, ibid.] In 1991 Robert Park, [30] wrote the following in a *Washington Post* review of the book by Frank Close:

> "..... Close asks in the first chapter, 'Was this a delusion, an error, or a fraud?' By the end of the book, it is clear that cold fusion progressed through all three. What began as wishful interpretations of sloppy and incomplete experiments ended with altered data, suppression of contradictory evidence and deliberate obfuscations.
>
> Fleischmann and Pons were no longer alone. Inept scientists whose reputations would be tarnished, greedy administrators who had involved their institutions, gullible politicians who had squandered the taxpayers' dollars, lazy journalists who had accepted every press release at face value -- all now had an interest in making it appear that the issue had not been settled. Their easy corruption was one of the most chilling aspects of this sad comedy.
>
> To be sure, there are true believers among the cold-fusion acolytes, just as there are sincere scientists who believe in psychokinesis, flying saucers, creationism and the Chicago Cubs. The lesson from *Too Hot to Handle* is that a PhD in science is not an inoculation against foolishness -- or mendacity."

The on-line database at LENR-CANR.org lists 3,400 papers on cold fusion written by 4,688 authors and co-authors, as of April 2006. Most of these papers have been positive, and none of the authors has benefited financially or otherwise. On the contrary, many of them have seen their careers stalled or ruined because they pursue this research. [Beaudette, ibid.] So there does not appear to be any motive to commit fraud, and it would be difficult for roughly 4,000 people to commit fraud and keep this fact secret.

==Claims that all cold fusion researchers are deluded or incompetent==

Articles in the press and in major scientific magazines have often said that all cold fusion scientists are practicing pathological science and all are deluded or incompetent. Robert Park made that assertion in the *Washington Post* article quoted above, in his weekly column, and in e-mail letters to cold fusion researchers. One of the members of the 1989 DoE ERAB panel, Prof. W. Happer, said that: "Just by looking at Fleischmann and Pons on television you could tell they were incompetent boobs." [Taubes, ibid.] F. Slakey, the Science Policy Administrator of the American Physical Society, said that cold fusion scientists are "a cult of fervent half-wits" "While every result and conclusion they publish meets with overwhelming scientific evidence to the contrary, they resolutely pursue their illusion of fusing hydrogen in a mason jar. . . . And a few scientists, captivated by [Fleischmann and Pons'] fantasy .....pursue cold fusion with Branch Davidian intensity." [31] S. Koonin said in May 1989 at an APS meeting, "My conclusion is that the experiments are just wrong and that we are suffering from the incompetence and delusion of Doctors Pons and

Fleischmann." [32] Skeptics sometimes say they have not made such intemperate comments, but there are hundreds of well-documented examples from major establishment scientists, publishers and officials. [Mallove, Beaudette, ibid.]

The people making these comments repeated them often, and they have never retracted or apologized. They say they are not exaggerating and they honestly believe that Fleischmann, Pons and all other cold fusion researchers are severely deluded and grossly incompetent. The people listed above were assigned a direct role in establishing U.S. policy toward cold fusion, in the ERAB panel and elsewhere, and their views have had great influence.

As noted above, leading cold fusion researchers and theoreticians include many prominent experts in electrochemistry and physics. It is unlikely that such people are deluded or incapable of performing experiments in their own fields.

==Claims that experimental errors have been made==

Since cold fusion is an experimental claim, cold fusion researchers feel that the only way to prove it is wrong is to demonstrate there is an error in the experimental technique or instruments. However, only a few skeptical authors have searched for such errors. Skeptics have written one book, at least five papers, and one magazine article citing errors, but cold fusion researchers feel the skeptics have failed to make their case. Some well-known examples include:

* D. Morrison versus M. Fleischmann debate [33] Morrison accused Fleischmann of employing "a complicated non-linear regression analysis" . . . "to allow a claim of excess enthalpy to be made." Fleischmann pointed out that they did not use that analysis. Morrison estimated that recombination might have produced 1.1 MJ at 145 W maximum power; Fleischmann pointed out that chemistry textbooks prove it could only produce 600 J at 5 mW maximum power. Several other points are disputed.

* N. Hoffman, *A Dialogue on Chemically Induced Nuclear Effects* [23] Much of this book is devoted to the hypothesis that all tritium results in cold fusion were caused by contaminated heavy water. This heavy water was contaminated, the author says, because the Ontario Hydro Company sold used moderator water from Candu fission reactors through chemical supply houses, to members of the public. There are two problems with this hypothesis. First, tritium levels are always measured before the experiment begins, so if the heavy water was already contaminated this would be noted. Second, upon learning about the book, Ontario Hydro vehemently denied selling used moderator water. They pointed out this would be illegal because this water contains roughly 100 million times more radioactive contamination than allowed by law, and it would cost tremendous amounts of money to remove this contamination and make the water safe. (Other sections of the book dealing with the Joule-Thompson effect and helium studies do not dispute the published results.) Cold fusion researchers at SRI pointed out that this book does not mention any experiment showing excess heat even though most experiments in the field have been done to look for heat.

* W. B. Clarke and Mass Spectrometry. Clarke published several articles with coworkers examining various aspects of helium detection in cold fusion-related samples. One study [42] has led to suggestions that some of the cold fusion researchers have not adequately handled the analytical chemistry technique of mass spectrometry.

* K. L. Shanahan and Calibration Constant Shifts. K. L. Shanahan has published 3 articles proposing a non-nuclear means to obtain apparent excess heat signals in cold fusion cells. In the first[34], Shanahan proposed that the system heat distribution and/or heat flow pathways might change and that this would induce a change in the calibration constants for the cell. He reanalyzed some actual cold fusion data published by E. Storms[37], under an assumption of zero excess heat, and found a variation in calibration constants of +/- 3% would explain the results, which is within typical error bounds of a fairly high quality scientific study. Subsequently, Szpak, Mossier-Boss, Miles, and Fleischmann questioned the proposal[39], and Shanahan replied [35] with an expanded explanation and applied it to explain the authors results. E. Storms rebutted Shanahan [38] by pointing out that the data does not fit his model.

* A *Scientific American* article in 2006 with a sidebar that said there are four weaknesses in the cold fusion experiments. [40] (The article is here [http://www.sciam.com/article.cfm?articleID=00059015-99C5-1213-987F83414B7F011C&ref=sciam&chanID=sa006], but the sidebar is missing. It is quoted here: [http://lenr-canr.org/News.htm#SciAmSlam].) These statements are not in evidence in the experimental literature. In a letter to J.

Rothwell, the editors said they have not read any of the experimental literature on cold fusion, because, they say, this literature does not exist: no papers have been published "in major peer-reviewed journals." [Piel, ibid.] Presumably this explains why the editors made these four errors.

==Burden of proof argument==

Many skeptics have said that the burden of proof is on cold fusion researchers to prove their point. As the editor of the Scientific American put it: "But it is not up to mainstream physicists to disprove LENR-CANR [cold fusion]; it is up to LENR-CANR's physicists to come up with convincing proofs. The burden of evidence is on those who wish to establish a new proposition." [Piel, ibid.]

Cold fusion researchers feel they have met this burden. Cold fusion experiments are based upon traditional instruments and techniques, such as calorimeters (most of them developed between the 1780 and 1840), autoradiographs (circa 1890), and conventional tritium detection and mass spectroscopy. Calorimetry is based upon the laws of thermodynamics. Since most skeptics agree that autoradiographs, the laws of thermodynamics and so on are valid, cold fusion advocates argue that the skeptics should agree that cold fusion experiments are valid, and that the burden of proof is on those who say these techniques and laws are inoperative.

==Other skeptical arguments==

Some skeptics say they do not believe the results because there may be an error in the experiments which has not yet been discovered. This argument is invalid because it cannot be falsified, and because the same can be said for any experiment.

Skeptics quote Carl Sagan's axiom that "extraordinary claims require extraordinary evidence." Cold fusion researchers disagree. They feel that extraordinary claims are best supported with ordinary evidence from off-the-shelf instruments and standard techniques, and this is the kind of evidence they have published. They also feel that all claims, and all arguments (including skeptical assertions that attempt to disprove cold fusion) must be held to the same standards of rigor.

Hagelstein has encountered skeptics who say "a commercial product is the next hurdle to be jumped through before any significant funding can be justified." He responded, "This is simply not right." He explained:

> "Scientists in the field have gone to extremes in attempts to satisfy skeptics. Cells were stirred, blanks were done, extremely elaborate closed cell calorimeters have been developed (in which the effect has been demonstrated), the signal to noise ratio has been improved so that positive results can now be claimed at the 50 sigma level, the reproducibility issue has been laid to rest; but still it is not enough." [41]

Hagelstein and others point out that plasma fusion has failed to produce a practical power reactor despite 60 years of research and over $100 billion in funding, yet no one questions the existence of plasma fusion for that reason. They also point out that countless other natural phenomena have no practical application, but are not disputed.

Lindley [ibid.] and many other skeptics have said that before they believe the experimental results, cold fusion researchers must first provide a complete theory to explain the phenomenon. This also violates a fundamental tenet of the scientific method, since there are and always have been countless unexplained phenomena which are unquestionably real (such as high temperature superconductivity and radium fission, as noted above). Cold fusion researchers feel that it is the job of science to explain anomalies rather than to dismiss them.

Additional input from Jed. (4/23/06):

Writing this Wikipeida article has been an education for me. It has revealed aspects of the skeptical imagination and thought processes I was unaware of. One thing that shocked me is how many skeptics are livid with anger because I am quoting verbatim Huizenga and other leading skeptics. Several times they have erased these quotes. They do not want to hear their own side!

Here is an example of what I have learned. This is kind of trivial yet thought provoking. The skeptical argument that all researchers are incompetent or frauds is weak. It has to apply to 100% of researchers. If a skeptic admits that 1% or 2% are competent and honest, that makes cold fusion real. There are very roughly 3,000 to 4,000 authors of the positive papers at LENR-CANR. So 1% would be ~40 researchers in ~10 institutions. Most researchers worked ~10 years. (Most are now retired or dead.) So that would be 10 or more independent replications repeated dozens of times. I have never heard of anyone publishing a claim that only one cell in run produced heat, or tritium, or transmutations. Bockris used to run 100 cells at at time.

Anyway, in normal science, that many replications would be considered conclusive proof that an effect is real. Some people want to see 3 or 4 replications, others hold out for 10. But dozens of repeated experiments at 10 labs would surely meet anyone's standard of proof. I guess this is why some skeptics are so adamant. Their claim must be airtight or it fails. Cold fusion has been replicated hundreds if not thousands of times. Of course most skeptics are unaware of this. They think there were only a dozen experiments. But take a skeptic who is vaguely aware of the facts -- one who has glanced at the list of papers at LENR-CANR, and shivered inwardly. He has to force himself to believe that every single one of these tests was a mistake, or fraud. It must a terrible mental burden, forcing yourself to believe such crazy ideas, in violation of all your professional training and common sense.

That is why so many skeptics suffer from cognitive dissonance. They shout to drown out their own inner doubts. They insist that I have distorted their views in this article, when in fact I have reproduced their views faithfully and completely, with verbatim quotes from the best sources available. If a skeptic were to write what Huizenga wrote, 'we know a priori all excess heat results are wrong,' his fellow skeptics would clap him on the back and say 'right on bro, Amen to that.' When I quote Huizenga, and source it, and compare that to Schwinger's rebuttal, they become hysterical and they accuse me of "POV violations" (expressing a point of view). One of them came in and immediately erased all of the rebuttals. He wanted to see skeptical claims in isolation, and he had no sense that they represent a "point of view" (POV). But when they were paired with the CF researchers point of view, he felt it was an abomination.

294) A 1995 overview of the field by Richard Oriani

Ludwik Kowalski; 4/20/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Looking for something else I found an interesting reference to a 1995 overview of the cold fusion controversy. It is a document worth preserving. The overview was presented orally in an address by Richard Oriani to alumni of the Institute of Technology at the University of Minnesota. I worked with Dr. Oriani about one year ago and know how strongly he is motivated to solve the mystery of cold fusion. Richard's background in physical chemistry, metallurgy and material science made him .well prepared to study cold fusion as soon as it was announced. What I am posting below was taken from an e-mail message of <apatula@ub.d.umn.edu> posted on 3/2/1995. The author tells us that Oriani's address was printed in the University of Minnesota's Office of Technology "Research Review," Vol. 24, No. *. February 1995, pages 1, 4-5.

Cold fusion, Richard Oriani told an audience of Institute of Technology alumni, "is certainly worthy of study and funding."

There are good reasons for skepticism, he acknowledged, but there are also good reasons for genuine interest. "Here is some new kind of nuclear physics, and it is too late to heap ridicule on it," he said.

Oriani, professor emeritus in the University's Department of Chemical Engineering and Materials Science, spoke at a December 7 seminar sponsored by the IT Alumni Society. He wished to give his audience "an appreciation of where cold fusion research is after these five years," he said. "People have made a lot of headway."

Oriani framed his presentation with comments on the reputation and abuse of cold fusion, but he devoted most of his time to reviewing two sets of data from the scientific literature: first, "credible experiments" by twelve groups of researchers, including Oriani's own group, who have measured energy production from palladium and deuterium at relatively low temperatures; second, reports from ten groups who have measured tritium, helium, neutrons and charged particles released from combinations of deuterium with palladium or titanium. Throughout his review, Oriani emphasized the lengths the experimenters went to avoid contamination of samples and error in instruments.

When nuclear reactions release energy, Oriani's explanation of the data began, it is because some part of the mass involved is converted to energy. For example, in one of the reactions theoretically associated with cold fusion, an atom of deuterium combines with an atom of tritium to yield helium, a free neutron, a decrease in mass of 0.0188 atomic mass units (amu), and energy at the rate of 1.49 x 10 raised to the -10 joules per amu (equivalent to 8.97 x 10 raised to the 13 joules per mole).

In the five most accurate energy- measurement experiments, the energy output ranged from 106 percent to 170 percent of the energy put into a palladium- deuterium system. For two groups of experimenters, there was a net gain of energy every time they tried the experiment. Oriani's group produced a net gain in two attempts, but thirty subsequent attempts produced no energy. The inconsistent results, said Oriani, seem to depend on the sample of palladium. His third success came after the thirty
failures when he obtained a new sample of palladium from a palladium was obtained from Texas A&M University. Other groups have measured, in three less accurate experiments, energy production ranging from 5 to 15 times the

energy input.

Oriani's second set of reports dealt with observed effects that could only result from nuclear reactions. For example: Fritz Will et. al., electrolyzed heavy water with cathodes made of palladium from two different suppliers. (Heavy water is D (subscript) 2 O, i.e. water containing deuterium rather than common hydrogen. Will was director of the Utah Cold Fusion Institute). One type of palladium yielded no tritium. The other type yielded tritium at 50 times the background level, in four trials out of four. From that second type of palladium, 140 samples not subjected to electrolysis were found to contain no tritium.

Melvin Miles and Benjamin Bush, using palladium and heavy water, produced helium in concentrations ranging from 5.4 parts per million to 9.7 ppm. The background concentration of helium in air is 5.2 ppm. George and Stringham, using sound to cavitate heavy water on palladium foil, produced helium at 10 times background levels in ten trials out of ten. Y. R. Kucherov, et. al., by means of "glow discharge" with a palladium electrode in low- pressure deuterium gas, produced helium at 4 to 100 times background levels and counted 10 raised to the 7 neutrons per second.

Skepticism and ridicule of cold fusion began in 1989, Oriani remembered, when Stanley Pons and Martin Fleischmann announced their discovery through publicity rather than peer review. "They described their work so poorly it seems they wanted to keep it obscure," said Oriani. His own interest in cold fusion was sparked shortly after that, by the work of Steven Jones at Brigham Young University.

Since the Pons and Fleischmann debacle, cold fusion experiments have not been adequately published, Oriani argued, because the journals Science and Nature have been "caustic and abusive" toward the work. When Oriani tried to publish his own experiments, he said, the two journals' replies were to the effect of "We already know cold fusion doesn't work, and you don't understand your results. We're not going to publish them." Oriani's reply: "Many things are published without full understanding, and that's the way it should be."

Oriani then published in the December 1990 issue of Fusion Technology (Oriani, John C. Nelson, Sung-Kyu Lee, and J. H. Broadhurst, "Calorimetric Measurements of Excess Power Output During the Cathodic Charging of Deuterium into Palladium," volume 18, pp. 652- 658). Fusion Technology and the Journal of Electroanalytical Chemistry and Interfacial Electrochemistry, where Pons and Fleischmann first published, are the only two journals still publishing such work, said Oriani.

"I want you to understand my attitude," said Oriani. "A new idea should expect to fight its way to recognition. But in this particular case the fight has been particularly hindered by ridicule. Cold fusioneers have been accused to incompetence, self-delusion, and pathological science. Bockris at Texas A&M was accused to fraud by Gary Taubes in Science [vol. 248 (1990), pp. 1299-1304], of doping his experiment with tritium. That certainly was not the case."

Among sound reasons for skepticism regarding cold fusion, Oriani acknowledged several:

One, "the results are not yet [consistently] reproducible, and we don't know why," he said.

Two, no one has satisfactorily explained what is taking place. "There are as many theories as theorists," said Oriani.

Three, classical physics says the nuclear reaction supposedly taking place can only take place under tremendous heat and pressure, like inside the Sun.

Four, "Cold fusion has attracted a lot of crackpots and mystics," said Oriani. "You have no idea the letters I receive from people who know cold fusion works because the spirit has told them."

It may not be odd, then, that cold fusion research has been difficult to publish or fund. Small federal funding has come from only one agency, the Office of Naval Research, said Oriani. A half-dozen other U. S. groups are working "on a shoestring." The University of Minnesota originally funded Oriani's experiments. They are now "self-funded," he says. In addition, the U. S. Patent Office rejects all applications that mention cold fusion.

Nonetheless, said Oriani, there are pockets of rich funding for cold fusion: SRI International (formerly the Stanford Research Institute) has $2 million a year from the Electric Power Research Institute (EPRI), Japanese interests have equipped a lab in Southern France for Pons and Fleischmann, and significant work is being done in several labs in Japan. "The Japanese are really going after this," said Oriani. "The U. S. is getting behind the 8-ball." A U. S. corporation is, however, buying every cold-fusion-related patent application it can get its hands on, he added.

And the reason EPRI and the Japanese are investing in cold fusion? "If cold fusion is real," said Oriani, "it's an inexpensive source of energy."

295) Chiropractors had to fight for recognition

Ludwik Kowalski; 4/22/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

The situation in the CMNS area made me think about chiropractors. These are people trained to deal with musculoskeletal problems. Not long time ago they were denounced by our medical establishment as incompetent intruders. Browsing the Internet I found an interesting short web site

http://www.chiropractic.ie/history.html

devoted to history of that field. At the web site of Dr. Furr I found that the "profession has long been and continues to be ridiculed for advocating the broader clinical utility of manipulative procedures, for example, for patients with cancer, diseases of the viscera, cardiovascular disorders and psychiatric conditions." In other words, chiropractors were accused -- usually by medical boards in different states -- for something the practitioners did not do, or at least were not supposed to do. The field was criticized not on the basis of practical successes but on the basis of ad hoc theories. The founder of chiropractic, D. D. Palmer, believed that his hands had magnetic effect on patients. Claims of "magnetic healing" are still being promoted by business-oriented organizations but this is not considered, as far as I know, to be a theory explaining successful attempts to remediate certain disorders.

Instead of addressing the issues of validity of procedures the establishment fought the emerging discipline by administrative procedures, most often in the form of legal accusations of practicing medicine without a license. And here is another quote, extracted from:

http://www.worldchiropracticalliance.org/consumer/history.htm

"At first, even though it proved to be a successful way of healing the body, chiropractic adjustments were not readily accepted. Years after Harvey Lillard's hearing was restored, the news media delighted in vilifying the pioneer chiropractor, whom they labeled a "charlatan" and a 'crank on magnetism.'

The medical community, afraid of his success and discouraged by its own failure to heal diseases, joined the crusade and wrote letters to the editors of local papers, openly criticizing his methods and accusing him of practicing medicine without a license." That was about 110 years ago. Today the field is recognized as legitimate, with degrees granted by accredited institutions, but some physicians are still antagonistic. How much of this is based on evidence against the effectiveness of chiropractic procedures and how much on economic competition for patients?

296) About the origin of Mizuno-type excess heat

Ludwik Kowalski; 4/25/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

My personal participation in high voltage electrolysis experiments (Mizuno type) has been described in several units, most recently in the unit #271. The goal of the Colorado-2 experiment was to check the excess heat claim made by Fauvarque et al. Reality of excess heat, as defined in Paris-1 experiments (COP>1), has been confirmed in our Colorado2 experiments. But what is the origin of that heat? Is it true that it cannot possibly be attributed to well known chemical reactions? Most people believe that chemical origin of excess heat, in Mizuno-type experiments has been ruled out by chemists. But I have not seen this issue being discussed. That is why I want to review earlier publications dealing with plasma electrolysis.

A brief description of the Mizuno type experiment was made by Eugene Mallove (1). I suppose that Jean Louis Naudin, who replicated many Mizuno-type experiments (2), was inspired by (1). Mallove would certainly refer to Naudin's experiments if they were performed earlier. I am not a chemist but I would not be surprised to learn that a large number of chemical reactions takes place during plasma electrolysis in a Mizuno-type cell. Some of these reactions are likely to be exothermic. What kind of evidence do we have that the unaccounted-for heat is not due to these reactions?

That possibility is not even mentioned in (1) and in (2). By naming his cells "cold fusion reactors (CFR)," Naudin implies that the unaccounted heat had nuclear origin. Mallove also made that assumption. Referring to (3) he writes: "Ohmori and Mizuno found major evidence for transmutation of elements and volcanic ejection of metals from the tungsten surface -- these SEM photos were reproduced in their article. They find Hg, Os, Kr, Zn, Cu, Ni, Fe, Cr, Si, and Mg -- with anomalous isotopic content." Yes, that was a good indication that some nuclear processes take place during plasma electrolysis. A detailed description can also be found in Mizuno's book (4).

But, as far as I know, neither Mizuno, nor anyone else, demonstrated a quantitative relation between the excess heat generated and number of nuclear reactions taking place in the cell. Suppose the excess heat is generated at the rate of 50 W. This translates into $3.12*10^{14}$ MeV per second. Assuming that, on the average, a nuclear reaction generates 10 MeV of energy one would expect $3.12*10^{13}$ reactions per second. A typical Mizuno-type experiment lasts about 600 seconds. During that time the number of reactions would be close to $2*10^{16}$. (or more if less than 10 MeV per reaction is released). I suppose that detecting such amounts of reaction products, even if they were stable, would be an easy task for a good analytical chemist. No comparable amounts of reaction products were reported by those who experimented with Mizuno-type cells.

The list of references in (3) points to a paper of R.M. Shaubach and N.J. Gernert (5). The authors of that paper reported very high coefficient of performance (COP=8). Their excess heat was generated at the rate of 41 W. But the number of nuclear reaction products was found to be negligible. On that basis the authors rejected the idea of nuclear origin of excess heat. They believed that new kinds of chemical reactions -- involving hydrinos -- are responsible for excess heat. The experiment described in (5) did not involve electrolysis. I am mentioning it because it was mentioning in (2). The paper attempted to explain excess heat without nuclear reactions. But reality of hydrinos is even more controversial than reality of cold nuclear transmutation.

Another reference in (3) is the paper of P.M. Kanarev and T. Mizuno (6). The plasmaelectrolysis experiment of Kanarev was performed at 220 V and the current was between 0.5 and 2 A. The experimentally measured COPs, up to 1.5, were said to be "less than the results of the calculations originating from the existing cold fusion theories [6]." The author of the theory, by the way, is Kanarev himself. That theory is far from being clear to me, probably due to my insufficient background. The experimental setup in the Figure 1 is also very confusing; I would prefer a simple drawing focusing on the principle of operation and not a patent illustration with unexplained labels.

The authors claim that excess heat, generated at the rates of tens of watts, was due to cold fusion. My first impression was that Tables 3 and 4 will show how excess heat is correlated with the number of reactions products. But that turned out to be an illusion. The percentages shown in the tables (for example, 1.1% for Al) refer to surfaces; what is needed is the total number of atoms produced in the cell. The total number of atoms of the surface of the cathode is not specified and this prevents one from turning percentages into numbers of atoms.

Added on 4/28/06:
Unable to find what I wanted (justification of nuclear origin of excess heat in Mizuno-type experiments) I turned to (3); Mallove and Naudin were presumably inspired by that paper. In the introduction Ohmori and Mizuno wrote: "To our surprise, we observed the strong excess energy evolution to such an extent that the electrode became incandescent . . . " The COP, in this seminal experiment, was reported as 2.6 while excess energy was generated at the rate of 183 W. Tungsten was chosen as a cathode because "in order to withdraw greater nuclear energy" one needs a material whose binding energy per nucleon is low. Seven existing cold-nuclear-transmutation reports were listed as motivation for the first Mizuno-type experiment. Two electrolytes were used -- Na_2SO_4 (0.5M) and K_2CO_3 (also 0.5M).

Referring to high amount of excess energy, and to products of nuclear transmutation -- such as Pb, Fe, N, Cr, and C -- the authors conclude that nuclear reactions taking place in tungsten are likely to be responsible for its incandescent temperatures. But this is not very convincing. A claim "nuclear reactions occurred during plasma electrolysis" should not be confused with a stronger claim "excess heat in plasma electrolysis is due to nuclear reactions." The tentative conclusion of Ohmori and Mizuno would be much more convincing if the amount of nuclear reaction products were shown to be consistent, at least within one or two orders of magnitude, with the amount of excess heat.

Added on 4/29/06:
Trying to find more convincing evidence I turned to another paper of Mizuno et al. (7). In that paper the authors confirm production of new elements and generation of excess heat. The issue of non-nuclear origin of excess heat is addressed but a conclusion is reached that chemical reactions cannot possibly be responsible for the measured amount of excess heat. Here is the main line of reasoning:

1) It is well known that 380 kJ of heat is released when one mole (183.85 grams) of W is consumed to produce H_2WO_4.

2) In reality only 0.1 grams of tungsten was lost during a test in which excess heat was measured. That, could produce 0.207 kJ of heat. The amount of excess heat measured, 54.4 kJ, was found to be considerably larger. Thus no more that 0.4% of excess heat measured could be due to chemical consumption of tungsten.

3) This 0.4% fraction is actually an exaggeration because the 0.1 grams of tungsten lost from the cathode was found at the bottom of the cell in the form of pure metallic powder. In other words, tungsten did not react with oxygen, it was simply removed "by hydrogen corrosion as well as heat damage."

4) Another chemical reaction taking place in the cell, during plasma electrolysis, is "the decomposition of the carbonate in a water solution." That reaction is said to be endothermic; it removes 274 kJ of heat per mole of K_2CO_3.

I do not understand the last comment. The 0.2M of K_2CO_3 is dissolved in water when the electrolyte is prepared, usually hours or days before the experiment. At the time of an experiment the potassium exists in the form of ions, not in the form of K_2CO_3. How can decomposition of K_2CO_3 take place during the experiment? But the argument against the "tungsten is a chemical fuel" idea makes sense to me. What is missing, however, is a statement that no other

exothermic reactions can take place during an experiment. Should I assume that formation of $H_2 WO_4$ from W is this the only possible exothermic reaction?

It is important to keep in mind excess heat per si was not the main part of the CMNS controversy when Fleicshmann and Pont published their findings. What was violently opposed was the hypothesis that excess heat has nuclear origin. I recall reading that, according to F&P, and others who investigated the phenomenon, the chemical origin of excess heat was ruled out. That was accomplished by considering all exothermic reactions that were possible in the cell. The combined heat released by these reactions was shown to be negligible in comparison with the excess heat measures. That is how the idea of nuclear origin was justified. A similar statement is needed about plasma electrolysis. What is true for the F&P effect is not necessarily true for the M&O effect.

Personally, I do not exclude a possibility that excess heat we measured might be due to chemical processes. But that is a matter of attitude, not the matter of conviction based on knowledge of chemistry. Hopefully, recognized authorities in the field of electrochemistry will reassured people like me that the Mizuno type excess heat cannot be attributed to known chemical reactions. That will be a very significant step forward, with respect to what was stated in (7). But the issue will not be resolved until excess heat is shown to be compatible with the number of reaction products, at least to within two orders of magnitude. Such compatibility has been demonstrated for the F&P effect (accumulation of excess heat at the rate close to 23 MeV per ^{4}He atom). Will it also be demonstrated for the F&O effect? I hope so.

taken from <http://jlnlabs.imars.com/cfr/index.htm>

The home page is <http://www.hydrino.org/> which is the hydrino study group (Mills). The reports page contains some reproductions of Mills done by others.

[You wrote: "But reality of hydrinos is even more controversial than reality of cold nuclear transmutation." If by 'hydrino' you mean "hydrogen with tighter orbitals", the statement is correct. However, the empirical 'odd / new hydrogen' is available for viewing in many of Mills RoD ionic vapor experiments anytime you care to run one for yourself.

297) From recent messages on the CMNS list

Ludwik Kowalski; 5/7/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) What is the current situation with Colorado2 results?
1) Experimental results (COP=1.24, st.dev. = 0.13), described in the unit #271, at my CMNS web site, should be summarized and published. As I wrote before, I will start writing the draft as soon as Pierre Clauzon sends me conclusions from Gerard's analysis, and the appendix written by their reputable chemist. I expect that Gerard's investigation will determine the percentage of tiny droplets in the escaping mixture of vapor and liquid. Presumably that percentage will be much smaller that 24% needed to create an illusion of COP=1.24. Richard also promised to investigate the possibility of that kind of illusion. The appendix will presumably rule out a possibility that excess heat is due to well known chemical reactions.

While waiting for these two things I started worrying that the COP>1 might be an illusion due to the temperature dependence of L, latent heat of evaporation, as shown in:

http://www.spiraxsarco.com/learn/modules/2_15_01.asp

But this turned out to be a false alarm. The latent heat of evaporation is nothing else but the difference between the enthalpy of one kilogram of water in our highest state, escaping vapor, and our lower state, liquid water at 100 C. In other words,

L=H(v)-H(l).

Enthalpy, H, is a state function. It means that L does not depend on what might happen to a unit mass of water between the initial and final states. Inspired by a contribution of Michel Jullian (spreadsheet for thermochemical calculations) I wrote:

"Mizuno, Naudin and Iorio did not comment on what I wrote about the possible illusion of excess heat resulting from the temperature dependence of L. Why are they not responding? Does it mean they agree about the possibility of illusion or that they agree with what Michel J. and John N. wrote about the issue? For some reason messages from Michel and John were not clear to me. But this morning someone explained their position to me. This convinced me that the temperature dependence of the enthalpy of evaporation, L, cannot possibly be the cause of an illusion, at least not in the way that I was thinking.

The argument goes like this. Enthalpy is a state parameter. Suppose that one gram of water goes from state A to state Z in a sequence of steps,

A --> B --> C --> D --> E --> . . . --> Z

A is when water is at 100 C
B is when water is at 300 C (for example, very close to the cathode)
C is when that water becomes vapor
D is when that vapor changes into XXX (for example, by a sequence of nuclear reactions)

E is when XXX turns into YYY, etc. etc.
. . . .
Z is when the LSE (last something else) becomes one gram of steam escaping from the Mizuno-type cell.

The amount of electric energy, Q, needed to transform 1 gram of water from A to Z does not depend on what happened between A and Z, it must be equal to (Hz-Ha), where Hz and Ha are enthalpies in the states Z and A. ..... In other words, poorly understood intermediate processes (what happens during plasma electrolysis) are totally irrelevant in the contest of excess heat, as in Paris1 and Colorado2 experiments. The COP>1 can be an illusion associated with tiny droplets (mistakenly assumed to be vapor), but that has nothing to do with the temperature dependence of L."

Richard Slaughter is experimenting with a new cell; it is the beginning of his Colorador3 experiment. Instead of using an open cell, as in Paris1 and Colorado2 setups, his new cell is nearly totally closed. A small hole in the lid prevents accumulation of potentially explosive hydrogen and oxygen. The pressure in the cell is very close to one atmosphere. Only a small amount of vapor escapes into the air, most vapor condenses inside the cell. The mass of the escaping vapor is measured, as in Colorado2 experiment. With this approach the COP is calculated as:

COP = (Q1+Q2+Q3) / E

where E is the electric energy received by the cell during an experiment while (Q1+Q2+Q3) is the thermal energy removed from the cell. As before, Q1 stands for the energy needed to produce the escaping steam while Q2 stands for the energy lost by conduction, convection and radiation. The ways of measuring E, Q1 and Q2 were described in unit #271. And what is Q3? It is thermal energy removed from the cell by a flow calorimeter. The cell is designed to minimize Q1 and Q2. But these two quantities are measured, as in Colorado2 experiments.

The flow calorimeter, also acting as a condenser, is the major addition. It is a flat spiral copper tube below the lid (inside the cell). Icy water enters the tube at one end and comes out at the other end, at a slightly elevated temperature. The Q3, for a known rate of flow, is calculated from the measured change in temperature. Most of the vapor created during the experiment condenses on the spiral tube. Suppose that 100 grams of liquid water is turned into vapor but only 10 grams of that vapor escapes from the cell. The remaining 90% condenses on the cold tube and drops down into the electrolyte. Condensation is the heat-releasing process; the latent heat of condensation is numerically equal to latent heat of evaporation. That is why Q3 becomes the dominant component of the thermal energy output.

According to private messages from Richard, preliminary results confirm previous findings -- the COPs are always between 1.1 and 1.3. The new approach is much less dependent on tiny droplets because the mass lost during an experiment is very small. The nearly-closed-cell approach, as in preliminary Colorado3 experiments of Richard, seems to be a very good way of validating reality of COP>1. The totally-closed-cell approach seems to be more complicated (I am thinking about the heated recombiner) and quite dangerous."

The message shown below (blue font) was posted on the restricted CMNS list the day before yesterday. But nobody responded, so far. For some reason most of the recent messages posted on the list do not discuss science. The authors prefer to share historical information, criticize pathological skeptics and discuss social aspects related to negative attitude of scientific establishment toward our field. My expectation was that the list will be used, mostly, to share information about ongoing experiments and to discuss scientific aspects of ongoing investigations. But that is not what I observe. Why is it so?

I did not plan to ask this question. It evolved from my private correspondence with Richard. He shared my initial concern about L and I decided to publicize it on the list. My expectation was that some scientifically-oriented people will comment on what I wrote below. The absence of replies forced me to ask the "why is it so" question. If somebody asked me to comment of a scientific topic, and if I had something to contribute, for example, to criticize or to agree with an idea or proposal, I would do so at once. That is why I expected to hear from Mizuno and Naudin. Why didn't they answer, one way or another?

[I am removing that message because it was wrong. Was this obvious to Mizuno and Naudin? If it was then why didn't they correct me?]

2) What is pure research for?
An interesting message appeared on the list, several hours after the above was posted. Referring to an article in The New York Times (4/27/06), one subscriber asked about benefits society received from research in the area of high energy physics. My reply was as follows:

"Suppose a politician asked Michael Faraday about usefulness of electromagnetic induction that he was discovering. The answer would probably be "Someday you can tax it." I know that many are familiar with this phrase; it is often attributed to Faraday. The episode presumably took place around 1830s. Faraday was probably motivated by desire to discover laws of nature, not by vision of transformers and generators supporting the way of life of future generations. I do not think it was possible to anticipate usefulness of electromagnetic induction when it was discovered, nearly simultaneously, by Faraday and by Henry. That is what I used to tell students each year. How can I resist to say it again?

I do not know what fraction of our GNP (gross natural product) should be allocated to pure research. The National Academy of Sciences should answer this question. Yes, I know, that this is a political and economic issue, not a scientific issue. The primary purpose of this list was to discuss CMNS topics. Yes, I know, everything is interconnected. Yes, I know that CMNS was nearly killed by politically-oriented people. But what I would like to see more often are message describing work in progress, and issues generated by ongoing projects."

3) Added on 5/8/06:
Two messages I posted during the weekend did not generate any replies. Does it mean that people agree with me about a possibility of illusive COP>1? I do not think that it means this. It probably means that people do not care. They prefer to express opinion on topics which belong to sociology and history of science rather than on scientific topics per sei. About ten such messages appeared in the last two days. Here is an interesting quote from one of them. Responding to what others wrote Jed Rothwell observed:

". . . I think that on balance, at least with regard to revolutionary discoveries such as cold fusion, if we must choose between anarchy and excessive control, anarchy is better. Perhaps that is not the case with more conventional or incremental breakthroughs.

Consider this. If people such as Mizuno and Miles had not been fully tenured, and a Fellow of the Institute in Miles' case, they would not have been allowed to do cold fusion research. They had the freedom to defy the norms and do "forbidden" research. They paid a high price for their actions, by the way. The people in charge would have stopped them if they could have, just as they tried to stop Bockris and others.

Anarchy also works better in free market capitalism. In fact, I doubt anything else can work. If large companies such as IBM were given any control over one-man startups, such as Microsoft in 1975, progress would come to a halt. Gates succeeded because no one had any right to tell him what to do. If IBM or any other established company had been aware of his activities, or if they had been allowed to interfere, we would still be using mainframe operating systems..... "

4) Added on 5/9/06:
Responding to a message posted last night I wrote: "I think that X, who is new to this list, is correct. We need more sharing about what we do, and more messages focusing on science, as opposed to sociology of science. Why our best electrochemists, mentioned by Jed -- McKubre, Storms, Miles and Oriani -- did not share their ideas about the GDPE (glow discharge plasma electrolysis) on this forum? Mizuno-type cells of Naudin, Favaurque, Iorio and Slaughter yielded reproducible results. But can we be sure are these results demonstrated reality of excess heat? What should be done to make these results more convincing, as far as excess heat is concerned? Only highly qualified chemists can help us. Why are they consistently silent on that topic? Yes, I am also a newcomer; perhaps there were debates about this in the past and people do not want to repeat themselves. Please summarize past debates for newcomers. Or maybe our experts feel that criticizing each other is not appropriate when we are surrounded by enemies. Something seems to be wrong among us. But I do not know what it is. Yes, this message is also about sociology rather than about science. I am sorry about this.

5) Post Scriptum
I was ready to press the SEND button what this message from McKubre arrived. It was a reply to Jed's message:

On May 8, 2006, at 2:44 PM, Jed Rothwell wrote:

It is a safe bet that the present experts in cold fusion, such as McKubre and Storms, are the people most likely to find the answer. Shockley and his coworkers had the best chance of developing practical transistors in 1948. But you can never be *certain* of that. Someone might come out of left field with the theory or procedure that makes no sense to McKubre -- something that seems counterintuitive, or downright crazy. And yet that oddball person might be right. Such things have happened many times in history.

Mike McKubre wrote:
Thanks for the plug Jed, but the answer to our hidden variable(s) almost has to come out of left field; we have covered right field and it isn't there. I do think it is a bad strategy and very much counter productive to attempt to get responses on the CMNS forum by verbal bullying or induction of guilt. In such a forum you need to accept any wisdom shared as a gift, but you should not attempt or expect to compel a response. I don't speak for Dardik or the Energetics folks, or Mizuno or Bockris or any of the others mentioned below, but I know something of their character. I can guarantee you that if these folk believed the CMNS forum to be the most important way they could advance their knowledge - and the world's knowledge - of condensed matter nuclear effects, then you would have their full and active participation.

That reminded me of another group of highly qualified experts. Why are they silent on this list? I know that Darik and his colleagues are reasonably fluent in English. And why don't we hear from Mizuno himself, or from John Bockris? Or from Pamela and Stan? Or from John Dash and other material scientists? Yes, "something seems to be wrong among us."

6) Another 5/9/06 addition:
Here is how Jed Rothwell answered my question
"[McKubre, Storms, Miles and Oriani do not comment] because they have nothing to say about it. That's what they tell me. They say they have not done the experiment themselves, so they cannot comment. That's the mark of a good electrochemist: he does not speculate about a remarkable experiment that he has not done." Will each of them answer my question in that way? That remains to be seen.

Replying to Jed I wrote: ". . . I would like to know what Mizuno would say to someone suspecting that the COP=1.24 (st.dev.=0.13), as measured in Colorado2 experiment, might possibly be an illusion due to the temperature dependence of L. You communicate with Mizuno; please ask him this question. Mizuno probably saw my two recent messages about L. But to make things easy I am going to paste them below. Thanks in advance. And give him my regards. ....."

Added on 5/10/06:
Last night Rothwell wrote: "I have been meaning to comment on this for a long time. Whenever there is an effusion of creative effort, a large portion of the work is lousy. That is the nature of things. People make mistakes before they get things right. .....It takes a while to separate the wheat from the chaff." That was a comment about absence of mutual criticism, etc. Someone asked about thousands of papers
in the www.lenr-canr.org archive. What fraction of them contain invalid claims? Will this good question be answered? I do not think so. We are surrounded be enemies and some people might think that mutual criticism will be perceived as weakness. In my opinion, mutual criticism is a sign of strength. It lowers the probability of chaff being mixed with wheat. And here is how the question was answered by Jed Rothwell: "Ooofff ..... That's a delicate question for me. Naturally people should judge which papers are likely to be valid, and which are not. Storms and I listed some of the ones we find particularly impressive in the Special Collections. I think some of the other papers are marginal, sloppy, or farfetched.

However, I would not feel comfortable listing the ones I dislike. That isn't fair to the authors. Of course I am just the librarian. Not an editor or an arbiter! If anything, I resemble the guy who distributes push-pins and tape during a conference poster session. However, a librarian does have some influence over readers. He puts out books in the

"featured" shelf. He selects new books to be purchased. People ask librarians for recommendations, and readers do ask me for papers covering specific topics. Inasmuch as I have any influence I am determined to remain as neutral as I can. I would not want to prejudice readers against an unknown author who happens to have a good idea that I do not appreciate. . . . We have only turned down a handful of papers, mainly from perpetual motion machine inventors . . . This is a library, not a journal. We never turn down papers we disagree with. ..... "

Here is how Edmund Storms explained reasons for not being enthusiastic about Mizuno-type experiments. He wrote: "You ask why I don't share my ideas about the GDPE experiments. Here are several reasons:

a). I'm busy with my own studies which are hard enough to understand without adding an effort to understand various attempts at replication. Some very unexpected processes are operating that are hard to understand even when a person has access to all of the information, which is not the case when helping someone else.

b) The GDPE method, I believe, is not a good method to use to study LENR or to prove that the effect is real. It is too complex to replicate and interpret.

c) I have commented and made suggestions which were not accepted. It takes too much time to show why the suggestions are worth considering for the effort to be useful to me.

d) No additional replication of the effect will be useful to change minds unless the experiment involves measuring radiation and nuclear products along with heat. In addition, the relationship between the amount and nature of the nuclear products, and heat must fit a plausible model. Anything less than that will be just a good science experiment done for personal amusement and education. The field has gone beyond
needing just another replication.

e) Enough information is available in the literature to start such a project. Additional progress is only made by learning from mistakes and being forced to confront results that don't make any sense. My help would not advance this necessary process."

That is interesting. Would I get involved in GDPE experiments if I knew that Ed and other leading CMNS researchers think that results are too difficult to interpret? Probably not. My impression was that a large excess heat from a Mizuno-type cell is
easier to interpret than many excess heat experiments.

7) L for heavy water:
Referring to L (latent heat of evaporation) another leading CMNS researcher, Mel Miles, wrote that "it would be better to call L the ENTHALPY of vaporization. Nevertheless, the term HEAT is often used in textbooks." In another message Mel wrote:

"The symbol L represents the Heat of Vaporization-Often expressed as "Delta H(vap)". It is a state function like any other "Delta H" term. Similar to most thermodynamic quantities, it shows a temperature dependence. In my work for D2O ,I always used the following that I found in the published literature:

L =85263.9-173.429*T+0.2586*T*T-0.000191913*T*T*T-1805569/T

where T is in Kelvin and L is in J/mol. Thus, at 25.000 C or 298.15 K, L is calculated to be 45401.6 J/mol. The L values for the vaporization of D2O can be readily calculated at any other temperature of interest."

Using this formula for T=373 K (100 C) I got L=41753.6 J/mole. This translates into or 2087.7 J/g. For T=473 K (200 C) the formula gives L=36962.1 J/mole. This translates into 1848.1 J/g. There must be a similar formula for H2O and asked for it, and for a reference. It is easier to calculate L from a formula than from a chart I used before.

8) Appended on 5/11/06:
An interesting observation about the CMNS field was made by an stranger, Mr. V. Godbole (who did study some

physics. Life circumstances forced him to work in other fields but he does study theoretical physics on his own. In a message received yesterday V.G. wrote: "The solution of the Schroedinger equation - these strange counter-intuitive orbitals caught my attention. Does the particle (electron) spread itself into cloudy s-p-d-f-lobes, does it whizz around the nucleus along warped trajectories, how do the overlaps and hybrids come about - all that mystery or magic puzzles me (and many others). The deuteron is a (quasi) boson for distances above 10 raised to -15 m. How does that work out for an occasional slightly-mobile deuteron in a homogenous deuteride substrate? Can we devise a substrate-hamiltonian H that "condenses" deuterons into soliton-like or coherent-wave-like entities that emerge as a beam (surely a non-trivial difficult and challenging task)? . . .

Are the physicists a frightened (self-) terrorizing community? How can there be anyone an "expert" regarding a purely speculative new quasi-phantastic idea? . . . I have read many "successful" routine experiments in the journals which were just a waste of time and money (but meticulously done and exquisitely presented on expensive paper only for getting a trivial doctorate or habilitation). It is disappointing to say the least. Gone is a Julian Schwinger or Richard Feynmann. If a man has titles (Dr., Prof., Director etc.) then he wants to protect his "reputation". That's the end of pioneering physics.

Apparently, Mr. V. Godbole made several attempts to approach professional physicists but failed to gain their support. Not too many physicists are trained to discuss advanced theoretical ideas. They probably do what I do, when facing a topic with which they are not familiar -- they try not to expose their ignorance. It is hard to find a person capable to discuss a specialized problem. I do not think the refusals to get involved always indicate desire to protect one's reputation.

9) Added on 5/13/06:
The CEO (chief Executive Officer) of particular company, who is also a researcher, was criticized recently, on the restricted list for CMNS researchers. One of the issues was a promise, to potential investors, that a 1000 W will be on the market in several months. This is not the first time that a commercial application of CMNS is being promoted as nearly ready. But time passed and nothing happened. People feel that such episodes hurt our already bad reputation.

I do not think GDPE cells (glow discharge plasma electrolysis), also known as Mizuno-type cells are ready for practical applications. I am still waiting for an appendix about the expected heat from possible chemical reactions, the issue of the percentage of droplets mixed with steam remains unresolved. I would not invest a penny into a company that would try to commercialize GDPE cells at this stage of development. Several people responded. One of them wrote:

" There has been numerous posts as to the promise of a kilowatt OU unit from D2Fusion. I was waiting for someone to bring up Patterson's CETI. They had
a Palladium bead cell electrolysis column demonstrating this kilowatt ability already back in 1995 at ICCF-5 and the 1995 PowerGen Conference in Southern California. Eugene Mallove, Jed Rothwell and, I am sure, some members now belonging to this CMNS have witnessed the units. CETI was ready then to entertain interested parties then."
Another contributor wrote: ". . . But CETI seems to have faded out, particularly after the premature death of Jim Patterson's grandson, who was then their President. . . . " Jed Rothwell, wrote: ". . . I recall Patterson told me that this [inability to reproduce] is not true. He said he could make more beads "any time." But he never did make any as far as I know. Who knows what to make of it. It was yet another lost opportunity."

This was long before I discovered, in the summer of 2002, that cold fusion research was going on in several countries. Was it the first warning that one should not jump to commercial applications prematurely? That topic generated a long discussion. Let me end this unit with quotes from Mike McKubre and Jed Rothwell:

Mike wrote: " . . . The cf community has been aware of (in Jed's words) "exaggerations" for some time. We have overlooked them until now as we have been assailed from the outside and have naturally protected family first. Newer members do not have the perspective of seeing who did the work and how work groups were organized. Now that the era of commercial interest has arrived we can and should no longer turn a blind eye."

Jed wrote:

".. . As far as I know, nobody has ever been able to run GDPE cells with a steady output. Not 100 W or even 10 W. The excess power fluctuates wildly and uncontrollably. It seldom exceeds 30% of input. If you could generate 100 W steadily then of course it would be easy to asssemble several cells and generate higher power. However, with all of the cells I know about, if you assembled 10 of them you would end up with power varyingi from moment to moment, with input up to 700 W, and excess output ranging from 0 W to ~10,000 W (an explosion). This would be extremely dangerous. .....I do not think anyone knows how to run GDPE cells for a long time. People here have speculated about various methods, but I do not think these methods would work. ....." Then Jed added: "Jim Reding, the president of Patterson's company, was so upset by what I published about his experiments and business plans that he threatened to sue me. Krivit's expose of IESI was FAR more damning than what he has said about D2Fusion." In the last message Jed ,wrote"

"There is a claim at the D2Fusion website about kilowatt scale devices. It is here:

http://www.d2fusion.com/index.php?option=com_content&task=blogcategory&id=22&Itemid=49

This hyperlink in his message may be difficult to use. Here is the text: 'SUMMARY - D2Fusion Inc., a US company, is now preparing a fast track product development program to build and test solid state fusion energy modules. The first modules will produce a few kilowatts of thermal energy in a compact device comparable to a common household electric space heater. We plan to build and exhaustively test these prototype thermal modules during our first year of operation.'

That is audacious. If they can pull that off, I suppose they must have made a major breakthrough. Nobody I know could pull this off in a year This website is none of my business, and the people at D2Fusion have every right to ignore what I say, but I think they are asking for trouble with statements like this." Somebody asked about what to expect from a company that succeeded to make a big discovery but is still working on practical details. Once again, Jed was the first to reply and I am quoting him again.

"I am *not* dismissing that [possibiity]! Nobody here is dismissing that. We have only said that if they have accomplished this (or something similar), the way they are presenting it on the web looks suspicious. They are putting themselves in a bad light. I also said the accomplishment would be astounding, but: '.....maybe I read the wrong papers. Since I have not read D2Fusion's papers, I cannot judge the situation." [I also wrote:] "That is audacious. If they can pull that off, I suppose they must have made a major breakthrough.' [A also wrote] 'Of course there may be breakthroughs which I have not heard about. .....I interpret the statement at D2Fusion to mean there *has been* such a breakthrough. I hope this is the case.'

They [in the company] seem to be telling the world they stumbled on the clue. That's how I read the web page. It is a bad idea to tell the world that without offering any proof. It makes you look like a perpetual motion machine scam, even if you are actually legitimate. If they wanted to, and they felt it is advisable, they could easily publish loads of convincing proof without revealing any technical secrets. All they have to do is sign up independent experts to test the thing under NDAs, and then publish the technical outcome of the tests (calorimetry) without describing the hardware: "Prof. Smith tested the machine and found it produced 500 MJ with no input power ..... Here is a summary of his report....." Performance can easily be made public without revealing specifics about how that performance is achieved. .....If D2Fusion wishes to keep everything about this strictly secret, including the calorimetry, I think it would be best to say nothing. But apparently they disagree with me. That's okay. It's their website."

Added on 6/6/06:
This is another message from Jed Rothwell. It posted on the list as a reply to a suggestion made by another subscriber. The suggestion was to form a cold fusion party and to change this list into a platform of that party. I do not like this idea; I would unsubscribe if political topics became more important on this list than scientific topics. Jed does not have formal scientific background but his knowledge is some areas is impressive for a self-educated person. Here is his reply to a suggestion to form a "Cold Fusion political party."

It sounds a lot absurd to me. Third parties have often been formed around single-issue groups. They usually give the public the impression they are fanatics. I cannot imagine why we need a conventional political party. We do not need

millions of votes. We need only one vote of confidence from one influential person such as Bill Gates. As Margaret Mead put it: "Never doubt that a small group of thoughtful, committed people can change the world. Indeed, it is the only thing that ever has."

I think history shows how we may succeed -- if we can succeed at all. We must use conventional outreach strategies that have worked for scientists in the past, when they brought about unpopular reforms against entrenched opposition. Scientists pushed through sanitation, pasteurization, air pollution control, dietary reform in the U.S. Deep South to eliminate pellagra, child labor, automobile safety, and countless other science-based, science-led reforms. They fought ruthless opposition by vested interests. Sometimes it took decades. In New York City, the dairy industry prevented effective pasteurization of milk from the 1860s until 1917.

We have the tools to accomplish this task. We have much more to work with than the lonely public health warriors who fought pellagra did. We face a small number of angry physicists at the APS; they faced the Klu Klux Klan! We have many potential supporters; they had to overcome 300-year-old habits and economics that led to malnutrition and vitamin D deficiency then (and obesity today, alas). We have a body of impressive papers; distinguished researchers who could get a modicum of attention if they tried; a large latent group of supporters in the public; and we have been blessed by some of the stupidest opponents in history. Evolution's first great foe, "Soapy Sam" Wilberforce, was a genius compared to Park, Huizenga and Taubes. As Beaudette showed, Huizenga handed us victory on silver platter in his book. Why have we not made better use of this? We should work to appeal to students and young people, and at the other end of the scale, we must break through the wall of opposition to reach one or two influential people who can start the flow of funding.

There are simple rules and time-tested techniques for accomplishing this sort of thing, and cold fusion researchers have violated just about all of them. Instead of showing their results, they have hidden them. Instead of cooperating with one another they have fought over trivial matters. Instead of asking young people and others for support, they have alienated the public. Instead of appealing to hope and idealism, some have pandered to greed and the false promise of "cornering the market." As I said in the book:

"History has been a test of strength between the rapacious, foolish, greedy, shortsighted minority and the sensible majority. I expect the future will be the same. So far, in cold fusion, the fools have won every round, suppressing nearly all research. I have had a ringside seat at this fiasco. No one knows better than I how powerful the fools can be, and how badly the cold fusion researchers have muffed the few opportunities that have come their way. Without public support, researchers will never receive funding, yet they have often scorned opportunities to convince the public of the validity of their work. ....." Cold fusion researchers could do far more to help themselves and their cause. They have enormous latent power to influence society and win friends. Yet I have struggled for years -- begging, pleading, cajoling -- just to get them to send me 500 papers!

Appended on 6/14/06
Technical and scientific topics are occasionally discussed on our CMNS lists but comments on sociological aspects of science represent much more than one half of what is being posted. Let me describe another thread that belongs to the same category.

Two days ago Scott Little posted this message: “Group, I would appreciate some criticism on the following statement describing cold fusion and our work thereon that I have drafted for a paper I am giving at the upcoming AIAA Joint Propulsion Conference entitled, "Null Tests of Breakthrough Energy Claims". (no, I am not particularly proud of that title but that is how our cards have played out thus far). I will be discussing a wide variety of claims that we have tested at Earthtech and I feel that cold fusion should be included.

If possible I would like my statement to be acceptable to both camps; those that believe that cold fusion is real, and those that sneer scornfully at it. The statement comes after I have explained in general how energy claims are tested, including a brief discussion of calorimetry:

‘In March of 1989 Martin Fleischmann and Stanley Pons of the University of Utah announced that they had succeeded in making the D-D fusion reaction occur in an electrochemical cell near room temperature. Compared to the ordinary

conditions required for this reaction, this claim was aptly named “cold fusion”. The announcement of cold fusion generated intense interest as it promised to solve most if not all of our energy problems here on Earth. The fuel is plentiful and the waste products are relatively benign. However, widespread failure to replicate the phenomenon soon resulted in rejection of cold fusion by the mainstream scientific community.

Despite this rejection a number of scientists continue to investigate cold fusion. Hundreds of papers reporting positive results have been published and international conferences are held every couple of years. However, to this day, there exists no cold fusion demonstration experiment. That is because either the cold fusion phenomenon is extremely difficult to reproduce or the phenomenon does not exist. Notwithstanding the significant positive evidence that has been amassed, the latter possibility must remain until cold fusion can be reproduced on demand.

The primary signature of the cold fusion phenomenon is excess heat, which means that the electrochemical cell produces more heat energy than the electrical energy used to stimulate it. Thus calorimetry is necessarily involved in testing cold fusion experiments. In our laboratory we have expended a great deal of effort on the development of calorimeters suitable for cold fusion experiments. Over the years we have had the opportunity to test a relatively small number of cold fusion experiments, some that we constructed ourselves and some that were brought to our laboratory by other investigators who had seen positive signs of excess heat in their own labs. None of these cold fusion experiments have shown any convincing evidence of excess heat in our calorimeters. We cannot say that we have never seen *any* signs of excess heat in our laboratory because all calorimeters drift somewhat and, inevitably, that drift sometimes goes in a positive direction and looks just like a low level of genuine excess heat. When that occurs we strive to check the calorimeter’s calibration as quickly and thoroughly as possible. Usually the drift in calibration is evident and its magnitude matches, and thus explains, the apparent excess heat signal. In a few cases the calibration check did not explain the apparent excess heat signal. But when we returned the cell to the calorimeter after the calibration check, the excess heat signal did not reappear. This tantalizing behavior either means that the cell did produce low levels of excess heat for a while or the calorimeter was simply drifting up and down in unfortunate synchrony with our observations.

To put this drift issue into perspective, the calorimeter in question was designed with an accuracy goal of +/- 0.1% relative. At the typical input power level of 10 watts, that is equivalent to +/- 0.01 watts. One a good day, when freshly calibrated, this accuracy is actually achieved. A month after calibration, the system typically drifts off calibration by about 0.03 watts. The largest apparent excess heat signal we have ever seen that was not subsequently explained by a calibration check was about 0.05 watts, or 0.5% of the 10 watt input power.

Despite our disappointing experiences with cold fusion we feel that the potential importance of this phenomenon warrants further effort. We are actively involved in efforts to observe the excess heat phenomenon.’ Thanks for your consideration, . . .”

What follows shows how some people, reacted to Scott’s statement on cold fusion. The immediate reply from Jed Rothwell was:
”

[You wrote:] Notwithstanding the significant positive evidence that has been amassed, the latter possibility must remain until cold fusion can be reproduced on demand.

That is complete and utter nonsense. First of all, cold fusion has been reproduced on demand hundreds of times, including 100% of all experiments at Mitsubishi for the last 5 or 10 years. Second, even if it were not reproducible, this has no bearing on whether it is real or not. Reproducibility on demand has never been held as relevant to whether an effect is real or not. I can list dozens of discoveries and claims which are either extremely difficult or utterly impossible to reproduce. Examples include: Many of Martin Fleischmann's previous breakthroughs -- extremely difficult.

Cloning. The success rate is less than 1% -- far lower than CF ever was. Making a Pentium processor -- only two companies on earth have sufficient expertise and capital. Thermonuclear bombs -- very difficult and expensive to reproduce, fortunately. The top quark -- could only be done once, in one lab. Earthquakes, supernovas, the creation of life on earth -- can only be observed. Frankly, this assertion reflects appalling ignorance of the scientific method and

the history of science. Many people have said this kind of thing, even in the pages of so-called science magazines and journals, but still, the people who say this are completely wrong and they do not understand the scientific method.

Yesterday, replying to Jed I wrote: "Recent reading about the so-called 'scientific method' made me aware that it is mostly about validations of hypotheses and theories. It does not explicitly deal with validation of experimental facts. Scott's message is about facts, not about explanations. Yes, some experimental facts are difficult to confirm, especially at the beginning. What we need is at least one simple 'reproducible on demand' demo that can be studied in most science labs. ....." But nobody commented on this.

Replying to Scott, Edmund Storms wrote: " Universal reproducibility has no relationship to proving an event to be real. If a sufficient number of people see the same event under the same circumstances, the event is real even though the event can not be produced every time. Too many examples exist to make this concept even a debatable issue. The issue is not proving reality, but having sufficient control over experimental conditions to allow the event to be studied. LENR has been observed so often that the reality of the phenomena has been demonstrated. However, insufficient understanding is available to make it work very often. This has nothing to do with proving the phenomenon is real."

As I wrote in another item, CMNS (a more recent name for what used to be known as LENR or Cold Fusion) is not yet science; it is still protoscience. A protoscience will be recognized as science when at least one of its simple experiments becomes "reproducible on demand" in the hands of experts. Ed. is correct that "sufficient control over experimental conditions" is a prerequisite for reproducibility on demand.

Steven Krivit wrote: "Scott, you've asked a question which can't be truly answered. What you wrote is your view, and your experience. And that is the truth for you. Some of the people on this list have significantly different backgrounds, experience, skill and understanding than you relative to CMNS. Consequently, you asking for their opinions on your thoughts and views is a non sequitur.

I would only say this - and honestly I only read it once and I don't have it anymore so bear with me - I think you underrepresent the possible conditions that a) some researchers who have not submitted to your evaluative process may have more significant results and b) the cmns effects could just very well be extremely difficult to create and observe and if so, may only appear clearly in the primary researcher's lab as a result of these complexities.

I would say that you might be better off in the long run emphasizing that it is still to early to tell. If you are going to bother to publish a paper with 'negative results' and you are not intending to appear hostile, you may want to express some of these possible conditions I just stated. .....I'd say that too many people have wasted their time trying 'prove' that "cold fusion" is real and too many people have wasted other's time trying to demand proof, which they often vaguely refer to as extraordinary evidence. "Proof" for one person is not for another. 'Proof' is a personal thing."

Replying to the above comments, Scott Little wrote: "After consideration of the few responses to my statement, I have decided to revise the objectionable paragraph in an attempt to reduce the tendency of my words to appear as complete and utter nonsense to the reader. The new version says:

'Despite this rejection a number of scientists continue to investigate cold fusion. Hundreds of papers reporting positive results have been published and international conferences are held every couple of years. However, to this day, there exists no cold fusion demonstration experiment. That is because the cold fusion phenomenon is extremely difficult to reproduce. There is no experimental recipe that will yield positive excess heat results even 50% of the time. This situation greatly hampers cold fusion research and, in the eyes of some, supports the possibility that the cold fusion phenomenon does not actually exist.' Is this better?"

Steven Krivit wrote: "Alright Scott, Here you go. I'm gonna lay into you - nothing personal, okay, but you've asked for critique. You're not an expert in cold fusion, you're not a journalist and you're not a representative of this research community so you're on very thin ice with a few of your statements.

This sentence is a problem: 'However, to this day, there exists no cold fusion demonstration experiment.' You know just as well as I that if there were a demonstration experiment that were publicly known, it would have been on the

front page of the NYT -yesterday. You're asking for trouble with it and I know you better than to think you are someone who is being intentionally provocative. Why don't you drop the sentence? I don't see what it gains for you except to display unfavorable characteristics.

This sentence is correct and helpful: 'the cold fusion phenomenon is extremely difficult to reproduce.'

This sentence is a problem: 'There is no experimental recipe that will yield positive excess heat results even 50% of the time.' You cannot speak from a position of absolute authority - nor can I. It is erroneous and offensive if you would consider doing so. I presume you are just not aware of the sensitivities of text and editing. You could make this change to it and have a completely better effect: 'ETI is not aware of an experimental recipe that will yield positive excess heat results on a regular basis.'

This sentence is a problem: 'This situation greatly hampers cold fusion research and, in the eyes of some, supports the possibility that the cold fusion phenomenon does not actually exist.' This sentence is shallow and biased. First of all, the fact that it is difficult to repeat and replicate does not hamper the research, it hampers only the commercial viability of the work. The fact that it's a difficult science problem means, drum roll please, *it's a difficult science problem*. Period. . . .

What hampers cold fusion research is **1)** the fact that the claims are so astounding, people have difficulty considering it and its proponents seriously **2)** an institutionalized set of myths http://www.newenergytimes.com/PR/CFMythsFacts.htm **3)** a lack of significant funding http://newenergytimes.com/PR/FusionAdvantages.htm **4)** a stigma that not only affects non-CMNS researchers but also those in the field. (For example, a researcher with the Naval Research Laboratory, was not permitted by his commanding officer to use the words "cold fusion" in his forthcoming paper, accepted in the *Journal of Surface & Coatings Technology*.) This is the real cold fusion problem: http://newenergytimes.com/Reports/ColdFusionProblem.htm .

Responding to someone else Jed Rothwell wrote: "This is true, but there are any number of indisputable experiments (not demonstrations). The Iwamura experiment is indisputable, 100% reproducible, and it has been independently replicated and independently confirmed by examining the isotopes. But it cannot be run by anyone in front of a crowd of people at a conference.

It should be noted that most scientific experiments and industrial processes cannot be demonstrated. You cannot demonstrate a Tokamak plasma fusion reactor, a steel mill or a new computer chip fabrication machine, but nobody claims these things do not exist. I think this demand for a demonstration to prove the effect is real is absurd, and a demonstration would not convince a single one of the pathological skeptics. Even though a demonstration would add nothing to believability or scientific validity, it would still be valuable, for other reasons:

As Storms pointed out, easy reproducibility would be a huge advantage because it would allow more research, and it would be a step toward commercialization. A demonstration would convince many people who are not pathological skeptics. These people are not scientists and they do not understand the ABCs of the scientific method. If they did, they would be convinced already. However, it would be great to win their support. A demonstration might also convince investors to fund research. Some of these investors are convinced that cold fusion is real, but they do not think it has near-term profit potential. (I agree with them.)."

Responding to someone else Scott wrote: "I appreciate your thoughts. Yes, the title could have been better, but it is not nonsensical. The paper is a report on my efforts in testing energy claims and all of those tests have turned out negative. . i.e. null. Here's the abstract for the paper (remember the audience is a bunch of aerospace types):

'Null tests of breakthrough energy claims

Mankind desperately needs a better source of energy both for space travel and for terrestrial uses. This need spawns invention and claims of new energy devices abound. A number of such devices have been evaluated, with a singular lack of success. Interesting case histories are presented with the goal of promoting a better

understanding of the problems encountered in the evaluation of energy devices.'

Much of the report deals with our efforts to extract energy from the zero-point field. But I feel that our efforts in cold fusion also deserve mention, mainly because cold fusion has such enormous potential value to mankind. I'm not saying cold fusion is bogus but I want the audience to realize where it really is today and to appreciate some of the difficulties in the way of progress in the field."

Replying to another message from Scott, Jed wrote: ". . . As you have often done in the past, you are putting your own personal experience and your own personal skills above the whole history of science and technology, and above the textbook basis of the scientific method, and about the expertise of thousands of professionals. You were saying that because *you personally* have often made experimental errors, or seen other people make them, you think it is plausible that 500 to 1000 professional scientists worldwide over a 17 years have made error after error in observing high sigma data. You think that the people at BARC, who are world-class experts in detecting tritium, may have been wrong, even though they used three different instruments types and made hundreds of autoradiographs. For some utterly inexplicable reason there was no tritium. Every major method of detecting tritium developed over the last 100 years was repeated by three different divisions within BARC. Tritium was detected at thousands of times over background. You can see that for yourself: the autoradiograph was black. Yet it was all a mistake! All of these methods failed utterly, and nobody noticed. The safety division experts failed, even thought their very lives depend upon detecting tritium at much lower concentrations, and even though they have devoted their careers to dealing with tritium. You give no reason -- but you think they are wrong. Plus you really, honestly, seriously think that Fritz Will, Bockris, and Storms and 100 others were also wrong about the tritium they detected.

And you base this assertion entirely on your own personal experience! That is not a defensible point of view. Frankly I do not know what to make of it. It appears to be blind self-assurance based on overweening chutzpah. It is not rational. It is not falsifiable. It is not a scientific point of view by any standard. No textbook or philosophy of science treatise gives you even the slightest grounds for advocating this bizarre notion that hundreds of replicated experiments might be wrong. ....."

In another message Scott wrote: " My apologies to the list owners. Thanks for the constructive criticism. Please resume productive usage of this list." And here is the last message from Jed: "Let us be clear about this. In this exchange Scott Little represents the voice of the self-willed, self-satisfied, and self-deluded -- people like Close and Huizenga who betrayed science, and those who never understood it in the first place. They are the outcasts. We are the mainstream. They trash tradition and ignore precedent. We uphold tradition. They offer no falsifiable argument and they make assertions without evidence, while we publish irrefutable autoradiographs and data from hundreds of experiments. They are the perpetual motion machine fanatics, not us.

Little has made important contributions to cold fusion, and he is smart and capable, but in this case he fails to understand the bedrock principle of the scientific method: that *replicated experiments are the only standard of truth*. No one can second guess autoradiographs and instrument readings. No one can dispute them or outvote them, or claim on the basis of his own experience and gut feelings that they may be wrong. If you allow subjective personal experience to overrule facts, you open to the door to chaos. No question will be settled conclusively.

By every standard and by all the traditions of science, we stand on the inside and they are outside. Because the times are out of joint, and because the barbarians at *Nature* have temporarily taken over mainstream science, people do not see it that way. But Schwinger, Fleischmann, Gerisher and the others are right, and *Nature* is wrong."

And my last comment on this thread was extracted from a message on global warming. That message appeared on Phys-L discussion list for physics teachers.

"As every lawyer knows, it is always possible to make an argument on any side of any proposition. As many physicists know, not all such arguments are credible."

Earlier in the thread I wrote that a simple Mizuno-type cell (Glow Discharge Plasma Electrolysis) seem to be the best candidate for a demo. Somebody also made this suggestion. To which I responded by showing this:

List of successful replications of Mizino-type excess heat:

1) J.L. Naudin see his website --> http://jlnlabs.imars.com/cfr/
2) V. D. Cirillo et al. see their ICCF11 report
3) J.F. Fauvarque et al. see their ICCF12 report
4) R. Slaughter et al. Colorado2 experiment (we are working on the report)
5) J.F. Fauvarque et al. -- Paris2 (preliminary results after Colorado2)
6) University Labs in Japan

Experiments in preparation or in progress:
7) R.Slaugther -- Colorado3 (preliminary observations of excess heat)
8) J.P. Biberian -- Marselles1
9) J.F. Fauvarque et al. + another lab at CNAM -- Paris3
10) S. Little -- Texas2

What about your lab? I am not going to list names; many researchers on this list are highly qualified to replicate Mizuno-type experiments. And some are likely to have what is needed. Working on nearly identical experiments, and sharing results from our non-patent-motivated work, we are likely to promote the CMNS field faster than working on separate experiments and keeping things secret. Naturally, one must be aware of possible dangers, as described earlier on this thread.

298) Nuclear alchemy aspect of CMNS

Ludwik Kowalski; 5/28/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:

It is not the first time that I am describing a report claiming that nuclear reaction products are produced by certain chemical reactions. T. Mizuno, a Japanese electrochemist published a book on that subject several years ago (1). It is unfortunate that, due to his medical condition, I missed a chance of working with Mizuno after the last cold fusion conference in Japan. But I was lucky to work with another scientist, J. Kasagi. Based on that experience, and on other observations, I can say that Japanese scientists are highly qualified and extremely careful about what they publish. Yes, I know that a generalization from one example might be wrong. But it is better than generalization from zero examples. In any case, the purpose of this piece is to review a paper coauthored by Mizuno (2); that paper will be published in the ICCF12 proceedings.

What attracted my attention to this report was a plasma-electrolysis cell that operated continuously for 15 days; the cell we used in Colorado2 experiments (see items #271 and #270) operated for less than half hour. After that time our tungsten cathode would erode. The cathode and anode used in (2) were made from Pd (whose melting point is considerably lower than that of W) and they did not erode during 15 days of operation. After that the electrodes were examined and chemical elements, presumably created during the electrolysis, were found on the cathode. The potential difference between electrodes was approximatively 50 V. This is considerably lower than voltages at which excess heat was measured during plasma electrolysis. The low voltage reminded me of another paper (3) devoted to plasma electrolysis. The authors of that paper cooperated with E. Stroms and with J. Rothwell. But their contribution to CMNS phenomena (excess heat, excess hydrogen and excess elements) was minimal.

Experimental Setup:

The volume of the teflon cell used by Abe et al. (2) was only 300 cc, as illustrated in Figure 6 of their paper. It had a lid with small hole. The hole prevented accumulation of hydrogen and oxygen; it was also used to periodically add water (to keep the volume of the electrolyte constant). The electrodes and the thermocouples were mounted on the lid. The electrolyte was the 1M solution of K_2CO_3 in distilled water. Its nearly constant volume was 200 cc. Palladium rods inserted into the cell had the diameter of 1 mm. They were partially coated with teflon. The distance between the electrodes, according to Figure 6, was about 6 cm. Extreme precautions were made to keep the cell components as clean as possible.

Main results:

The surfaces of electrodes, after 15 days of operation, were examined with a scanning electron microscope (to observe structural details) and with energy dispersive X-ray analyzer (EDX to identify elements). Crater-like features, found on the cathode but not on the anode are considered to be evidence of nuclear reactions. The energy spectra of scattered X rays (Figure 7) show peaks due to well known elements. These peaks were not present when electrodes were examined before the electrolysis. That is an indication that they were produced during the electrolysis. Furthermore, some elements, such as Cu, Zn and Mg, were found on both electrodes while others, such as Fe, Ti, and Cr, were found on the cathode only. The height of the iron peak, for the cathode, is nearly three times above the background. This can be contrasted with the height of the same peak for the anode. The iron peak (if any) for the anode is nearly negligible in comparison with the background.

Peak appearing on the cathode only are identified by bold letters (in Figure 7) while peaks appearing on both electrodes are identified by italic letters. The authors conclude: "If [the identified elements] were transmutation products, at least two processes may explain their existence. The first [process is a] nuclear reaction presumably occurred at the cathode and only produced the bold letter elements, while the second reaction occurred at both electrodes, and produced the italic letter elements. Since we have not analyzed the samples by other methods, we cannot determine the origin of these elements yet." The "yet" implies that work is in progress; I hope the isotopic composition of iron will be reported at the next cold fusion conference (ICCF13). Will that composition be the same as that reported by Karabut (see item #13) or will it be different? That remains to be seen.

Unfortunately, peaks in Figure 7 are quantified in terms of arbitrary units (counts). It would be more useful to identify them in terms of absolute units, such as numbers of atoms per square centimeter, averaged over the entire surface. As far as know nobody was able to demonstrate that excess heat produced in Mizuno-type cells is commensurate with the number atoms produced via nuclear reactions. By the word "commensurable" I mean at least 0.01 MeV of excess heat per atom. Any other evidence that excess heat is due to nuclear reactions is much less convincing.

Plasma protocols:
The issue of "the right kind of plasma" was mentioned in the unit #271. Mizuno told me, at ICCF12, that the current must be very low and that it should be decreasing with voltage. Figure 2 of the paper is a plot of the voltage and current versus time, for about 3 hours. During the first 9000 seconds the applied potential increases nearly linearly (in small steps). The rate is about 2.5 volts per minute. The current also grows, up to about 2.5 A. After that the current goes down when the voltage goes up. After about one hour the potential difference is about 120 V while the current is about 0.6 A. The current becomes ~ 0.4 A when the potential becomes ~300 V.

The above description refers to a cell whose electrolyte was 0.2M K_2CO_3 and whose cathode was a tungsten wire of 1.5 mm diameter. The anode geometry is not mentioned. Assuming the cathode was cylindrical one might say that the cell was not very different from the cell used in Colorado2 experiments. The Colorado2 cathode, however, was about two times thicker. I suppose that this was the reason for which our current at 300 V was several times higher than 0.4 A. The "right plasma region" corresponds to currents below 1 A (when potentials are between 60 and 300 V).

The term "right plasma" means right for experiments in which excess heat is generated. That region is characterized by rapid deterioration of cathodes. That kind of operation, however is not appropriate for accumulation of transmutation products. To study such products one must operate the cell under ". . . another, milder type of electrolysis, which does not severely damage or disintegrates the electrode. . . " In Figure 4 that operation region is near the point at which the current is maximum (2.5 A at 45 V). The cell geometry to which the Figure 4 refers is not identified, it seems to refer to the cell with the tungsten cathode and with the 0.2 M electrolyte.

299) Nuclear or Exotic-Chemical Reactions?

Ludwik Kowalski; 6/6/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:

This morning someone e-mailed me two audio files containing a recent interview with Randy Mills. Randy was a cold fusion researcher. Then he developed a theory according to which excess heat, usually attributed to cold fusion of atomic nuclei, is supposed to be due to chemical reactions involving unusual hydrogen atoms. These atoms were named "hydrinos." A company, BlackLight. Inc., has been created by Dr. Mills in New Jersey. The mission of that company is to conduct hydrino research and to promote hydrino technology.

The 20-minutes interview, conducted by the energy analyst and consultant, Alan M. Lammey, took place on May 6, 2006. (***Energy Week,*** FM Radio News Channel 97.5 Houston, TX). The files sent to me can be downloaded from (www.FmNewsChannel975.com) AND (www.HoustonEnergyAnalyst.com)

Unfortunately, the focus was on speculations about possible future applications of BlackLight technologies, and on social issues of acceptance. I would prefer more emphasis on experimentally confirmed facts and on their significance. The files were e-mailed to me by John Neergaard. Some of his messages on the CMNS list made me aware that he is well qualified to describe scientific findings of Mills. Therefore I asked him for an essay on that topic.

After seeing his rough draft (several hours later) I replied: "My general comment is that the essay is too theoretical (which does not mean too mathematical). What experimental fact are being explained by his theory? How well are these facts established? My impression was that hydrogen states with negative 'excitation[' energies, described by fractional quantum numbers, play the central role in Mills' explanations. Am I wrong? I will let you to decide how well your description matches the essence of Mills' findings. I know practically nothing about his experimental work. The size of the essay is about right and I will post it in the form you send it to me next time. Thanks for being prompt."

John modified his essay and sent me the new version. It is better organized and less theoretical, as you can see below.

Randall Mills as an Innovative Chemist

John Neergaard (BS ChE, PhD Ph)

Introduction

The principles of Randal Mills experiments can be understood by considering a vacuum containing a wire into which system is injected H_2. Voltage is then applied to the wire to carry current. During the time when each atom in the wire is missing an electron, it is an ion with a stronger electric field than the atom. The heat from the wire disassociates the

H_2 near it. The hydrogen is then attracted to the ions at the surface of the wire. One then lets the experiment progress for an adequate time, turns the current off, examines the system, and finds absolutely no change. Did anything happen? There is no end product to examine. Each element has returned to its original state.

Chemistry reactions are analyzed in terns of an end product. If H_2 reacts with O_2, then H_2O can be found and measured to determine how much H_2 and O_2 reacted. The water is the end product, also known as chemical ash. Randall Mills, predominantly, works with ashless chemistry, simply studying behavior of H in the presence a catalyst ION. What is observed before he turns the current off, before the catalyst ion returns to its atomic state, coming from a location away from the wire, coming from the location where H leaving the wire would mix with H not exposed to the wire, is previously unknown light and heat in significant excess of the energy supplied to the wire. All this returns to its original form after the current is removed, albeit it does persist for a time without the catalyst. There is no permanent ash. (There are minimum ion states for success.)

When he forms a reaction product from a similar circumstance, by injecting a third element into a system similar to this, the end product, the ash, is completely new, never before seen in a chemistry lab. The hydrogen in this ash has properties never before seen in the lab. Other than in these synthesis conditions, the fuel, hydrogen or the catalyst ion, is not consumed.

Randall Mills claims that the energy from this process can be 1000 x the typical energy of normal hydrogen reactions. Since the per event energy from such is still similar to chemistry reactions, tens of eV (or perhaps this x10 in some cases), one expects that this includes development such as driving the process, accelerating the reaction process, perhaps by returning the catalyst to neutrality, freeing the hydrogen more quickly than would be expected under dc conditions in the above wire.

One can imagine the rejection which chemistry would normally experience for such claims. Even now, knowing what I know, I am reluctant to discuss the radical claims of Randall Mills. Unless one runs such experiments for himself, even though the Mills lab is open for inspection of experiments and results, only illuminata can be expected. The Novelties? There are three new properties for this odd hydrogen.

1. Previously unknown photons are found.

2. The new H can generate a self starting plasma with previously unknown heat and light when interacting with normal H,

3. The new H appears to gain the ability to bond twice.

The Experimental Facts

www.blacklightpower.com/theory/theorypapers/PhysicalSolutions032306.pdf and other.

Unknown photons

Experiments 108-112 in http://www.blacklightpower.com/Abstracts.pdf describe methods used to find the new photons. They are quite real and can be observed in any lab which runs the experiments using many different techniques. They occur when the, let's call it 'new H', when the new H makes contact with H. These photons, usually (there are H energies which do not), follow an inverse Bohr model. Bohr photon energies are proportional to 1/n. The Mills photon energies are proportional to 1/1/n = n. They are said to be 2 x 13.6eV, 3 x 13.6eV, etc. There are photons which do follow this model into the ultraviolet range, not consistent with, and opposite to, normal atomic photon emissions. The photons in this energy scheme are real. There is something profoundly new involved in this emission circumstance.

Self starting plasma

Look at http://www.iop.org/EJ/abstract/0963-0252/12/3/312 . This abstract describes the consequences of heating a wire coated with K_2CO_3 in the presence of hydrogen. It is one reference of the 'capable of generating its own plasma' remark in the audio file interview. The iR heat of the wire ionizes the K atom in K_2CO_3. Subsequently, there is a glow

apart from the wire. The photon emissions are arising from the interaction of H, after it has bonded with the K ion and departed, with 'normal' hydrogen separated from the wire. There is no known explanation of this property within existing text hydrogen literature. Thus, this odd property exists and is available for viewing reproducibly on demand in his lab or any lab which runs the experiment. It is a reasonably simple experiment to run for those who have vacuum equipment which allows current carrying wire access. The temperature for this K ionization is ~ 600 - 700C.

Hot Hydrogen
This is as close to isolation of the beastie as Mills has, to the best of my knowledge. He ionizes inert gases in the presence of H_2 . Hyrogen is detected with excess energy, as 'hot', with unexplained energy throughout the system. It's a spread out variation of the clustered plasma above. The experiment was run to exclude various objections to the conversion of H being the source of the energy.

Extreme Ultraviolet Spectroscopy of He - Hydrogen plasma
See in http://www.iop.org/EJ/abstract/0022-3727/36/13/316

New Compounds
Mills statement with respect to the odd H compounds is that ' the H appears to gain the ability to bond twice'. The compounds include various compounds of the KHI form and apparently an inorganic mer group. The compound KHI illustrates the point. This compound can be synthesized in any appropriate lab although the introduction timing of the Iodine is not specifically given. The K is ionized at a given T in the presence of H, apparently followed by the introduction of Iodine. This is mostly an efficiency of reaction concern. In principle the H must bond with K (ION) before I dominates the K. These compounds are illustrated by 'Synthesis and Characterization of Lithium

Chloro Hydride', #44
Look at http://www.blacklightpower.com/pdf/REFERENCES%20042006.pdf
Such compounds exist on the shelf in his lab. Many other reproducible on demand experiments for these properties exist. http://www.blacklightpower.com/techpapers.shtml

A Fundamental Question of Theory

[L.K. wrote]'My impression was that energy states with negative "excitation" energies, described by fractional quantum numbers, play the central role in Mill's explanations. Am I wrong?' No. That's exactly what he uses. In order to account for the photons, the sequence, the photon energies, and their 'relative quantities', he assumes the new beast is a hydrogen atom, extends QM from principle quantum number n to 1/n. He does this by imposing boundary conditions on Maxwell's equation. He calls such a hydrogen atom a hydrino. However, he goes significantly beyond that with non proven ideas that just boggle the mind.

In philosophical terms the math of the theory is nothing more than a shorthand method of remembering the emission scheme. It contains no new epistemologically certain knowledge. This is also a criticism of QM. Further criticism exists. Further, the theory does not address the implied charge on the H in compounds such as KHI. The odd H charge has never been studied (in public) in isolation. The new photons have not been observed to arise from a true H = p + e atom. All the H did was contact a catalyst ion. What is the cause of any newness? If it is in a shrunken orbital, why does contact with an ion do that? Or what is it that contact with an apropos ion really does?

For example, the implied charge on the new H can imply new H = p + e+. This hypothesis leads into cold nuclear fusion, in part because two of the three above properties, and possibly the third, are present in the conditions of the excess producing Mizuno plasma. (Discussed elsewhere on this site to produce some transmutation.) Isolating the new H for a simple charge check would distinguish and might attract huge interest depending on the result.

In short, the shrunken orbitals can be used to describe the photons but the premise / assumption has not been empirically verified, and does not explain KHI, inter alia. The new H empirically exists with the above properties with or without explanation. Thus one can employ the empirical properties for prediction to better use than the theory. That is, the conditions in which new chemistry arises in Mills' lab will produce new chemistry effects in other experiments also with or without a theory.

There are many other reasons for being wary of Mills as a theorist /physicist. (On the physics side, he does produce uses for Maxwell's equation under his terms which have not been used before.) He is a very legitimate pioneer in the chemistry lab, a future chemistry Nobel prize winner, assuming he is not ostracized forever for producing 'impossible' results, as the cold nuclear fusion community also presently is.

P.S.
What are the odds that two such anathema experimental circumstances, Mills and CF, are unrelated? The experiments of Mills and those of cold fusion relate to the original disagreement between Bohr and Einstein regarding (Einstein's phrase) the 'missing causal substratum'. (Bohr's rules are actually independent of v, meaning c can substitute for it with no change other than mental interpretation.) At the time, and to this day, Physics had no ultimate causal understanding of charge behavior in the bond between p and e, a particle, charge, unified field theory deficiency. (Thus, Physics must either choose Bohr and Schroedinger or stand in complete public atomic theoretical ignorance for nearly a century. They chose B & S. The inability of Mills experiments and cold fusion experiments to be explained by existing theoretical material exposes this ultimate deficiency from the past.)

Appended on 6/12/06:

After seeing the above Mike Carrell wrote: "There are a number of serious problems here. First, Mills is not, and never has been, a "cold fusion" researcher. He has been at great pains to distance himself from the cold fusion world since his earliest work. There is an early patent which alludes to cold fusion, and a number of people who look at the Mills and CF worlds have tried to find links and associations which are not made by Mills, inplying that Mills' results are "really" CF resultes.

Neergaard has tried to 'explain' Mills' reactions and reactor setups in a 'chemical' interpretation and creates unnecessary confusion. He does correctly state that very unusual phenomena occur in the Mills reactors, and the contextual theoretical edifice is audacious in the extreme.

Mills has recently been very active in applying his theory to the calculation of the structure of conventional chemical compounds. His method gives accurate results using simple closed-form equations. I understand that this aspect of his work has attracted intense interest from some quarters, although it does not relate to energy production or the shrunken 'hydrino' state of hydrogen resulting from the strongly exothermic catalytic reactions discovered by Mills. If Ludwik is interested, I can prepare a short essay on Mills & BlackLight Power for his website."

My reply was short: -- "I would be happy to append a short essay about the idea that excess heat in Mizuno-type experiments might be the same thing as excess heat measured by Mills. Arguments for or against this idea would be equally welcome." The first version of Mike's essay came at once. Carrell wrote: I will here respond to X comments and provide a compact statement of Mills' Blacklight Power (BLP) reactions, based an years of close observation of his published work and public statements." I posted that version. Another version was received next day. What follows is that second version. Mike prefers it to be a set of comments inserted into John's essay. John's essay is in black and Mike's comments are in blue. Yes, this created some repetitions. But that is OK with me.

Introduction

The principles of Randal Mills experiments can be understood by considering a vacuum containing a wire into which system is injected H_2. Voltage is then applied to the wire to carry current. During the time when each atom in the wire is missing an electron, it is an ion with a stronger electric field than the atom. The heat from the wire disassociates the H_2 near it. The hydrogen is then attracted to the ions at the surface of the wire. One then lets the experiment progress for an adequate time, turns the current off, examines the system, and finds absolutely no change. Did anything happen? There is no end product to examine. Each element has returned to its original state.

Only in the thermally driven experimental cells is a heated wire in a hydrogen atmosphere a starting point. Hot tungsten wire functions as a dissociator to split H_2 molecules from a supply source into two H atoms which can participate in the BlackLight Power (BLP) reactions. The proper starting point for understanding is an isolated H atom

in a gas at about 1 Torr with catalyst ions also present.

The statement that there is no end product to examine is false. An end product, shrunken H atoms, called hydrinos, is produced, detectable by signature lines in the UV emission spectra from the reactor, and by mass spectrometry of gases from certain specially designed experiments.

Chemistry reactions are analyzed in terns of an end product. If H_2 reacts with O_2, then H_2O can be found and measured to determine how much H_2 and O_2 reacted. The water is the end product, also known as chemical ash. Randall Mills, predominantly, works with ashless chemistry, simply studying behavior of H in the presence a catalyst ION. What is observed before he turns the current off, before the catalyst ion returns to its atomic state, coming from a location away from the wire, coming from the location where H leaving the wire would mix with H not exposed to the wire, is previously unknown light and heat in significant excess of the energy supplied to the wire. All this returns to its original form after the current is removed, albeit it does persist for a time without the catalyst. There is no permanent ash. (There are minimum ion states for success.)

It is not true that Mills works with "ashless" chemistry, if "ash" is understood to be the tangible end product of a chemical reaction. The 'resonant transfer' reaction between an H atom and a catalyst ion changes the H atom to a lower energy state, called a hydrino. Hydrinos have been detected by diffusion through a thin walled cathode in an electrolytic cell into a vacuum system coupled to a mass spectrometer. With gas-phase cells, the exit gases when condensed in a liquid nitrogen trap contain atoms chemically identifiable as hydrogen, but with other abnormal characteristics identifiable as hydrinos.

When he forms a reaction product from a similar circumstance, by injecting a third element into a system similar to this, the end product, the ash, is completely new, never before seen in a chemistry lab. The hydrogen in this ash has properties never before seen in the lab. Other than in these synthesis conditions, the fuel, hydrogen or the catalyst ion, is not consumed.

The abstracts cited below include experiments in which hydrino hydride compounds are formed with other elements. These exist in macroscopic quantities and have been shown in photographs [I have seen these in Mills' conference room]. The statement that otherwise the hydrogen fuel is not consumed is not correct. H atoms are transformed to the hydrino state and are so "consumed" as H but conserved as hydrinos. The proton and electron count remains unchanged.

Randall Mills claims that the energy from this process can be 1000 x the typical energy of normal hydrogen reactions. Since the per event energy from such is still similar to chemistry reactions, tens of eV (or perhaps this x10 in some cases), one expects that this includes development such as driving the process, accelerating the reaction process, perhaps by returning the catalyst to neutrality, freeing the hydrogen more quickly than would be expected under dc conditions in the above wire.

The phrase "in the above wire" indicates a serious misconception of the BLP reactions. Neergaard appears to still be thinking of BLP reactions like CF reactions occurring in the solid state. They do not. Preferentially, the gas state is used, at about 1 Torr. Examination of the hydrogen alpha line in a typical BLP reactor shows H atom energies in the tens of eV, equivalent to temperatures in the range of 100,000 K. As I have stated elsewhere, water bath calorimetry of a gas-phase reaction between H and He+ [as catalyst] shows 'excess heat' energy release 100 X that of combustion. Other observed reactions indicate still higher ratios, but these have not yet been demonstrated in calorimeters.

One can imagine the rejection which chemistry would normally experience for such claims. Even now, knowing what I know, I am reluctant to discuss the radical claims of Randall Mills. Unless one runs such experiments for himself, even though the Mills lab is open for inspection of experiments and results, only illuminata can be expected. The Novelties? There are three new properties for this odd hydrogen.

1. Previously unknown photons are found.

I am not sure what is meant by 'unknown photons', unless he is referring to novel spectral lines seen from BLP reators.

2. The new H can generate a self starting plasma with previously unknown heat and light when interacting with normal H,

I am not sure what he refers to. In the thermal reactor a high energy plasma is produced when the right conditions are present, where normal chemistry would not produce a plasma at all. It is not self-starting, it has to be heated, along with the hot tungsten dissociator.

3. The new H appears to gain the ability to bond twice.

Again, I am not sure what is meant. Hydrinos can gain an electron and become hydrides. Hydrinos can form diatomic molecules as well.

The Experimental Facts

www.blacklightpower.com/theory/theory **papers/PhysicalSolutions032306.pdf and other.**

Unknown photons

Experiments 108-112 in http://www.blacklightpower.com/Abstracts.pdf describe methods used to find the new photons. They are quite real and can be observed in any lab which runs the experiments using many different techniques. They occur when the, let's call it 'new H', when the new H makes contact with H. These photons, usually (there are H energies which do not), follow an inverse Bohr model. Bohr photon energies are proportional to 1/n. The Mills photon energies are proportional to 1/1/n = n. They are said to be 2 x 13.6eV, 3 x 13.6eV, etc. There are photons which do follow this model into the ultraviolet range, not consistent with, and opposite to, normal atomic photon emissions. The photons in this energy scheme are real. There is something profoundly new involved in this emission circumstance.

This is quite correct. I am accustomed to thinking in terms of emission lines, but the photon terminology is also correct.

Self starting plasma

Look at http://www.iop.org/EJ/abstract/0963-0252/12/3/312 . This abstract describes the consequences of heating a wire coated with K_2CO_3 in the presence of hydrogen. It is one reference of the 'capable of generating its own plasma' remark in the audio file interview. The iR heat of the wire ionizes the K atom in K_2CO_3 . Subsequently, there is a glow apart from the wire. The photon emissions are arising from the interaction of H, after it has bonded with the K ion and departed, with 'normal' hydrogen separated from the wire. There is no known explanation of this property within existing text hydrogen literature. Thus, this odd property exists and is available for viewing reproducibly on demand in his lab or any lab which runs the experiment. It is a reasonably simple experiment to run for those who have vacuum equipment which allows current carrying wire access. The temperature for this K ionization is ~ 600 - 700C.

This is the Conrads paper, an important independent confirmation of the BLP thermal reactor. Neergaard does not have the experimental structure quite right. Hot tungsten dissociates H_2 to 2H. K_2CO_3 crystals are coated on a titanium sleeve, which when heated dissociates the K_2CO_3 , releasing K+++ which is a BLP catalyst with the H atoms. Conrads substitutes halogen lamps for the bare tungsten wire, and the plasma does not appear until the lamps are wrapped with tungsten wire, which when heated dissociates the H_2 to 2H. He removes the titanium sleeve and no plasma. He substitute Na2CO3, and no plasma; Na is not a catalyst.

Hot Hydrogen

This is as close to isolation of the beastie as Mills has, to the best of my knowledge. He ionizes inert gases in the presence of H_2. Hydrogen is detected with excess energy, as 'hot', with unexplained energy throughout the system. It's a spread out variation of the clustered plasma above. The experiment was run to exclude various objections to the conversion of H being the source of the energy.

The input to the reactor is He, Ar, plus H_2, or simply H_2O. Microwave energy ionizes the gases except H, with He+, Ar+ and O++ becoming catalysts. Critics have cited field acceleration as the source of 'hot' hydrogen observed in glow discharge cells; the microwave cells do not have high field acceleration regions.

A Fundamental Question of Theory

[L.K. wrote]'My impression was that energy states with negative "excitation" energies, described by fractional quantum numbers, play the central role in Mill's explanations. Am I wrong?' No. That's exactly what he uses. In order to account for the photons, the sequence, the photon energies, and their 'relative quantities', he assumes the new beast is a hydrogen atom, extends QM from principle quantum number n to 1/n. He does this by imposing boundary conditions on Maxwell's equation. He calls such a hydrogen atom a hydrino. However, he goes significantly beyond that with non proven ideas that just boggle the mind.

The whole theoretical edifice is indeed mind-boggling. It is important to separate the body of experimental evidence from the novel structure of the electron and the rest of Mills theory. Hydrinos have physical reality, the chemistry of hydrinos with other elements is largely unexplored. The high energy produced by the BLP reactions is real. Mills appears to be better positioned to move ahead into commercial development of energy sources than the CF world.

In philosophical terms the math of the theory is nothing more than a shorthand method of remembering the emission scheme. It contains no new epistemologically certain knowledge. This is also a criticism of QM. Further criticism exists. Further, the theory does not address the implied charge on the H in compounds such as KHI. The odd H charge has never been studied (in public) in isolation. The new photons have not been observed to arise from a true H = p + e atom. All the H did was contact a catalyst ion. What is the cause of any newness? If it is in a shrunken orbital, why does contact with an ion do that? Or what is it that contact with an apropos ion really does?

Criticism of Mills' theoretical edifice will continue. What happens in the "resonant transfer" reaction between the H atom and catalyst is not clear and may be the object of years of study. Mills points out that a non-radiative energy transfer between atoms is known in certain phosphors, for example. This is truly new territory, as in a way what happens in a CF reaction is also new territory. As Ludwik states, the perfect must not be the enemy of the good. So if parts of Mills work appears paradoxical, this should be regarded as an invitation to deeper understanding.

For example, the implied charge on the new H can imply new H = p + e+. This hypothesis leads into cold nuclear fusion, in part because two of the three above properties, and possibly the third, are present in the conditions of the excess producing Mizuno plasma. (Discussed elsewhere on this site to produce some transmutation.) Isolating the new H for a simple charge check would distinguish and might attract huge interest depending on the result.

My understanding is that hydrinos are electrically neutral, as are normal H atoms, but that they can weakly bond and extra electron, forming hydrides, which can then form chemical compounds with unusual properties. There is no

thread leading to fusion reactions.

In short, the shrunken orbitals can be used to describe the photons but the premise / assumption has not been empirically verified, and does not explain KHI, inter alia. The new H empirically exists with the above properties with or without explanation. Thus one can employ the empirical properties for prediction to better use than the theory. That is, the conditions in which new chemistry arises in Mills' lab will produce new chemistry effects in other experiments also with or without a theory.

Indeed, with or without a theory. Theories are useful in predicting what to try next.

There are many other reasons for being wary of Mills as a theorist /physicist. (On the physics side, he does produce uses for Maxwell's equation under his terms which have not been used before.) He is a very legitimate pioneer in the chemistry lab, a future chemistry Nobel prize winner, assuming he is not ostracized forever for producing 'impossible' results, as the cold nuclear fusion community also presently is.

In all fairness to John, I must acknowledge his generally positive report on Mills' work and recognition of its seminal nature. I had reservations, based on a quick first reading. There are some errors and terminology I am not accustomed to, but the shape and thrust of his essay is in the right direction.

P.S.

What are the odds that two such anathema experimental circumstances, Mills and CF, are unrelated? The experiments of Mills and those of cold fusion relate to the original disagreement between Bohr and Einstein regarding (Einstein's phrase) the 'missing causal substratum'. (Bohr's rules are actually independent of v, meaning c can substitute for it with no change other than mental interpretation.) At the time, and to this day, Physics had no ultimate causal understanding of charge behavior in the bond between p and e, a particle, charge, unified field theory deficiency. (Thus, Physics must either choose Bohr and Schroedinger or stand in complete public atomic theoretical ignorance for nearly a century. They chose B & S. The inability of Mills experiments and cold fusion experiments to be explained by existing theoretical material exposes this ultimate deficiency from the past.)

My take on all this is that the BLP world and the CF world are two aspects of a new physics to painfully emerge. At some point they may be seen as complimentary, but it may be wise not to force the issue; rather, pursue both to their depths and see what is found. Mills claims to have found a theory consistent over 85 orders of magnitude, including an estimate of the period of an oscillatory universe. Mike Carrell

300) Preliminary Colorado2 report

Ludwik Kowalski; 6/28/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As some of the readers know, about one year ago I decided to devote some time and energy to a relatively simple experiment whose purpose was to either confirm or to refute reality of excess heat in Mizuno-type cells (*1). That decision was influenced by two authors who had already confirmed reality of such heat -- Eugene Mallove (*2) and Jean-Lois Naudin (*3). Their descriptions of experiments made me think that a Mizuno-type cell is an ideal device for low-budget student-oriented investigations possible in many physics labs. As described in the unit #252, I was directly influenced by a report sent to me by Pierre Clauzon from the Laboratoire d'Electrochimie Industrielle at Conservatoire National des Arts et Métiers, Paris (4*). He assured me, in a private message, that a possibility of chemical origin of excess heat, in Mizuno-type cells, has been investigated -- and declared impossible -- by a French chemist. That was a very important point; I am not qualified to deal with such issues.

In unit #252 I wrote: ". . . On the other hand, I anticipate problems with water condensation on the walls of the beaker, and with possible splashing, above 200 W. Each of these two effects, if not accounted for, can contribute to an apparent excess heat." Condensation turned out to be tolerable because water condensing on the inner walls of the beaker releases as much heat per gram as absorbed to create steam in the first place. Significant loss of water resulting from splashing was subsequently eliminated with drop reflectors. Units #253, 255, 256, 258 259 and 260, on this website, were composed before I had a chance to see the Mizuno-type cell in action. That was the cell built by Scott Little, in Austin, Texas. Some of the things I wrote were not clearly expressed. But that reflected the evolution of my thinking.

Work in Austin (Texas1 experiment) and subsequent work with Richard Slaughter in Boulder (Colorado1 experiment) did not reveal any excess heat. The setup used in this experiment was described in the unit #261. The unit recognizes a very important suggestion made by Dennis Cravens -- a possibility that excess heat is an artifact due to the presence of invisible droplets of electrolyte escaping with bubbles of oxygen and hydrogen. I wish this possibility were taken by us more seriously and that some kind of a test were invented to determine the percentage of the electrolyte in the lost liquid. The suggestion was ignored and we simply assumed that the escaping liquid was nothing but dry steam. Preoccupation with tiny droplets became an issue many months later, when Colorado2 results were discussed at the restricted internet list for CMNS researchers. But I am jumping ahead of this little overview

Negative findings, contradicting the conclusion of (*4) were reported at the 12th International Cold Fusion Conference in Japan (*5). Positive findings, confirming the conclusion of (*4), during the next sequence of experiments in Slaughter's lab., were reported over the Internet several weeks later (*6). They were discussed extensively at this list. To avoid confusion the following labels were introduced to identify recent and future Mizuno-type experiments:

Paris1 (*4) French work done before the last conference in Japan
Colorado1 (*) Work in Little's lab before the last conference in Japan
Colorado2 (*) Work in Saughter's lab after the last conference in Japan
Paris2 (*) A sequence of titration tests on the electrolyte used in Colorado2
Paris3 An anticipated new CNAM project in France
Colorado3 An anticipated new project in Slaughter's lab.

Marseilles1 An anticipated new French project in Biberian's lab

After analyzing Colorado2 data we decided to write a paper about our findings. I said that I will try to produce the first draft. The authors would be Richard Slaughter, Pierre Paul Clauzon, Jean-Francois Fauvarque, Ludwik Kowalski, Gerard Jean-Michel Lalleve, and Scott Little. The idea was to focus on experimental results, rather than on possible interpretations. The only electrochemist among us, Professor Fauvarque, would write an appendix showing that the excess heat measured was orders of magnitude larger than what could possibly be contributed to chemical reactions. What follows, after the list of references below, is the beginning of my draft. Do not confuse references with asterisks, which are for this unit, with references for our paper. The paper references are included because our introduction refers to them.

Is the Unexplained Heat Released During High-Voltage Electrolysis Truly Anomalous?

Abstract:

Reality of unexplained excess heat in glow discharge plasma electrolysis, first described by Ohmori and Mizuno (1), has been confirmed in a sequence of forty one tests. The results are described in terms of the coefficient of performance, COP, the ratio of the thermal energy released in a cell over the electric energy supplied to it, during the same time. The mean COP, and the standard deviation, turned out to be 1.24 and 0.13, respectively, as illustrated in Figure 1. The 24% of excess heat, in our setup, corresponded to about 30 kJ of thermal energy in five minutes (100 W). We refer to excess heat as unexplained because we were not able to attribute it to known chemical reactions, as discussed in Appendix 2. The author of that appendix is a French electrochemist, Dr. Jean-Fracois Fauvarque, from the Laboratoire d'Electrochimie Industriel, CNAM, Paris.

Figure 1 Distribution of COPs resulting from 41 tests performed at several differences of potential between 300 and 350 volts. No significant effect of the voltage on the COP was observed in that region.

****

Introduction:

The controversy surrounding excess heat is part of a broader controversy about the so-called “cold fusion.” The broader controversy started to evolve in 1989 after two electrochemists, M. Fleischmann and S. Pons discovered a strange energy releasing process (2). Their hypothesis, actually a guess, was that the unexplained heat was due to an exothermic nuclear process. Such processes are usually associated with emission of neutrons, and with production of radioactive nuclei. The hypothesis was rejected when it became clear that neither radioactive nuclei nor neutrons were produced in amounts commensurate with excess heat. If the unexplained heat, confirmed in many subsequent experiments, is real then it cannot possibly be due to well known nuclear reactions. Fleischmann and Pons discovered excess heat in conventional electrolytic cells. Several years later reality of unexplained thermal energy was discovered in high-voltage electrolytic cells (1), and in some non-electrolytic processes, for example, when deuterium gas diffuses through palladium (3). Numerous experiments devoted to excess heat are described in (4). Critical reviews of early cold fusion studies can be found in (5,6).

This paper focuses on measurements of excess heat similar to those initially described by Ohmori and Mizuno. Other aspects of high-voltage electrolysis, such as investigation of products of nuclear reactions (7) and abnormal generation of hydrogen (8) were outside the scope of our investigation. In their first high-voltage electrolysis experiment Ohmori and Mizuno reported that “the electrode became incandescent.“ Their COP was 2.6 and their excess energy was generated at the rate of 183 W.

Excess heat generation was confirmed in several Japanese experiments, as described in (20, 21 and 8). In Europe reality of excess heat was confirmed in experiments performed by: J.L. Naudin (9), by D. Cirillo et al. (10), and by J.F. Fauvarque et al.(11). All these studies confirmed reality of excess heat. Scott Little (12), on the other hand, was not able to confirm reality of excess heat in a Mizuno-type experiment. Negative findings were also published by L. Kowalski et al. (13). Their negative report, presented at the conference, was discussed by several participants, including Mizuno. The discussion revealed that plasma in (12) and (13) was considerably different from that in (11). The investigation described here was undertaken to resolve the controversy between (11) and (13). The main conclusion of (11) -- the over unity of COP -- has been confirmed, as illustrated in Figure 1.

Continuation of my draft is below the list of references.

Experimental setup:
High-voltage electrolysis, also known as GDPE (glow discharge plasma electrolysis) takes place when the electric field near the cathode is sufficiently high to ionize bubbles of hydrogen and oxygen created during the electrolysis (14,15). As in (11), our tests were performed in an open cell with two electrodes, a tungsten cathode and a platinized titanium anode. The applied differences of potential were in the range between 300 and 350 volts while the currents were in the range between 2 and 3 amperes. Our cell had cylindrical geometry, as illustrated in Figure 2.

****

Figure 2 Simplified schematic diagram of the open cell. Holders on which the electrodes and the thermometer were mounted are not shown. Also not shown are the ohmic heater, inserted into the electrolyte, and buffers designed to eliminate consequences of boiling splashes. The tungsten rod was surrounded by a ceramic tube (dotted pattern) whose

purpose was to confine the glow discharge to the lower part of the cathode.
****

The electrolyte was the 0.2 M potassium carbonate, K_2CO_3 in distilled water. The 0.02 M concentration was also tried; the effects were not noticeably different from those observed at 0.2 M. Likewise no noticeable differences were observed when the diameter of our cylindrical anode was changed from 4.4 cm (platinized Ti) and 8 cm (platinized Nb). Our tungsten cathodes were standard welding rods, purchased in a welding supply store. Two kinds of rods were tried: with 2% of thorium and without thorium. No significant difference between them was observed. The diameter of the cathode, on the other hand, had an effect on the voltage at which the plasma column was formed; thinner cathodes ignited at lower voltages than thicker cathodes. This observation is consistent with what has been reported in (16).

Excess heat was generated when the electrolyte was boiling and when the lower end of the cathode (below the ceramic tube) was surrounded by a deep orange column of glowing vapor. Our protocol was similar to that described by Naudin (17) and Mallove (18). The voltage was increased to the desired value slowly, for example, to 300 V in one to several minutes. During that time the current increased and then dropped down progressively, for example, to 2 A. It is reasonable to explain this in terms of the resistance of the plasma column surrounding the cathode. The current starts to decrease when the glow discharge is ignited. This can be interpreted by assuming that the column of the plasma becomes thicker at higher voltages and that its resistance increases with the thickness. A typical experiment lasts several minutes, as in (11). Depending on the voltage, one can perform 5 to 10 consecutive tests before the tungsten cathode is eroded.

Measuring electric energy:
A DC power supply was used as the source of electric energy. A set of two electrolytic capacitors (3100 mF and 450 V each) was connected in parallel with the cell. That was sufficient to keep the voltage constant, as verified with an oscilloscope. The electric current, however, turned out to fluctuate rapidly due to the random nature of the glow discharge. Electric energy Ee, supplied to the setup during a test, was initially measured by the method of fast samplings. This was accomplished by using a computer-based data acquisition system. The rate of sampling was 100 per second. The value of Ee was then calculated as the sum of v(t)*i(t)*dt, where the dt=0.01 seconds is a time between sampling while the v(t) and i(t) are instantaneous values of the voltage and amperage.

The second method of measuring the electric energy consisted of reading the Ee from a digital kWh-meter, U-390 (U stands for Unigore). That commercial instrument was designed to deal with sinusoidal and non-sinusoidal inputs. As expected, the discrepancy between the two methods were less than two percents. Independent digital voltmeter and digital ammeter were also used to visually estimate the mean values of v(t) and i(t) during consecutive minutes. Visual averaging is less reliable than fast electronic averaging but discrepancies between the last method and the first two were usually less than several percents. Unfortunately, our computer-based system became disabled due to an accidental short. For that reason about 80% of measurements of Ee were made with the digital kWh-meter. We believe that these measurements of Ee were accurate to within two percents. That confidence is based on the random nature of plasma current fluctuations. Fluctuations that are not random can lead, under certain conditions, to significant systematic errors, as illustrated in Appendix-1.

According to technical specifications the U-390 is reliable even when the current is non-sinusoidal. Our thermal calibration of the instrument confirmed that claim. The calibration was performed by connecting the power supply in series with an electrolytic cell (beaker #1) and with an ohmic heater of about 100 ohms, immersed in the beaker #2. That second beaker contained boiling water. The only function of the electrolytic cell, in the calibration experiment, was to modulate the electric current randomly. The electric energy, Ee, delivered to the heating resistor in about 20 minutes, was measure with the U-390 kWh-meter. The result was compared with thermal energy, Et, released in the beaker at the same time. The two energies turned out to differ by only 0.43%. Measurements of thermal energy are described in the next section.

Such result would be impossible if measurements of Ee were associated with large systematic errors. It is important to emphasize that the current flowing through the ohmic resistor, during the thermal calibration of U-390, was essentially of the same non-sinusoidal kind as the current flowing through the electrolytic cell when the COPs were measured. Two independent calibrations of our kWh-meter (by measuring thermal energy and by using the fast computer-based

data acquisition setup) confirmed that the instrument is indeed reliable, even when the current is not sinusoidal.

An additional confirmation of the reliability of the U-390 instrument came from the comparison of its readings with the kWh received by the power supply at the a.c. side, as measured with another kWh instrument (DMMetering, model DRM75A). The two energies, measured at the same time, differed by ~ 3%. That difference was more or less consistent with the amount of heat dissipated inside of our simple home-made power supply. In order to bring the mean COP to unity (from 1.24) the true Ee would have to exceed the U-390 readings by 24%. This would conflict with the kWh measured at the a.c side of the rectifier.

Measuring thermal energy:
Thermal energy, Et, released in an open cell during a test, consists of two parts: Ev, used to evaporate water, and Ec, escaping through conduction, convection and radiation. The Ev during the electrolysis was calculated from the evaporated mass, m; the Ev is simply L*m, where L is the latent heat of evaporation, 2260 J/g.
The same approach was used to find the Ev in the tests with the ohmic heater, for example, in the beaker #2, during the calibration of the U-390 kWh meter.
The non-evaporative losses of thermal energy, Ec, were calculated from the Ee and Ev measured when boiling was due the ohmic heater, that is when Ec=Ee-Ev. The heater was connected to the 110 volts a.c. line. Electric energy received by the heater was measured with two kWh-meters: U-390 and a much less sophisticated ??? (designed for sinusoidal currents only). No significant difference between the readings of these two kWh-meters was observed.

The cell shown in Figure 3 was standing on a digital electronic scale. In that way the mass, m, lost through evaporation, during each test, or during calibrations, could be measured with the accuracy better than 1%. If m=10 grams in t=60s then the thermal evaporative power is $Pv=E_v/t=377$ W. Switching from energies to powers is convenient because duration's of experiments are not identical. In what follows the Pe=Ee/t will be called electric power and the Pc=Ec/t will be called the non-evaporative thermal power. The coefficient of performance is

$$COP = (Ev+Ec)/Ee = (Pv+Pc)/Pe$$

Note that under identical boiling and mixing conditions the Pc during ohmic heating is expected to be essentially the same as the Pc during plasma electrolysis. For our two-liter beaker (our electrolytic cell) the values of Pc turned out to change linearly from about 50W to 80W when the Pe changed from 300W to 850W. The values of Pc were measured before and after the electrolysis experiments.

Experimental results
In a typical GDPE experiment, lasting 300 s, the Pe and Pc were close to 300 W and 50 W, respectively. About 40 grams of water was lost during such experiment. That gives Ev=90400 J, Pv= 301 W and COP=1.17. The values of COP fluctuated slightly from one experiment to another. The mean COP, and the standard deviation, from our forty one tests, turned out to be 1.24 and 0.13, respectively, as illustrated in Figure 1.
Experiments were performed at potentials between 300 V and 350 V. Contrary to what was reported in (11) the voltage had no significant effect on the COP.

Discussion
The results were discussed on the restricted Internet list for the CMNS researchers. The acronym stands for Condense Matter Nuclear Science -- it is a new name for what used to be called cold fusion. In our opinion the word “Nuclear” is premature. As far as we know, no one was able to show that the rate of accumulation of nuclear reaction products, in Mizuno-type cells, is close to one atom per several MeV, of excess energy, as in many well known nuclear reactions. Additional experiments will be necessary to clarify a mechanism, or mechanisms, through which excess heat is produced. The only statement we can make, at this time, is that well known chemical reactions cannot possibly be responsible for the excess heat measured. That topic is discussed in the Appendix 2, written by a French electrochemist, Jean Francois Fauvarque.

To illustrate difficulties encountered in trying to attribute execs heat to chemical fuels let us consider tungsten. In one experiment, lasting ten minute, the measured excess heat was 60 kJ (at the rate of 100 W). During that time about 1.3

grams of tungsten was lost by the cathode (diameter 2.4 mm). According to (1) the loss is due to melting; it cannot be due to heat-producing oxidation because negative ions containing oxygen are repelled by the cathode, as explained in the Appendix 2. But suppose that one ignores this fact, as done in (1), and assumes that all excess heat comes from formation of H_2WO_4. It is easy to show that if 60 kJ of thermal energy is due to consumption of 1.3 grams tungsten then each atom contributes 88 eV of the measured excess. In our experiments about 50% of tungsten removed from the cathode was recovered as metallic particles at the bottom of the cell. That means that the number of reacting atoms of tungsten was one half of the 1.3 grams.

Taking this experimental fact under consideration the rate of generation of energy becomes 176 eV per atom. This is 44 times larger than what is expected -- oxidation of one mole of tungsten, with subsequent formation of H_2WO_4, generates 220.84 + 179 = 380 kJ of heat. In other word, attributing our measured excess heat to the oxidation of tungsten would conflict with what is known about the $2W+3O_2=2WO_3$ and $WO_3+H_2O= H_2WO_4$.reactions. This has already been emphasized by Mizuno et al. (1). The only possible exothermic reaction, according to Appendix 2, is decomposition of water. That reaction contributes only 4.3% to the excess heat measured. To exclude its contribution the reported value of the COP, 1.24, must be replaced by 1.21. Other possible reactions, discussed in the Appendix 2, are endothermic and their combined contributions to the COP was estimated as -5%. In other words, the net effect of well known reactions, on the value of the COP, is essentially negligible.

Can the over unity of the COP be due to an erroneous assumption that the Pc measured during the electrolysis was the same that the Pc measured when the current was flowing through the ohmic heater? Suppose that a layer of foam is formed on the surface during the electrolysis but not when the current flows through the ohmic heater immersed into the electrolyte. In that case, as recognized by Michel Julian, convectional losses used to calculate the COP would be exaggerated leading to an overestimation of the COP. We have two reasons to rule out this possibility. The first reason is that no significant differences between surfaces was observed during our experiments. The second reason is based on a control experiment performed to investigate this issue. In that control experiment the electrolyte was in dewar rather than in a much wider beaker. This reduced the Pc but the values of COP was not significantly lower than 1.24.

Can the over unity of the COP be due to an error in the mass m used to calculate thermal losses. We assumption that the liquid lost during an experiment was nothing but pure vapor. But suppose that this was not correct. Suppose that 25% of the lost mass, m, consisted of escaping droplets. In that case our Pv, calculated from the 2260*m, would be strongly exaggerated. An exaggerated Pv, in turn, would create an illusion that COP is larger than unity. Emission of visible drops has often been observed during our experiments. The mass of visible drops was estimated on the basis their volumes. In some cases a paper towel was used to collect drops and to measure their combined masses. The typical estimated mass was less than one gram per test. That was much smaller than the total lost mass m, typically 40 grams per test. On that basis the effect of visible drops on the COP was estimated as less than 2.5%.

But what about the much smaller, invisible droplets? That issue was not addressed during the experiments. Most of such invisible droplets are likely to evaporate before being intercepted by the paper towel. The effect of tiny droplets, however, was assessed after experiments. ..... [WORK IN PROGRESS]

Can excess heat measured be attributed to some kind of energy accumulation process? To answer this question we considered a possibility that our cell acted as a rechargeable electric battery. In a control test the cell, after being connected to the power supply for several hours, was suddenly disconnected and discharged through a resistor. [WORK IN PROGRESS] Another possibility considered was short-time storages and releases of thermal energy. That hypothesis was ruled out the basis of high reproducibility. The mean COP of 1.24, and the standard deviation of 0.13, from 41 tests, would not be possible if such mechanism played a significant role. Furthermore, significant random thermal accumulations and releases would be associated with significant temperature fluctuations during consecutive tests. The actually observed temperature fluctuations, about one degree or so, probably contributed to the size of the standard deviation.

Conclusion:
The overall conclusion is that the GDPE thermal-excess energy, discovered in (1), and confirmed by other investigators (9, 10 and 11), seems to be real. Generation of excess heat, at the 0.1 kW level, turned out to be

reproducible. The origin of that energy is not clear to us. Can several cells be used in a battery generating excess heat at a much higher rate? Not having an accepted theory one must rely on empirical investigations. Systematic studies of effects of various parameters (size, composition, and geometry), on the performance of Mizuno-type cells, seem to be warranted.

Can excess heat be attributed to a well known nuclear reaction, such as D-D fusion? The answer to this question must be negative. Familiar nuclear reactions generate radioactive byproducts. A thermonuclear D-D reaction, for example, generating excess heat at the rate of 0.1 kW, for three hours would produce about $4*10^{19}$ neutrons. That would be sufficient to create radioactive isotopes in many objects near the cell. A Geiger counter we used, however, showed that the level of radioactivity, near the cell, was not higher than natural background. The time of three hours, by the way, is used because that was not very different from the total duration of our 41 experiments. Speculations about the origin of excess heat are less important, at this stage, than establishing its existence.

Appendix1: Measuring electric energy by sampling.
The electric energy E, delivered to a cell, is the integral (over a test duration) of dE = i(t)*v(t)*dt, where i(t) and v(t) are instantaneous values of the current and potential, respectively, while dt is a very short time interval. The glow discharge current is known to fluctuate randomly. This was confirmed by using an oscilloscope. Fluctuations of i(t) were not associated with significant fluctuations of v(t) because a large electrolytic capacitor (0.001F and 500 V) was connected between the cell electrodes. It fact, the v(t) was essentially constant during each test. As previously indicated, digitized samples of v(t) and i(t) were recorded by the data acquisition board controlled by a computer.

Suppose that the sampling frequency is much lower than some frequencies contributing to the shape of the current waveform. Can this lead to a systematic error in a measured value of the electric energy delivered to the cell? The answer is negative, unless the current fluctuations are not random. To justify this answer consider a current waveform shown in Figure 3. It has been generated by using random numbers (from a uniform distribution between 0 and 2). The time intervals between consecutive current changes were 0.1 ms, as indicated. It is clear that the spectral composition of that waveform contains frequencies higher than 10 kHz. The mean current, over a long period of time, is 1 A, by design.

Suppose that the shape of this waveform must be determined by sampling. The rate of sampling would have to be considerably higher than 10 kHz , for example, at least two or three measurements during every 0.1 ms, depending on the desired accuracy. The dark circles show the waveform one would obtain if the sampling rate were only 2 kHz. Connecting the dark points with straight segments one gets a shape that is quite different from the real shape of the waveform. But the situation becomes dramatically different when the purpose of sampling is to determine the mean current over a long time interval, for example between 0 an 20 seconds. In that case the mean value from the two waveforms would be practically identical. This fact was numerically verified by using a computer code. The six mean currents, obtained by executing the code six times (six different waveforms) were: 1.000, 0.999, 0.993, 1.001, 0.992 and 1.004 A.

In other words, the sampling frequency necessary to determine the mean current can be much lower than what would be necessary to determine the shape of the signal. The only requirement, to obtain a reliable mean value, is to gather a sufficiently large number of unbiased samples during an experiment. This conclusion is intuitively obvious for any random waveform. The situation, however, can be different for a periodic waveform, as illustrated in Figure 4. In that example the sampling interval -- 1 ms -- is the same as the period of repetition. The apparent mean current would thus be 0.2 A; that is several times smaller than the true mean current.

Note that the apparent mean current of 0.2 A would occur only at sampling frequencies of 1 kHz, 0.5 kHz, 0.25 kHz, 0.125 kHz, etc. At all other sampling frequencies the apparent and the true means would be nearly identical, provided the sampling interval is negligibly small in comparison with the duration of the waveform. In other words, an error due

to a poor choice of sampling frequency, for a periodic waveform, is possible but not very likely. To eliminate possible systematic errors periodic waveforms must be sampled at randomly distributed intervals (rather than at equal intervals, as in Figures 3 and 4). Using consecutive sampling at two different frequencies, such as 13 kHz and 17 kHz, and showing that the means are nearly identical, would be a good indication that a sampling error did not occur.

Someone who also built a Mizuno-type cell examined the v(t) waveform with a 20 MHz digital oscilloscope. The examination revealed presence of pulses whose duration's were several microseconds. These were said to be similar to the well known Trichel pulses in corona discharge (19). Is it possible that presence of such pulses may lead to an underestimation of the Ee, and consequently, an overestimation of the COP? To answer this question, in the context of sampling, one would have to analyze what happens when a sample is collected. We simply assumed that an instantaneous value of voltage, captured during several milliseconds, is already an average based on what happens at the level of microseconds, nanoseconds and picoseconds. It is unlikely that ultra-fast pulses would lead to nearly identical systematic errors in different kinds of kWh meters used in this investigation. Same observation can be made about possible effects of electromagnetic interference.

Appendix 2:
Contributions of possible chemical reactions to excess heat.
Appendix is going to be sent to me, probably in the middle of July. I hope it will provide ammunition to argue against chemical origin of excess heat, and against presence of the electrolyte in the escaping steam. Can a battery-like effect be responsible for generation of excess heat at the rate of about 0.1 kW? I hope that this question will also be answered in the appendix written by the author, an electrochemistry professor in Paris.

301) Colorado2 results must be revised

Ludwik Kowalski; 6/29/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

As described in unit #300, I have been involved, for about one year, in an experiment, named Colorado2. It was similar to several glow discharge plasma electrolysis (GDPE) experiments performed by other investigators in several countries (see references in unit #300). The purpose was to convince myself, and others, that Mizuno-type excess heat is not an illusion due to experimental errors, or to some well known effects. The conclusion we reached was that some unexplained source of energy was responsible for the excess heat measured. The draft of the manuscript was nearly ready to be shared over the Internet when one interpretational error was discovered. Unit #300 shows my draft; as it was about two weeks ago. The purpose of this unit is to follow new disturbing developments. I will assume that the reader is familiar with concepts and terminology introduced in unit #300; this unit is a continuation of what was written there.

A question about invisible droplets of electrolyte escaping from cell has been raised but not answered in unit #300. Two experiments were performed to answer that question, one based on titration of the electrolyte remaining in the cell, after an experiment, and another based on the examination of the wet steam escaping from the boiling electrolyte. The result of the first approach is not clear to me; I hope it will become clear after Appendix 2 is received. But the second approach is more simple. It was nothing more than a determination of exact masses of four samples. The first three samples, at least one gram each, contained drops of steam condensed on a cold surface, the fourth sample was the original electrolyte.

The method was introduced to us by Scott Little; here is his own description of it:
". . . I conducted a simple dissolved-solids test on the samples you [R.S.] sent. First I weighed 4 Al weighing cups. Then I dispensed some of each sample into each cups. I used a new disposable pipette for each sample to prevent contamination. Then I weighed the wet cups. Then I gently dried the samples in a 70C oven for 4 hours This gentle drying should leave the salt as K_2CO_3+1.5H_2O. I recorded the first set of dry weights. Then I returned the samples to the 70C oven for another 8 hours. I recorded a 2nd set of dry weights."

Scott's net masses, for the first three samples turned out to be: 2.06, 1.15 and 1.84 mg, per cubic centimeter of the condensed liquid. The mean and standard deviations are 1.68 and 0.47, respectively. For the sample #4 (the original electrolyte) the mass of the solid deposit was 27.4 mg per cc. What does this mean? Under ideal conditions (no electrolyte escaping with the steam) the net solid masses, from the first three samples would be zero. But the measured mass, 1.68, was 6.1% of 27.4. That means that the amount of the electrolyte, in the escaping liquid, was about 6%. The mean COP, determined when three samples were collected, was 1.15. But that was calculated by assuming that the escaping liquid is pure water. In other words, our mass m, and Pv were overestimated by 6%. This leads a sizable correction, close to 0.05, in the value of COP. The correction would be 0.06 is the Pc were zero. More specifically, the mean COP=1.15 becomes 1.10. That is too close to unity, considering the standard deviation calculated above.

If this preliminary observation of Scott is confirmed then experimental COPs, reported in unit #300, are certainly exaggerated. A simple reduction of the reported results by 0.05 would not be appropriate because percentages of the

electrolyte in the escaping liquid were not measured. Conditions under which experiments were performed to collect three samples were not the same as conditions under which the bulk of Colorado2 data were collected. We are certainly not ready to write a paper that would be difficult to reject.

What is surprising is that researchers who performed similar experiments before us never mentioned, or tested, as far as one can say, a possibility of a systematic error in m due to the escaping electrolyte. They all fell into the same trap as we. How can this be explained?

Appended on July 5, 2006

1) I am disturbed and disappointed. The following questions were asked, on June 29, at our CMNS list: "Is Mizuno a member of this list? Is he aware of new development, Jed? [I know that Jed, who if fluent in Japanese, if a friend of Mizuno] If not you should inform him by phone. Naudin and Iorio are also on this list. I expected all three of them to be busy performing Little-type tests at this time." Four days later, I wrote that absence of messages from them is very disturbing. Two more days passed and we do not hear from them. How can this be explained. How can authors of influential papers remain silent after learning about Little's results? Having the necessary hardware I would simply condense the escaping liquid and measure the percentage of the escaping electrolyte under two kinds of conditions: (a) boiling due to the ohmic heater and (b) boiling due to the current flowing through the electrolyte. Perhaps nearly pure steam comes out in the first (usual) case and steam mixed with electrolyte comes in the second (not very usual) case. That would be much easier to do than measuring the COP.

2) It is only a matter of time before the mystery of "tiny droplets" is solved. I know, from private messages, that the Little-type test is now being conducted in Boulder by Richard Slaughter. Similar tests are planned during the upcoming Paris3 experiment, probably in a month or two. But what about the second main issue? Would I be able to say, referring to the appendix, that "known chemical reactions cannot possibly be responsible for the main part of excess heat? The first draft of the appendix, written by Jean Francois Fauvarque, did not allow me to say so. But some progress in that direction was made yesterday. It came after I posted the following problem on the restricted list for CMNS researchers.

"A cell contains one liter of the 0.2 M K2CO3 electrolyte. The cathode is tungsten and the anode is platinum. The temperature is already 100 C. How much heat is generated when a constant potential of 30 V is applied for 100 seconds? Assume that a constant current of two amperes is flowing through the cell. Part of the answer is obvious, the thermal energy is 30*2*100 + X = 6,000 + X joules, where X is the energy released (positive or negative) via anticipated chemical reactions. What is the value of X?"

Note that 30 V was chosen to avoid complications associated with the glow discharge plasma electrolysis (GDPE) that is ignited above 100 V. The outside temperature of 100 C was chosen to make sure that the cell temperature remains constant. The idea was to establish the value of X in a simple situation before trying to establish it for a much more complicated situation. Two Ph.D. chemists on the CMNS discussion list wrote that the dominant reactions, are: decomposition (electrolysis) of water and production of CO2 from the K2CO3. Not being a chemist I am happy to take this for granted.

3) I will return to this topic a little later below. My impression was that contributions of chemical reactions to excess heat from Fleischmann-type cells have been discussed extensively in papers written by Fleischmann and Pons. Statements that chemical heat was negligible are easy to find but not in F&P papers. The only one that I found today, after browsing through their papers (downloaded from the library at www.lenr-canr.org), is shown below. The title of the paper was "Calorimetry of the palladium-deuterium-heavy water system;" it was published in J. Electroanal. Chem, 1990.

". . . The total specific energy output during the bursts as well as the total specific energy output of fully charged electrodes subjected to prolonged polarization (5-50 MJ cm^3) is 100 - 1000 times larger than the enthalpy of reaction of chemical processes."

Two or three orders of magnitude is impressive. But specific energies are in J/cm^3. Did they divide the total excess heat by the total volume of the cathode or by the volume of a thin layer at the surface of the cathode? The same question can be asked about chemical processes. Are these all conceivable reactions in the cell or only reactions conceivable inside the cathode? It would certainly make no sense to compare MJ/cm ^{3} with MJ. Furthermore, the bursts to which the 1990 paper referred were of very short duration, as illustrated in several figures. Did they produce less ambiguous statements in later publications? I do not know. My search for a better reference will continue; the quote will be inserted here, if found.

4) It is well known that the electrolysis of water is an endothermic reaction. In other words it absorbs heat instead of releasing it. If the current is 2A, as in my illustration above, then the contribution of the electrolysis is -295 J. The negative sign is used to indicate the endothermic nature of the dominate reaction. And what about consumption of K2CO3, I asked. That reaction is also endothermic but the energy absorbed depends on how much of the potassium carbonate is consumed. For each gram of consumed salt the contribution to X is -82 J. Let me assume, to be specific, that only five grams of the K2CO3 is consumed. In that case the contribution of the two reactions to X becomes -295 - 5*82 = -705 J.

Yes, you might say, but what is the purpose of discussing a 30 V experiment when real experiments (Paris1 and Colorado2) were performed at 300 volts? That is certainly a valid concern. My two chemists wanted me to be aware that a large number of unknown reactions become possible under the GDPE. One of them wrote: “what happens at the anode for high voltage electrolysis- is interesting and important. And in great part, new- a place for discoveries.” My 30 V illustration is an instrument for thinking; call it a gedanken-ing tool. I will use it to subdividing all possible reactions, chemical and non-chemical, into two categories: (a) well known to chemists and (b) all others. I am aware that the term "well-known to chemists" is not very precise. But this term must be defined if one wants to make a claim that "the excess heat we measured cannot possibly be attributed to well known chemical reactions."

As indicated before, our Colorado2 report would not be worth publishing without a credible statement of that kind. Perhaps such statement will appear in the new version of the appendix written by Fauvarque. For the time being I am defining well known reactions as those for which the excess heat contribution (X in my illustration) can be estimated. Suppose that someone makes a claim that thermal energy released, during a 30 V experiment, exceeds the electric energy supplied by 4000 J. How large is the unexplained excess heat? My answer would be 4000 + 705 = 4705 J. The 705 J is the heat absorbed by the two well known reactions (for the current of 2 A and for 5 grams of K2CO3 consumed).

Note that 2A can be treated as a measured quantity. But 5 grams was only a guess. So what should the error bar be to account for the uncertainness in the guess? The smallest possible amount of K2CO3 lost was zero grams. In that case the contribution of the second reaction to X would be zero and the unexplained excess heat would be 4000 + 295 =4295 J. The other extreme (highly unlikely) would be that all the K2CO3 present, about 25 grams, was consumed to produce the CO2. In that case the value of X would be -(295+5*410) = -2345 and the unexplained heat would be 6345 J. The well known reactions underestimate excess heat because they are endothermic. Being able to say that excess heat is between 4295 and 6345 joules is due to unknown processes, chemical or non-chemical, would be a great step forward. Note that even under the lower limit the rate of generating excess heat would be close to 43 W.

What is wrong with that kind of speculation? It is based on my own definition of “well known reactions.” Other knowledgeable chemists might be able to extend the range of “well known reactions” by calculating their contribution to X. In that case the value of X would have to be modified. We cannot exclude a possibility of exothermic reactions under conditions of plasma electrolysis. Suppose that X turns out to be close to +4000 J. In that case we would say that the entire excess heat is due to well known chemical reactions. My main point is that excess, as measured in Colorado2 experiments, cannot be attributed to non-chemical reactions unless contributions of chemical reactions is ruled out by chemists.

A much more convincing approach would be to show that the amount of non-chemical byproducts is directly proportional the amount of excess heat generated. No experimental evidence of that nature exists, as far as I know, for Mizuno-type experiments. Presence of products of nuclear reactions has been discovered by Mizuno but the amounts were extremely low. Will these amounts be shown to be correlated with amounts of excess heat measured? That

remains to be seen.

5) I like coincidences. After composing the above I received this junk-mail message:

"A Genuine University Degree in 4-6 weeks! Have you ever thought that the only thing stopping you from a great job and better pay was a few letters behind you name? Well now you can get them!" Well I am certain that my chemical consultants did not graduate from the Genuine University. Only highly knowledgeable experts can estimate X from exotic chemical GDPE reactions.

Appended on July 7, 2006

Let me show extracts from some recent messages posted on the CMNS list. They show interactions among the CMNS investigators. How do these interactions differ from those in other areas of physical sciences? Keep in mind, however, that this is a multi-discipline list; backgrounds of contributors are very different.

Scott Little wrote:
. . . I agree that your scenario above does not violate the 1st Law and I distinctly recall challenging you that it was instead a violation of the 2nd Law. My reasoning was that the heat absorbed from the environment was, in effect, "free air-conditioning" (very valuable here in Texas) and that for a "price" of 1.23V*Q in input energy you were getting out of the cell 1.48*Q in output energy (in the form of H2 and O2 "fuel" gas).

But now that I have the accepted the concept that dG is the maximum amount of work a reaction can perform, it is beginning to look like there is no 2nd Law violation here at all. ..maybe. Can you suggest a reference that discusses these concepts, particularly thermoneutral potential, electrolysis of water, etc. in detail? All my Pchem (e.g. Moore) and thermo (e.g. Sears, Sonntag) books just seem to graze the surface and don't really discuss this very issue.

Mel Miles wrote (responding to a question about two electrolytes**):**
Fleischmann and Pons selected LiOD as their electrolyte to avoid the possibility of other cell reactions. If we assume that K2CO3 is oxidized to form CO2 and O2 at the anode and that water is reduced to form H2 at the cathode, then the cell reaction becomes

2 H2O + K2CO3 = H2 + CO2 + 0.5 O2 + 2 KOH

At standard conditions, Delta H =+395311 J for this reaction. Thus . . .

I wrote:
If I had to start another Mizuno-type experiment I would use fresh electrolyte for each test. Then the amount of the K2CO3 reacted would be measured for each test. Little-type test would be used on samples of the electrolyte. Suppose a sample of the electrolyte, extracted moments before a test, shows that each cm^3 contains 26 mg of the solid deposit (after 1 cm^3 of water is evaporated). Suppose the sample extracted after the experiment has only 22 mg of deposit per cubic centimeter. Then one would probably say that no more that 4 grams of the K2CO3 (from the total of 26 g initially added to one liter of distilled water) was consumed. The "no more" is appropriate because one cannot exclude a possibility that some tungsten, lost by the cathode during a test, is also present in the solid deposit. The amount of tungsten lost during a test would be measured by comparing the weight of the cathode before and after. If I worked with a chemist I would insist on measuring the amount of tungsten in the solid deposit and in the electrolyte. A complete chemical analysis of the sample would be preferable. But focusing on tungsten would be a big step forward. Knowing the result, a competent chemist would be in a much better position to estimate X due to formation of CO2, and probably due to other chemical reactions. I guess that was the essence of what Peter wrote two days ago.

And here is another suggestion, it was made by Pierre Clauzon, in a private message yesterday. Measure temperatures very accurately and do not start collecting excess heat data before thermal equilibrium has been established in the cell. He was probably thinking about power differences. Excess heat must be measured after thermal equilibrium is established inside the cell. The temperature must be constant and the rate of evaporation must be constant. Fortunately,

a fast electronic data acquisition system can be used to make sure that this precondition is met. That is how data were collected during Texas1 experiments. Colorado1, and Colorado2 data were collected without using the fast data acquisition system. But we usually waited several minutes before starting a new run. The rates of evaporation, from run to run fluctuated randomly. A systematic trend would probably be noticed but that is far from being certain. Recent Paris2 measurements were made under the thermal equilibrium. The results were more or less the same as in Paris1 and Colorado2 experiments. Is this correct, Pierre? As you can see, what I write is an extrapolation from what you mentioned yesterday. I am sure that what we learned from previous experiments will be taken under consideration in future experiments, such as Paris3 and Marseilles1.

Peter Gluck wrote:
This is not the essence of what I wrote 2 days and more days ago. The results of this experiment -- as described above cannot be interpreted univoqually -- what's more (less) they are not interpretable:

a) because a part of water is evaporated the concentration of solid salts are increased and because a part of K2CO3 is decomposed, the concentration of solid is increased. Which wins? Who knows? [actually, fresh water was added constantly to replace what was evaporated in Paris1. In Colorado2 we did this periodically, to keep the total volume more or less constant.]

b) only CO2 is lost via decomposition/decarbonation, K remains in the solution or is lost via droplets entrainment and it is not possible to distinguish between all these facts- how much of the residue is carbonate, how much is hydroxide;

c) tungsten gives heavy, bulky, granular precipitate that is absolutely non-uniformly distributed in the reaction vessel. It stays at the bottom. You will not find a representative quantity of W in one cubic cm of sample extracted aleatory from the solution.

What I am trying to tell is that the material balance has to be performed for the integral quantities of all the participants: water, K, CO2, W- before and after the test.

I wrote:
Thanks for good suggestions, Peter. The bottom line is that a well equipped analytical chemist must be part of a better team of researchers. Let me make another suggestion for Paris3 and Marseilles1 experiments. It is based on what Pierre and Richard wrote to me in private messages.

Ideally one wants to operate under thermal equilibrium, that is when the dm/dt (rate of evaporation) remain constant. The way to accomplish this, in an open beaker during the electrolysis, is to use two power supplies, one feeding the electrolysis and another feeding the ohmic heater, immersed in the electrolyte. I am assuming one can measure the electric energy delivered to the cell by each power supply. One would have to add these energies to calculate the COP.

Suppose the mean dm/dt is evaluated every 3 seconds and the values are plotted versus time when an experiment is in progress. To keep the dm/dt constant one simply changes the voltage feeding the ohmic heater. If the dm/dt starts going up the voltage is decreased; if the dm/dt starts going down the voltage is increased. I think that keeping the dm/dt constant, within 2 or 3% would not be too difficult.

The temperature-versus-time plot could be useful below the boiling point. Stirring of the electrolyte is probably worth having in all cases. I thing that the last container in Colorado2 was too big for the power of 300-400 W, especially without stirring. One can probably work without stirring, at such wattages, when the beaker is much smaller, for example, one liter. Under such conditions boiling is sufficiently uniform to get a constant temperature within the cell.

Peter Gluck wrote:
All I want is to contribute to the success of this important experiment and I don't like to be kind of negativist critic. But you wrote: "Ideally one wants to operate under thermal equilibrium..." I think this is both useless and impossible:

- useless - CF/CMNS is created by dynamic dis- or non-equilibrium conditions; and it is not good to sacrifice the intensity of the process for the sake of the precision of the measurement (unfortunately this happens in many

CF/CMNS experiments!!! and this is what I call, unpolitely enough, metrologomania- focus on measurement instead of intensification.)

- impossible due to the huge inherent temperature gradient- 3000 degrees Celsius in the plasma and maximum 100 degrees Celsius in the water, the released gases-hydrogen, oxygen, carbon dioxide at some unknown intermediary temperatures It is such a mess that you need a bunch of angels in order to make some equilibrium. There is no symmetry in this cells, with our without stirring. The unique way to kind of equilibrium -- dynamic is a flow-through cell a la Philip KANAREV but this is an other way; let's keep us in our limits.

REMARK+ - an shortcut, absolutely independent from our troubles with droplets is the examination is the separation and careful examination of the W based residue -- what the devil is it? And the suggestion of our colleague HENRI LEHN has to be treated with priority -- it shows immediately if some nuclear phenomena takes place in the system. [Henri's suggestion was to perform isotopic analysis if iron presumably produced from another element during the electrolysis. That would certainly be an interesting experiment. But our goal was to accomplish something much less spectacular.]

I wrote:
Our goal in Colorado2 was to either to confirm or to refute Paris1 results. And we confirmed them. We showed that by performing a similar experiment one gets similar results, more or less. That was important. But now we are addressing a different issue. How do we know that the excess heat measured was not an illusion due to a prosaic effect, such as well known chemical reactions? That issue has not been answered satisfactory. Will it be answered in the new version of the appendix to our anticipated paper? I hope so. If not then we must wait for results from better-designed experiments. Colorado3, Paris3 and Marseilles1 experiments will probably be designed to show that excess heat is not an illusion. Those who are planning these experiments are probably paying attention to various suggestions made on this list. Are Colorado2 results publishable? I tend to be more and more pessimistc about this. But suppose Little-type tests, or titration tests, or some other test based on a setup similar to that used in Paris1 and Colorado2 show that the percentage of droplets of the electrolyte in the liquid was about 10%. That would be the answer to our question. It would mean that the probability of an illusion due to a prosaic effect is very high. We would have to rewrite the paper and publish it.

Michel Jullian wrote:
Peter I think on the contrary that Pierre's idea of operating the cell at constant thermal power, ensuring a more constant temperature distribution, is excellent. It will not hamper short term plasma instabilities in the least, and it will make sure that no thermal capacitance effects will interfere. Such effects can be responsible for illusion of non-unity COPs, don't you agree?

The scheme will also automatically maintain the vapor barrier I proposed to prevent ingress of possible atmospheric fuels such as N2 (forgotten in recent discussions it seems): stopping the discharge e.g. to replace the eroded cathode will make the ohmic heater step in automatically.

P.S.
Here are some nitrogen and oxygen based compounds which could form in a GDPE cell, together with their formation enthalpies [the units are kJ per mole of the product.]. Some of the formation enthalpies are negative, which tells us that the corresponding compound's formation from N2(g) and O2(g) from air (null formation enthalpies) dissolving into the solution and being processed in the plasma would be exothermic.

N2O(g) 82.05
N2O4(g) 9.16
N2O5(c) -43.1
N2O5(g) 11.3
NO(g) 90.25
NO2(g) 33.18
NO3 -(aq) -205

As I said many times before, it would be presumptuous for anybody to state that no chemical reaction involving gases from air (including common impurities such as ethanol, benzene, silicones etc...) can be responsible for the excess heat in a GDPE cell and it's plasma furnace. Hence my idea to block atmospheric ingress by maintaining a vapor barrier (less dangerous than a lid).

Peter Gluck wrote:
. . . N2 is in some air solved in water at the start. But ingress of air from outside is not possible- it has to go counterstream to the gases released from the cell.

Mitch Swartz wrote:
First, carbonates cannot be removed from the experiments unless the experiment is not exposed to the atmosphere. They enter the water as CO2 in hours no matter how many times the water has been distilled. Second, including for reasons of which we spoke briefly, it might be more important to determine your input electrical power with some accuracy and precision, by careful measurement of V and I, faster than the Nyquist threshold, before focusing on the chemistry at this point. Once you obtain excess energy of sufficient magnitude, then optimizing the chemistry could then be done on an active working system.

I wrote:
1) Is it not true that the concentration of the CO2, entering the LiOH electrolyte, could be estimated by a chemist? I also expect reaction rates to be estimable. That would allow to anticipate chemical contributions to excess heat. My expectation was that this was done and that estimated contributions were found to be orders of magnitude below what was actually measured. But I am no longer certain that this was the case. Please provide references in which impossibility of chemical contributions to excess heat was convincingly ruled by either Fleischmann or Mizuno.

2) Do not assume that everyone on this list knows what the "Nyquist threshold" is. My recollection is that in order to overcome this threshold the sampling rate should be several times higher than the highest frequency of the signal. As I wrote in unit #300 (at my CF website) the frequency of sampling does not have to be very high, when fluctuations are random. The only thing that counts is a sufficiently large total number of samples. One thousand would probably produce sufficiently reliable mean values of V and I. Do you agree with this, Mitch?

Mitch Swartz wrote:
We sample applied voltage, and the voltage across both the cell and the control, and the electrical current, between 100 Hz and a lower limit of, at least, 1 Hertz, for at least 70,000 samples per day, with most runs lasting several days. For some experiments involving specialized studies the sampling rate is much higher.

I wrote:
1) That seems to be perfect when fluctuations of V and I are random. By the way, imposing some randomness on the sampling frequency would extend the reliability of electric measurements to situations in which fluctuations of I and V are not random. I believe that the expensive instrument used by Scott Little, in Texas1 experiments, had the “built in” randomness of sampling. He will probably correct me if I am wrong.

2) What is the overall situation with excess heat from Mizuno-type experiments? The claim is clear -- excess heat is believed to be due to something unknown. That claim is being challenged on this list. It appears that not sufficient amount of information is available to exclude prosaic effects. The number of prosaic effects is large. In principle one should deal with them one after another. That can take a long time. Showing that one or two trivial sources of excess heat are impossible does not guarantee that another trivial source is not going to be suggested by a skeptic. But even a single acceptable evidence against the claim is sufficient to negate it.

Suppose that Little-type tests are independently performed in several laboratories. Presumably, the outcome of each tests gives the percentage of the electrolyte in the steam escaping from the open cell. Knowing that percentage one can calculate a correction for the COP measured. Suppose that corrected COPs turn out to be close to 1.0, in several laboratories. That would definitely negate the initial claim. The only way to rescue the claim would be to show that experimental or logical errors were made in evaluations of COP corrections. In other words, we are in a situation in which confirmation of a claim is much more difficult than showing the the claim is not valid. Justifying our positive

(extraordinary origin of excess heat) is much more difficult than justifying our negative (prosaic origin of excess heat).

That reminds me of two kinds of reasoning: inductive (from more specific to more general) and deductive (from more general to more specific). Conclusions drawn on the basis of inductive reasoning are often questionable. Observing 1000 white swans, and concluding that all swans are white, would be an example of inductive reasoning. Deductive reasoning, like in mathematics, is said to be more convincing; its reliability depends only on the reliability of the already accepted propositions, and on the absence of derivational mistakes.

Sorry for a philosophical digression. What we are after is not philosophy. We want to find the answer to a simple question, can Mizuno-type excess heat, as measured in Colorado2 experiments, be explained by a prosaic effect? At least one such effect has been identified on the CMNS list -- escaping of the electrolyte during electrolysis. Is it reasonable to assume that the COP=1.24 we reported was a mistake resulting from not taking that effect under consideration? The question will probably be answered in coming weeks.

Appended on 12/17/06
In preparing myself for another exciting electrochemical experiment I found this brief description of chromium electroplating: "Electroplating involves immersing the metal parts to be plated in a bath of chromium trioxide (CrO_3), typically prepared by dissolving crystalline CrO_3 in a mix of distilled water and sulfuric acid. A direct current is passed through the solution, and the resulting reaction leaves a deposit of chromium on the piece being plated. One problem in this process is the production of hydrogen and oxygen at the electrodes. The gas bubbles to the surface, creating a mist of the plating solution (which contains hexavalent chromium) that must be controlled. Additionally, mechanical agitation of the bath (used to improve plating quality) can also result in the release of this hazardous mist. . . " The fact that bubble of gas remove chemicals dissolved in the electrolyte is probably known to chemists. In the same way bubbles of steam remove some liquid electrolyte creating wet mist in air. Why were Mizono's and Naudin's results not explained by chemists familiar with wet mist?

I suspect that several CF researchers were aware of the possible explanation and decided to stay away from the Mizuno type effect. I would not do this; I would criticize conclusions based on erroneous assumptions. If Favaurque was aware of the trivial explanation of the "apparent excess heat" then why didn't he address the issue in the paper presented at ICCF12? The CNAM team was going to conduct tests similar to those of Scott Little. I suppose that this was done several months ago, considering the simplicity of the task. Do they still believe that the claim of Mizuno-type excess heat was real? I do not know; no one wrote to me about the outcome of investigations. What would I do if after presenting a paper at an international conference I later found that the claim was wrong? I would certainly try to correct the conclusion and explained why I no longer believe in it. That is why I am puzzled by the absence of messages. The appendix professor Fauvarque promised will probably not materialize. Something is not right. What a waste of time and money it was! But I did enjoy the adventure. We did our best but the paper cannot be submitted without valid chemical arguments supporting the claim of excess heat.

Appended on 2/12/07

Pierre Clauzon sent me the description of their new reproducible results from a better experiment; Perhaps this will be presented at the CCF13 (Sochi, Russia). Here is my reply: ". Hi Pierre, I am glad you continue working and this topic. Did you convince Fauvarque to address the issue of chemical origin of excess heat? You paper would be more convincing if it contained a section devoted to possible chemical reactions and the amount of heat they generate. Is it less than 1% of what you measure? Is it less than 10%? Is it only 50%? Such numbers, justified by an electrochemist, are essential at this stage of research. I would be very interested to read your paper.

I WILL WRITE MORE ABOUT THIS WHEN ADDITIONAL TESTS ARE PERFORMED.

This is a continuation of what was in the unit #301. What would happen to the CMNS field if the Mizuno-type excess heat is really shown to be an illusion? Not much. Mizuno-type experiments were only a small fraction of the EE (excess energy) sub-field. The CF and CT sub-fields (cold fusion and cold transmutations) cannot possibly suffer from an interpretational error in the case of GDPE (glow discharge plasma electrolysis). The only negative effect on the entire CMNS field can possibly come from a realization that it took ten years to find a trivial cause of the illusion. The fact that dominants researchers, Mizuno and Naudin, decided to remain silent when their conclusions were criticized will be noticed. People might generalize that all CMNS scientists are irresponsible. I hope that this will not happen.

At the beginning of unit #301 I wrote about preliminary results from Scott Little. Last night Scott send me final results. This morning these results were posted on the CMNS list (restricted Internet list for CMNS researchers). Three different methods were used to determine the percentage of the electrolyte: the method based on weight (already described in unit #301), the method based on concentrations of potassium (K) and the method based on concentration of tungsten (W). The XRF (X-Ray Fluorescence) instrument was used to measure the concentrations. How does this method work?

A narrow beam of X-rays is sent on a sample to be analyzed. The atoms in that substance are excited and emit characteristic X-rays. Like in optical spectroscope, individual elements can be recognized by unique characteristic X-rays. Scott optimized the instrument for the detection of peaks due to K and W. Once this is done he can compare intensities of characteristic rays, for different samples, with the intensity of a standard in which concentrations of atoms are known. An example of an XRF spectrum is shown in Figure 1. The abscissa is the wavelength of X ray photons while the ordinate is the number of accumulated counts. Characteristic wavelengths indicate presence of specific atoms while heights of peaks are proportional to concentrations of these atoms.

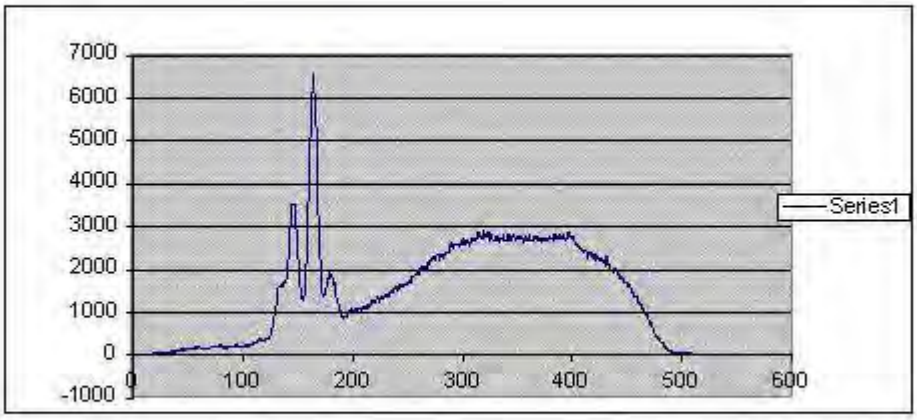

Figure 1
A typical X-ray fluorescence spectrum. Narrow peaks correspond to specific elements. The rest corresponds to the X-rays with which the sample was bombarded. The tail, under narrow peaks, is the background. Heights of peaks do not include that background. Numbers refer to arbitrary units.

Suppose, for example, that a particular peak is due K (potassium) atoms, as established by a preliminary calibration. How can this help us to determine the percentage of the electrolyte in the liquid lost during a Mizuno-type experiment? This can be done by comparing two spectra (a) that due to the sample of the original electrolyte and (b) that due to a samples of condensed liquid escaping from the cell during an experiment. The two samples must have the same volume, for example 27 cubic mm, and be analyzed under identical conditions. Suppose the height of the K peak in (a) is 8 units (after subtracting the background) while the height of the K peak in (b) is 2 units. Then one would say that concentration of K in (a) is 4 times higher than in (b). It is easy to consider two extreme cases: the escaping liquid is nothing but H_2O vapor and the escaping liquid is nothing but original electrolyte. In the first case the height of the peak for (b) would be zero. In the second case the height of the peak in (b) would be the same as in (a). The ratio of the peak height in (b) and the peak height in (a), multiplied by 100, is the percentage we are trying to establish. For the

hypothetical 2/8 ratio the contribution of the electrolyte to the escaping liquid would be 25%. That is the essence of the XRF methodology.

TABLE 1

sample	SCA conctr.	K conctr.	W conctr.	% drops by SCA	% drops by K	% drops by W	% 3 methods
#1	0.21	0.063	0.026	7.66	8.70	6.10	7.49
#2	0.12	0.041	0.026	4.38	5.66	6.10	5.38
#3	0.18	0.054	0.036	6.57	7.46	8.45	7.49
#4	2.74	0.724	0.426				mean = 6.79%
							st.dev=1.21%

Figure 2
Summary of results

Figure 2 shows the summary of results. It is based on what was posted by Scott Little last night. He provided numbers in the first four columns, I added additional columns to show the main conclusions. Sample # 4 was fresh K_2CO_3 electrolyte; its concentration was 0.2 M. Samples #1, 2, 3 were condensed liquids escaping from the electrolytic cell during a Mizuno-type experiment, similar to that in Colorado2. The four samples are identified in the first column. The next three columns show results obtained by using three different methods. Note that “SCA,” in the second column, refers to the method described by Scott at the beginning of unit #301. Numbers in that column are weights of solid deposits, in arbitrary units. SCA stands for a sensitive scale measuring the weights. Likewise, “K” in the third column stands for potassium. The numbers in the third columns are concentrations potassium atoms, in arbitrary units (heights of potassium peaks in the X-ray spectra). And “W” in the fourth column stands for tungsten. Numbers in the fourth column are concentrations of tungsten atoms in arbitrary units (heights of tungsten peaks in the X-ray spectra).

The columns 5, 6 and 7 show percentages of electrolyte in the escaping liquid inferred from numbers in columns 2, 3 and 4, respectively. That is what we really need to calculate the COPs correctly. Let me illustrate this by showing hoe the 8.7% result was obtained for sample #1 by using the K method. The concentration of K for the sample 4 was 0.724 arbitrary units. The concentration of K for the sample 1 was 0.063 arbitrary units. The peak ratio is 0.063/0.724 is 0.087 and this translates into 8.7%. Is this result consistent with what one finds by using the tungsten method. According to that method the percentage of the electrolyte in the escaping liquid is (0.026/0.426)*100 = 6.1%. And what was the percentage of droplets according to the “weight” method? The answer is (0.21/2.74)*100 = 7.7% Ideally all three methods should give the same result for the experiment in which sample #1 was collected. But measurements are not ideal. The mean results is (8.7 + 6.1 + 7.7) / 3 = 7.5, as shown in column 8. Results for the samples #2 and #3 were obtained in the same way.

The main conclusion is that the escaping liquid is not pure H_2O steam; several percents of the lost mass is probably removed as droplets of the electrolyte. We did not take this under consideration when COPs were calculated on the basis of data collected in Colorado2 experiments. All COPs would be significantly lower if percentages of the electrolyte in the escaping liquid was taken under consideration. After posting that conclusion on the CMNS discussion list (percentages from columns 5, 6 and 7) I found an interesting tutorial about steam at

http://www.spiraxsarco.com/learn/modules/2_2_01.asp

Here is a quote from it; it shows that the issue of "tiny droplets" is far from being new. ". . . Steam with a temperature equal to the boiling point at that pressure is known as dry saturated steam. However, to produce 100% dry steam in an industrial boiler designed to produce saturated steam is rarely possible, and the steam will usually contain droplets of water. In practice, because of turbulence and splashing, as bubbles of steam break through the water surface, the steam space contains a mixture of water droplets and steam. Steam produced in any shell-type boiler (see Block 3), where the

heat is supplied only to the water and where the steam remains in contact with the water surface, may typically contain around 5% water by mass."

I suppose this is a well known fact. But it is not mentioned in papers or Internet reports with which I am familiar. This can be explained by isolation in which CMNS research is done. A normal peer review process would certainly forced the authors to take the tiny drops effect under consideration. But reports published at yearly International Conferences on Cold Fusion, or over the Internet, are not scrutinized by selected experts, as papers published in mainstream journals. That is one of many undesirable results of exclusion imposed on the CMNS research about 15 years ago. On one hand no evidence of the pseudoscientific nature of CMNS was offered and on the other hand the field is not recognized as illegitimate. The situation is tragic; how can it be changed? Many think that this will suddenly happen as a result of commercial success; for example after a 100 kW generator, based on the CMNS effect, becomes available. I believe that focusing on scientific investigations, rather than on commercial applications, is more appropriate at this time. The CMNS field should be allow to evolve in the same way as other areas of science.

Let me return to conclusions drawn for Scott's results. These conclusions are based on a simplifying assumption which is most likely not valid. Ideally one need four samples #4, each removed from the electrolyte (with a pipette) only a moment before the experiment during which the corresponding sample (#1, #2 and #3) is condensed. We do not know what concentrations of the electrolyte were at the beginning of these experiments. I simply assumed that the concentration in sample #4 was the same as in the original electrolyte, and that fresh original electrolyte was used before each experiment. One can imagine several scenarios in which the inferred percentages of tiny droplets would be higher than shown in my table above.

For example, suppose that samples #1, #2 and #3 were extracted after a considerable delay. During that delay a significant fraction of the original electrolyte evaporated and replaced by distilled water. Knowing this one would correct concentrations of in sample #4 (for each of methods) , accordingly. The values would become smaller than those shown in my table. Suppose they become two times smaller. That would make all percentages two times larger. The mean of three means, 6.79% would become 13.58%. The COPs obtained during the three experiments, without accounting for the escaping electrolyte were close to 1.1. These values would have to be reduced to less than 1.0 for the 13.58% correction.

The bottom line is that conclusions made in my table are not reliable. Better experiments must be conducted. My suggestion is to use fresh electrolyte in each experiment, to extract samples of liquid electrolyte moments before experiments in which samples #1, #2 and #3 are extracted. Actually, three samples is hardly enough; we need 5 to 10 samples get reliable means and standard deviations (bars of errors). Will this be done in Paris3 and Marseilles1 experiments? I hope so. Will this be done to correct the COP's reported after the Colorado2 experiments (mean 1.24, st.dev = 0.13). It depends on us, the authors of the anticipated Colorado2 paper. I think that a simple CLA method of estimating percentages would be sufficient.

Appended in 7/13/06):

In a message posted today at the CMNS list I wrote that the problem that was labeled "tiny droplets" is far from being resolved. That contradicts what I wrote here earlier.

The mechanisms by which droplets of electrolyte are ejected are certainly worth investigating. But I would not start investigating them at this time, except in the context of our main question. That question is "should the total mass, M, lost during a GDPE experiment, be used to calculate thermal energy lost via vaporization?" The initial answer was "yes," the COPs were calculated from the uncorrected M in Colorado2. Then the question of tiny droplets was raised. We concluded that the mass used to calculate a COP should have been M-m, where m is the mass of escaping droplets of the electrolyte. Scott suggested a method for estimating m on the basis of weights of solid residuals, as explained at the beginning of unit #301.

That method was based on the expectation that the major component of solid remains, in two samples (initial electrolyte and condensed steam), would be K2CO3. But his XRF method revealed presence of tungsten. The original electrolyte cannot possibly contain a lot of tungsten; presence of W in that liquid was a proof that sample 4 was not

extracted from the initial electrolyte. That is why another set of samples must be analyzed. But a significant amount of W in solid remains from samples 1, 2, and 3 is alarming, as recognized by Peter Gluck. Let me elaborate.

First let me refer to the SCA method (explained by Scott at the beginning of unit #301). My conclusion, for example for Sample 1, was that m was 8.8% of M. But that was done by assuming that solid deposit in Sample 1 were chemically the same as in Sample 4 (the original electrolyte). But suppose that one half of the solid remains from Sample 1 was tungsten. Knowing this I would conclude that m was 4.4% of M, not 8.8%. And m would become 2.2% of M if 75% of the solid mass, in remains from Sample 1, were due to tungsten. To remove the ambiguity I would ask a chemist to extract tungsten from the Sample 1, before it is dried and weighted. Would the SCA method become reliable? Not really. It would be reliable only if other elements were not present, AND if only tiny droplets were responsible for the removal of the K and W, from the cell. Without these preconditions Scott's SCA method, as used in my table (see unit #302), could not be trusted, even if Sample 4 were extracted from the initial electrolyte. To make that method useful one must make sure that dominant non-water component, in all samples from condensed steam, is potassium.

But that is not all. How can we be sure that potassium, found in samples 1, 2 and 3, was removed from the beaker by tiny droplets? We simply assumed that this was the case. Suppose that K and W are removed from the cell as tiny colloidal particles present in the boiling electrolyte. The particles can be either dry or wet. Suppose they are dry. In that case a large concentration of K, found in the solid remains of condensed steam, could not be used as an indicator that m was large. One can easily have a situation in which $m \ll M$ while the concentration of K in the sample is not negligible. In other words, contrary to what I wrote in unit #302, we have no convincing evidence that the actually measured M must be corrected. How can one show that colloidal particles are "nothing to worry about?"

303) Well known reactions or something else?

Ludwik Kowalski; 7/12/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Unit 302 was devoted to possible interpretational error in calculations of excess heat. But that is only one of our problems. Suppose that all the data used to calculate the percentage of tiny droplets in wet steam are found to be reliable and that the COP (coefficient of performance) was indeed equal to 1.24, as described in unit #300. I will now assume that readers are already convinced that no experimental or interpretational errors were made when excess heat was determined. What is next? We must also convince readers that what was measured (excess heat generated at rates of nearly 100 W, and equal to 24% of the input energy) cannot be attributed to well known chemical reactions. Need for producing convincing arguments has been emphasized before. But no progress was made, I my opinion.

What follows are messages, posted on the CMNS list, devoted that topic. Most of it consists of short exchanges between Peter Gluck and myself. Other messages were from Mel Miles and Michel Jullian. All of them helped me to realize that the issue is not as simple as I imagined. Our messages are shown because I believe that they might be of some interest to others. Will Prof. J.F. Fauvarque, who is an electrochemist, produce a convincing appendix for our anticipated paper? I hope so.

Yes, I know that what is in all our messages can be reduced to one or two pages. But I decided not to do this. First because I am not a chemist and also because I believe that preserving sets of original messages is worth the effort. I wish more people participated; this list has at least several reputable electrochemists. They were probably too busy with their own problems. Perhaps they will later comment on what is now in this unit #303. I would be happy to append their contributions.

= = = = = = = = = = = = = = = = = = = =

On June 30, 2006, **Peter Gluck** (P.G.) wrote:
“Dear All, Given that the quantity of salt (actually K) lost is so difficult to measure, it has to be determined via a K balance - K initial vs. K left in the beaker. Without an absolute balance for H2O, K and CO2 we will have too much uncertainty for a credible scientific publication, I have said from the start of this discussion and I still think so. This is a difficult case - very hot gases in contact with a solution. The main perturbing factor is not chemical but physical - the loss of solution via entrainment. Gases at say, 3000 degree Celsius, can do a lot of things.

= = = = = = = = = = = = = = = = = = = =

Ludwik Kowalski (L.K.) responded:
Why should we exclude a possibility that what is escaping in tiny droplets of the liquid mixed with dry steam is [colloidal?] tungsten, or something else different from K? The method used by Scott (measuring masses) seems to be more universal. And it is very simple. Most laboratories have scales which are sensitive enough to detect solid remains. Confirming or refuting Scott's finding is important to all of us. One does not have to measure the COP to demonstrate that a sizable fraction of the lost mass is not pure water. A “solid remains” test, by the way, can be

performed by using stainless steel electrodes, as in many Naudin's experiments.

= = = = = = = = = = = = = = = = = = = =

P.G.:
Tungsten - and what happens with with it - c'est une autre chose- a different problem. The electrode is eroded and a precipitate forms. What is this? Based on my experience with the Cincinnati Cell I think the precipitate is mainly molten and frozen W droplets that capture inside a quantity of K. The droplets are formed by a known process that's called spark erosion. In the Cinci Cell, all the salts present are fixed physically in the molten metal. being removed from the solution, in the precipitate. The aqueous phase ceases to be electrically conductive.

The Cinci Cell has Zr electrodes - and Zr has a melting point of 2125 C, compared to 3680 C for W, but the mechanism is similar. However - to demonstrate this the precipitate has to be thoroughly analyzed. Anyway, it seems to be improbable that a part of the W electrode is flying with the droplets. Do we have soluble W present? And what's : "something else different from K?"

So **what is Scott weighing?** We know that a part of CO2 is also lost - carbonate, bicarbonate, hydroxide all can be present - K is the only thing measurable equivocally. In this case- the mode of thinking- including a hypothesis how the system works is as important as the execution of the experiment.

= = = = = = = = = = = = = = = = = = = =

L.K.:
That was my way of saying that "showing that amount of escaping K is negligible" is not the same as saying "what is escaping is pure water." The COPs were calculated by assuming that only pure water escapes. Now this assumption is being questioned.

= = = = = = = = = = = = = = = = = = = =

P.G. :
Ok, I understand what you say, but flying W could be easily detected. However we are able to know what happens in the system and we can decide - with certainty: there is excess heat, when, when not and perhaps later - why. The system is not awfully complex - the unique strange thing is the huge temperature gradient - molten W in contact with boiling water. How pyrolysis of water interacts with its electrolysis???? Is some synergy that causes the apparent excess heat?

= = = = = = = = = = = = = = = = = = = =

L.K. :
Yes, well known things and "strange" things do take place. The task is to summarize the well known reactions and to show that amount of heat they can possibly generate is orders of magnitude below what is measured. The system is not too complicated. And no additional experiments are needed to estimate chemical heat from known reactions. Perhaps I am wrong, but my guess is that for people with your background this should be trivial. It is only a matter of making reasonable assumptions about what is known and using the enthalpy table. Am I wrong, Peter? Can you perform such numerical calculations for us? Referees would certainly ask for convincing arguments that excess heat cannot be attributed to well known reactions.

P.S.
How much excess heat is generated in 5 minutes (a typical duration in Paris1 and Colorado2 test)? The answer is 100*5*60=30,000 J. How much gasoline must be burned to generate 30,000 J of heat? The answer is 30,000/50,000=0.6 grams. The heat of combustion is ~50 kJ per gram. Naturally, a Mizuno-type cell has no gasoline

in it. But what about other potential fuels? That is my question. How much can they possibly contribute to 30,000 J from "strange" things. My hope is that it will be a small fraction of one percent. But we need numbers from a knowledgeable chemist. Wishful thinking is not enough. Yes, I know that you will agree with this.

= = = = = = = = = = = = = = = = = = = =

P.G.:
No problem with the calculations. The problem is not with chemical phenomena. It is with a physical one, entrainment of droplets or mist by the very hot gases and this cannort be calculated yet. Many experimental data actually missing- composition of solution, of the precipitate, of the gases leaving the cell, we don't know a lot of things, sorry. No basis for a realistic calculation exists.

= = = = = = = = = = = = = = = = = = = =

L.K. :
That is not what I asked you for; sorry for not being clear. The incandescent temperature of the cathode belongs to "strange" things, not to well known and understood things. Here is my request to you again. Assume we are both 20 years younger and CF remains to be discovered.

A cell contains one liter of the 0.2 M K2CO3 electrolyte. The cathode is tungsten and the anode is platinum. The temperature is already 100 C. How much heat is generated when a constant potential of 30 V is applied for 100 seconds? Assume that a constant current of two amperes is flowing through the cell. Part of the answer is obvious, the thermal energy is 30*2*100 + X = 6,000 + X joules, where X is the energy released (positive or negative) via anticipated chemical reactions. Show, by making reasonable assumptions, that X cannot possibly exceed +60 J. That is what I am not able to do. How would you argue that chemical heat in only a negligible fraction of what is expected, Peter?

= = = = = = = = = = = = = = = = = = = =

P.G.:
What are the expected or possible chemical reactions? Participants are H2O, K2CO3, W - ignore glass-it is inert. Loci for reactions: cathode, anode, hot surface of W, plasma. Nature of reactions electrolysis and pyrolysis. What is unknown and I have not found in the electrochemistry literature - what happens at the anode- in principle carbonate, hydroxyl ions ions are going there but only (?) oxygen is formed. I have asked an electrochemist friend about anodic reactions at carbonate electrolysis but it seems they are not well known- at least in this special form of electrolysis.

However Mizuno has said he found some CO2 in the gases released from the cell too. How is this formed? Pyrolysis of K2CO3 is also a possibility. Carbonate captured by molten W is probably losing all its CO2. Anyway, I have hoped to have more data, systematic and complete after this series of experiments. A complete material balance could reveal what actually happens in this system. We still do not have such a balance.

The positive fact is that these reactions are all endothermic- with high probability endothermic. But unfortunately a physical phenomenon-entrainement of droplets of solution is a possible explanation of the calculated excess heat and we don't know its quantitative contribution to the results.

= = = = = = = = = = = = = = = = = = = =

P.G. :
I have already answered- we don't know exactly what happens at the anode, no pyrolysis is possible and in this case no droplets of solution are lost. Solution not boiling. (?) So what "anticipated chemical reactions"? This is a case of

logical error - replacing a case with a different one- not justified.

= = = = = = = = = = = = = = = = = = = =

L.K. :
1) Why trying to find out what happens in a simple case (30 V) before addressing a more complicated case (300 V with GDPE, pyrolysis and CMNS) is called a logical error? One learns by progressing from what is known to what is unknown. I am sure you know this.

2) I agree with "no droplets." In my illustration, the solution was boiling because the outside temperature was assumed to be 100 C. That was a simplification made to avoid changes of temperature inside the cell. Thus, what comes out is the H2O vapor mixed with H2 and O2. What is the upper limit of X, Peter?

3) In your earlier message I see "Participants are H2O, Na2CO3, W - ignore glass . . . " Na was probably a typing error. Right? But then I see " Pyrolysis of CO3Na2 is also a possibility." In any case, I asked you to ignore the 300 V case, in the first round.

4) I want to know if theoretically predicting the upper limit of X, in the case of 30 V, is possible. What is the answer?

= = = = = = = = = = = = = = = = = = = =

P.G. :
I am not able to find any exothermic reaction taking place in this system. In your opinion, what reactions have to be taken in account and used for the calculation?

= = = = = = = = = = = = = = = = = = = =

L.K. :
1) In other words, X must be negative. Right? That is an important point. I was not certain of this.

2) My opinion is that only dominant reactions should be taken in account. But I do not know reactions that accompany decomposition of water. And I do not know how to estimate their rates. That is why am asking you, a chemist.

3) Am I wrong in assuming that what is already known to chemists is sufficient to estimate X numerically? We will be nowhere without numbers. What is the value of X?

= = = = = = = = = = = = = = = = = = = =

P.G. :
I cannot speak for all my colleagues- by the way I am a chemical engineer, with Ph.D. in polymer technology. Now, for the real case I need the experimental results to know what reactions take place for all phases- solid, liquid, gases with analyses done correctly and professionally.

= = = = = = = = = = = = = = = = = = = =

L.K. :
OK, perhaps someone else will estimate the value of X for me. Knowing that it will negative is important but that is not a numerical answer. Please help !

= = = = = = = = = = = = = = = = = = = =

P.G. :
Who has tried till now? And what were the obstacles- I have explained that there more unknowns than equations.

= = = = = = = = = = = = = = = = = = = =

L.K. :
I was referring to an open cell with one liter of the 0.2 M K2CO3 electrolyte. The electrodes were W and Pt, potential 30 V, current 2 A and temperature 100 C.
Was it wrong to assume that the bulk of what happens under such conditions is well known to chemists?

= = = = = = = = = = = = = = = = = = = =

P.G. :
In this case, **very different from the case of plasma electrolysis,** the unique unknown factor is the fate of the carbonate ion at the anode, but there are no exothermic reactions conceivable. X is smaller than zero.

= = = = = = = = = = = = = = = = = = = =

L.K. :
Yes, you already wrote this, Peter. Can someone estimate the value of the negative X on the basis of what is known? If X is also negative when the COP is measured, then the apparent COP must be increased on the basis of the value of X. But how can we start talking about X at 300 V when we are not able to get it at 30 V?

= = = = = = = = = = = = = = = = = = = =

P.G. :
Let's take it stepwise - the main reaction is water electrolysis; its energy consumption depends on the temperature, current density, secondary reactions. How much of the electrical energy introduced in the system is used for water splitting? Theoretically!

= = = = = = = = = = = = = = = = = = = =

L.K. :
[Hmm, Socratic dialog?] Yes, this should be part of X. What is your answer? And what are contributions to X from other dominant reactions, based on anticipated rates?

= = = = = = = = = = = = = = = = = = = =

P.G.:
I think we are now near to the answer you wish. Normally electrolysis will take 1.48 V (approx.) from 30 V. The problem is with the "other dominant reactions"- I don't know what are they, where they take place and in which extent.

= = = = = = = = = = = = = = = = = = = =

L.K. :

Thanks Peter. You probably meant 1.48 eV, not V. Is this per atom of hydrogen produced or per H2 molecule produced? Assuming this is per molecule I concluded that X, for that reaction only, is -295 J. Do you agree?

a) 1.48 eV=1.48*1.6*10^-19 J = 2.36*10^-19 J Therefore X=2.36*10^-19 * number of H2 molecules.

b) How many molecules are produced when I=2 A and t=100 s? The charge is 2*100=200 C = 0.00208 faradays

c) IF (???) one Faraday produces one mole of H2 then the number of molecules is 0.00208*6*10^23 = 1.25*10^21

d) In that case, |X| = 2.36*10^-19*1.25*10^21 = 295 J.

e) That is nearly 5% of the electric energy supplied ! ! ! How significant can this be? Suppose a claim is made, NOT REALISTICALLY FOR 30 V, That the electric energy = 6000 while the thermal energy =7000 J. Dividing 7000 by 6000 one could say that the COP=1.17. But that would be wrong. The correctly calculated COP = 7000/(6000-295) = 1.23.

f) And that is only from one endothermic reaction, decomposition of water. We must also correct for other dominant reactions. I hope someone will calculate the value of X that accounts for all dominant reactions. Is it really so difficult for a chemist?

= = = = = = = = = = = = = = = = = = = =

P.G. :
No..., splitting of water needs~1.48 volts minimum, in practice 1.6-2.0 volts are used. The difference to 30 V is heating the solution. Approx minus 5-6% (1.5- 1.6 of 30) So much of the energy introduced is consumed for the main endothermic reaction. I don't know any exothermic reaction possible in the system. Do you agree?

= = = = = = = = = = = = = = = = = = = =

L.K. :
What is your value of X in joules? Volts are not units of energy. How many joules of energy were used in 100 seconds to produce hydrogen? I think that the answer has nothing to do with 30 V. It would be the same for 15 V or for 45 V. Only the total electric charge counts. Do you agree, Peter?

= = = = = = = = = = = = = = = = = = = =

Mel Miles (M.M.)wrote (7/1/06):
The minimum voltage thermodynamically possible for splitting water must be based on "Delta G" and is 1.23 volts at standard conditions. For enthalpy calculations, "Delta H" is used and is 1.48 volts at standard conditions.

On Jul 2, 2006, at 2:22 AM, Peter Gluck wrote:

What's the amperage?

1) Let me post extracts from what I already wrote. This is mostly for people like Mike C, who missed the beginning.

"A cell contains one liter of the 0.2 M K2CO3 electrolyte. The cathode is tungsten and the anode is platinum. The temperature is already 100 C. How much heat is generated when a constant potential of 30 V is applied for 100 seconds? Assume that a constant current of two amperes is flowing through the cell. Part of the answer is obvious, the thermal energy is 30*2*100 + X = 6,000 + X joules, where X is the energy released (positive or negative) via anticipated chemical reactions. Show, by making reasonable assumptions, that X cannot possibly exceed +60 J. That is what I am not able to do. How would you argue that chemical heat in only a negligible fraction of what is expected, Peter?"

It is not established a priori - depends on the experimental conditions.

2) Yes. And my request for X (number of joules) was for a specific (assumed) experimental conditions. Such concrete-operational approach is often helpful.

Excuse me- but I really think this hypothetical case is much too
different from plasma electrolysis in order to be of any use.

3) I strongly disagree. Why did I ask you to calculate X (positive or negative contribution of each dominant chemical reaction to excess heat) for 30 V? Because this is a case of basic electrolysis. It is not complicated by glow discharge plasma electrolysis. How can we be confident that our analysis of a more complex situation is correct if we are not able to get the answer for a much simpler case?

Mike Carrell has presented you a good idea that has to be taken
in account **when** finally we will have a **complete material balance**
of the Mizuno process.

4) Yes, we should not stop this discussion after the X is determined for a simple case. Recall what we decided to do this at the beginning. We agreed that "things" should be divided into two categories; well known and unknown. You used the term "strange" for pyrolysis and I placed the CMNS under the same category. The 30 V case was invented to deal with well known things only.

Till then, good old Kotarbinski, the father of praxeology, will roll
angrily in his grave. Let's be efficient and systematic, friends!

That is right, First 30 V and then 300 V. The Polish philosopher would agree with this. I am really disappointed that other chemists on this list do not help us to estimate X. The only thing we were able to do, so far, was to find the contribution of one reaction (decomposition of H2O) to X. Was my answer, -295 J, correct, Peter? Is it reasonable to assume that contributions from other known reactions (at 30 V) are negligible in comparison with that number?

= = = = = = = = = = = = = = = = = = = =

Michel Jullian (M.J.) wrote:
Ludwik: here is the explanation for the 1.48V (V, not eV) our friends keep throwing at you.

For water dissociation the enthalpy tables (e.g. those in my calculator) give:

H2O(l) -> 0.5 O2(g) + H2(g) - 285.83 kJ/mol (endothermic)

The delta H 286 KJ per mole is of course Avogadro's number NA (6.02*10^23) times the required electric energy to dissociate one single molecule, which is therefore:

E=(286 * (10^3)) / (6.02 * (10^23)) = 4.75*10-19 J per molecule

We also know that we need to circulate 2 electrons per molecule, so if V is the part of the electrolysis voltage used to dissociate the molecule and e is the electron charge 1.6*10^-19 C, another expression for the required electric energy (work) for the molecule dissociation is: E=V*2e. Thus:

V=E/2e = 4.75*10-19/3.2*10^-19 = 4.75/3.2 = 1.48V

Let me know if it makes sense, and if in this light you agree that the short paragraph I suggested for the "water electrolysis" section of your paper is sufficient.

= = = = = = = = = = = = = = = = = = = =

L.K. :
I do remember, vaguely, the dG and dH and T*dS. But how does this relate to the fact that 1.48 eV is the "electric energy to dissociate one single molecule?" Assuming that the 1.48 eV is the depth on the potential-energy-versus-distance plot what is the meaning of 1.23 eV mentioned by Mel yesterday? And what is the meaning of the 1.6 to 2.2 V range mentioned by Peter?

= = = = = = = = = = = = = = = = = = = =

P.G. :
1) [You asked] “and what is the meaning of the 1.6 to 2.2 V range?” That's because the efficiency of water electrolysis is only 70-50%. Working at more higher voltages does not help more.

2) [You asked about 295] In this very case 1.48 X 2X 100= 296 J and you are right. Endothermic reaction. As told I have no idea re possible exothermic reactions but my (our) worry is not reactions but physical phenomena as droplet mist entrainment. I acknowledge my ignorance or lack of imagination re exothermic reaction in the system at 30V.

= = = = = = = = = = = = = = = = = = = =

L.K. :
1) And what about endothermic reactions, Peter? My impression was that you gave up on calculating the X for them. Is it not true?
2) It appears that you are not the only chemist on this list who did not estimate contributions of well known chemical reactions to X. I was probably wrong in assuming that this should be a trivial problem for most chemists.
3) Do you agree that the Colorado2 claim, COP=1.24, would not be taken seriously unless it is accompany with a credible statement that "contribution of known chemical reactions to excess heat has been shown to be less than 1%," or something like this?

= = = = = = = = = = = = = = = = = = = =

P.G. :

I am contented with electrolysis as a great entoderm contribution and do not think there are other such reactions. What should motivate me to search for nonexistent reactions when I see that existent physical phenomena make us Great trouble? I need that complete material balance to understand the system. And we are discussing hypotheses as 30 V electrolysis. Not effective and not efficient. Tell please explicitly what real reactions do you will see analyzed dissected and measured.

The Colorado claim will not be taken seriously till we do not know what happens in the system, the real experimental system. We can exercise our fantasy beyond any limits but the paper has to be based on reality. My question is: How great is the contribution of the entrainment of droplets of solutions to the material balance? As soon I know it, plus we make the complete balance, our dialogue will continue. I am seeking for kairos not chronos at CMNS

= = = = = = = = = = = = = = = = = = = =

L.K. :
[Peter wrote] I am contented with electrolysis as a great endothermic
contribution and do not think there are other such reactions.

1) I am willing to accept this. --> The value of X is close to -295 J; contributions of other reactions to X are negligible. That means we can go to the next step. Suppose we start increasing the voltage. How does the 60 V situation, for example, differs from the 30 V situation? I am assuming that the current is still 2 A. The electrical energy delivered becomes 12000 J (instead of 6000 J in 100 seconds) but X remains essentially the same because the current is the same. Is this an acceptable expectation? I hope that other chemists on this list will agree.

[Peter wrote] The Colorado claim will not be taken seriously till we do not know
what happens in the system, the real experimental system. We can exercise our
fantasy beyond any limits but the paper has to be based on reality.

2) I hope you are not referring to the draft of our paper at:

http://blake.montclair.edu/~kowalskil/cf/300positive.html

Do you see any "fantasy" in that draft?

[Peter wrote] How great is the contribution of the entrainment of droplets of solutions
to the material balance?

3) Scott Little described a method by which this question can be answered. His preliminary answer is that droplets of the electrolyte contributed about 7% to the total mass lost during an experiment. That remains to be independently confirmed. . . .

= = = = = = = = = = = = = = = = = = = =

M.M. :
It is Delta G and not Delta H that determines if a reaction is thermodynamically possible at constant temperature and pressure (usual laboratory conditions). Consult any Physical Chemistry text for this result.

The splitting of one mole of H2O requires an applied energy of Delta G = +237129 Joules(1 J= 1 V*A*s). Converting to eV per molecule yields 2.45766 eV. Using Delta G=-zFE gives E=-1.22884 V at standard conditions(298.15 K temperature and 100000 Pascals pressure,slightly below one atmosphere). Note that 2.45766 eV and -1.22884 V differ by a factor of two but have different units and sign. The factor of two arises because the splitting of one molecule of water, i.e. H2O = H2 +0.5 O2, involves the transfer of two electrons for the electrode reactions at the anode and cathode. Note that these calculations are for splitting water into hydrogen and oxygen gases and not for the splitting

into H and O atoms.

To state in simple terms, multiplying the 1.23 V by 2 gives the minimum energy in eV(2.46 eV) required to split a single water molecule at standard conditions.

= =

M.M. :
Peter, for the LiOH-H2O electrolyte, I believe the reaction at the anode would be
2 OH- = H2O +0.5 O2 + 2e-
I cannot think of any other likely anodic reactions for the LiOH-H2O system. For carbonates, various electrode reactions are possible. This is especially true for the high voltages of plasma electrolysis. Reactions of the metal used as the anode should also be considered under the extreme conditions of plasma electrolysis.

= =

P.G. (A private message 7/13/06)):
Please feel free to use my name -- for everything I wrote and (hopefully) will write at CMNS..... Think about temperatures in plasma, and in the gases bubbling through the water phase -- in the vicinity of the cathode and the anode. This can explain a lot.

304) Recent representative messages

Ludwik Kowalski; 7/19/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

What follows are recent Internet messages posted on the CMNS discussion list. The debate started in 1989 is going on. On what basis are the authors of these messages accused of being pseudo-scientists? In my opinion their methods of validation are 100% scientific. They perform experiments, they discuss results and they develop theories, like in other areas of physical science. But our scientific establishment is practicing an unfair discrimination against the CMNS field. When will this end?

L.K. (7/14/06)
1) Yes, knowing the weight of every substance, before and after a COP test, would be highly desirable. But I would not do this without help from a competent, and well equipped, analytical chemist.

2) What did Fleischmann and Pons know about each chemical substance appearing and disappearing in their setup? Did they measure masses of these substances before and after excess heat experiments? Did those who validated their excess heat conclusions, for example, Longchamps et al., determine contributions of chemical reactions to excess heat? If so then I would very much appreciate a reference, or several references.

3) My impression, based on reading what others wrote about F&P, was that chemical contributions to excess heat was shown by them to be negligible, a very small fraction of one percent. But I was not able to find a paper describing this. Does it exists or everyone simply assumes that it exists?

Ed Storms (E.S.) (7/18/06):
Bockris published a paper addressing this concern. As any chemist can demonstrate, the components in a F-P cell cannot produce energy, they can only consume it because everything is in its lowest chemical state.

L.K. (not posted)
The reference given was a paper published by Kainthla et al. (in Hydrogen Energy,14, #11, 771; 1989). Bockris was listed as the last of eight authors. The title of the paper was "Eight chemical explanations of the Fleischmann-Pons effect." Here is how the issue was discussed by Ed Storms in review published in 2000. The title of the review was “A Critical Evaluation of the Pons-Fleischmann Effect;” it can be downloaded from the library at <www.lenr-canr.org>.

In the section entitled question 2.2, Ed wrote: **“**Can prosaic sources of chemical energy be ruled out? The hard-to-accept claim for a nuclear source is based, in part, on the belief that observed energy production exceeds any known chemical source. Therefore, the potential chemical sources must be examined. Before discussing this subject in detail, the reader should realize that a typical cell contains very few chemical components, all of which are stable with respect to each other. A chemical reaction can only be initiated by applying an electric current, a process which uses energy. Only after the water has been split into deuterium and oxygen can chemical reactions occur. This process causes several chemical reactions, including an uptake of deuterium by the palladium and slow deposition of lithium and platinum on the cathode surface. Each of these reactions involve very little energy. Strain energy accumulates in the palladium and small amounts of reaction products such as D2O2 can accumulate in the solution under proper

conditions.

These processes have the potential to store energy within the cell. Only release of stored energy can be used to explain the anomalous energy, which appears after many hours of electrolysis. The magnitude of such processes was addressed in several papers. Kainthla *et al.*[37] discussed eight possible sources, including recombination, which has been already discussed above. The other sources are the energetics of PdD formation, the energetics of PdLi formation, and energy accumulation as stress. Each of these was found to be much too small to account for even the smallest reported excess energy. Handel[38] proposed that heat could be pumped into the cell by a temperature gradient operating between the anode and cathode lead wires, *i.e.* a Peltier Effect. Two problems exist with this explanation. A significant temperature difference seldom exists between the two lead wires and the necessary difference between the Peltier coefficients of the wires must be unreasonably large to produce an observable effect. Most people use platinum for both wires, which would have a zero difference in the Peltier coefficient.

Balej and Divisek[39] compiled all necessary thermochemical values and calculated the energy involved in electrolytic formation of b-PdD. Measured energy using inert palladium is consistent with these values,[18] as is true of all negative studies. Berlouis *et al.*[40] reported a direct measurement of the heat of dissociation of PdH0.9, formed by electrolysis, using thermal analytical techniques. The result is consistent with values obtained by using other techniques. Consequently, no anomalies have been found in the energetics of b-PdD. However, it is possible for an unknown compound to form which, when decomposed, could give off the observed energy. While such a compound has been sought, it has not been detected. In addition, such a material would have to be able to store hundreds of megajoules of energy in the few grams of palladium normally used. If this were the energy source, the material would have an energy density greater than the most powerful chemical explosive.

12) McKubre, M.C.H., et al., Development of Advanced Concepts for Nuclear Processes in Deuterated Metals. 1994, EPRI.

Bockris is a highly respected electrochemist. I will accept his testimony (that the F&P excess heat could not be attributed to chemical reactions) on the basis of authority. Ed wrote that chemical composition of F&P cells is always the same. That is why other researchers took the initial findings for granted. Here is what I found about the above reference 12. According <www.tvwiki.tv/wiki/Cold_fusion> " McKubre et al. [12] have conducted careful inventories of chemical fuel and potential storage mechanisms in cold fusion cells, and they have found neither fuel nor spent ash that could account for more than a tiny fraction of the excess heat." That is also reassuring. Mike McKubre is one of those researchers whose excess heat data, in F&P type cells were highly reproducible at levels below 2 W.

Post Scriptum: Referring to the above quote from the wikipedia, Mike McKubre wrote: " On several occasions we did find and reported (at ICCF8 and elsewhere) a nuclear "ash" quantitatively (and temporally) correlated to the excess heat - Helium-4. With regard to chemical "ash" our statement is actually stronger than the one written above. We never saw any evidence of any net chemical reaction accompanying excess heat production. The statement of less than 1 part in 100 (or 1000) refers to any conceivable chemical reaction of the cell constituents - no matter how unlikely or unobserved."

5) Generally speaking, one can identify two ways of dealing with the issue of what is going on in a F&P cell. Let me name them "negative" and "positive." The "negative" approach, suggested by Peter and Michel, (see unit #303) is one of them. The best one can do with that approach is to produce convincing data that excess heat is not due to a well known chemical process. The"positive" approach would be to show that excess energy can be explained by a particular kind of a process, for example, fusion producing neutrons, protons, tritons and helium-3. What must be done, experimentally, to convince ourselves that excess heat is indeed due to emission of such particles? One must show that the total number of nuclear particles, and their energies, match the measured amounts of excess heat.

Many attempts in that direction have been made in the past but they were not successful. Excess heat was always found to be zillions of time larger than what could be made consistent with observed emission of neutrons, protons,

tritons and ^{3}He. Another particular process that was investigated was cold fusion in which dominant products are atoms of ^{4}He. Such process is extremely rare in hot fusion (collisions of isolated deuterons) but that does not mean that it must also be rare in cold fusion (where deuterons are not isolated). I know that accumulation of 4He has been studied by many researchers and that the rate of accumulation of excess heat (about 24 MeV per atom of ^{4}He) was found to be consistent with the expectation. It is well known that the mass-energy of two deuterons exceeds the mass-energy of one ^{4}He by 23.8 MeV.

In my opinion the "positive" approach -- showing that excess energy measured matches amount of "ashes" (products of specific processes) is likely to convince mainstream scientists that something unexpected is going on, than the "negative" approach suggested by Peter and Michel. People who studied accumulation of ^{4}He reported high reproducibility of results. Taking this for granted, I would recommend (if it were up to me) the following approach. Select five recognized experts in ^{4}He detection and ask them to replicate already reported results. If at least one of them confirms the ~24 MeV of excess heat per one ^{4}He atom then it would be reasonable to assume that the effect deserves further investigations. My expectation is that all five experts would report proportionality between accumulated excess heat and accumulated ^{4}He ash. The energies per atom would probably be different, for example, ranging between 15 and 35 MeV.

Even 5 MeV per atom of an ash would be six orders of magnitude higher than what is possible with a chemical reaction. But what would one have to say if reproducible results were 1 to 5 MeV per atom? That would tell us that ^{4}He is not produced via direct fusion of two deuterons. We would say that another nuclear process, or a sequence of processes, is involved. How else can atoms of a new chemical element be produced?

Post Scriptum
Accumulation of ^{4}He was one of the three categories of topics identified for the 2004 DOE review. The panel of appointed experts was asked about "production of ^{4}He as an ash associated with this excess heat, in amounts commensurate with a reaction mechanism consistent with D+D --> ^{4}He + 23.8 MeV (heat)." Unfortunately, not a single reexamination request was made by the DOE. What they did was to collect comments from experts who were asked to read existing reports. I was very disappointed by this. Here is how comments made by the appointed experts were summarized in the DOE report:

"The hypothesis that excess energy production in electrolytic cells is due to low energy nuclear reactions was tested in some experiments by looking for D + D fusion reaction products, in particular ^{4}He normally produced in about 1 in 10,000,000 in hot D + D fusion reactions. Results reported in the review document purported to show that ^{4}He was detected in five out of sixteen cases where electrolytic cells were reported to be producing excess heat. The detected ^{4}He was typically very close to, but reportedly above background levels. This evidence was taken as convincing or somewhat convincing by some reviewers; for others the lack of consistency was an indication that the overall hypothesis was not justified. Contamination of apparatus or samples by air containing ^{4}He was cited as one possible cause for false positive results in some measurements." Why was a reexamination of the effect not ordered by the DOE after some of the panel experts reported that the evidence was convincing?

Jacques Dufour (J.D.). . . the worst of our enemies is ourselves. We think our experiments perfect, we are sure that we have answered theoretically all the questions. This is very far to be true. Submitting the work you do to critics and having the lucidity to accept remarks when they are valuable is essential. It is a great error not to seak interaction with people on the ground that they are our enemies and that we don't have to take into account their advices. . . .

E.S.:
I agree with Jacques on a few of his points. Of course talking with people who do not yet accept cold fusion is important. It is essential to understand just what they lack to allow them to arrive at a rational conclusion. We are long past the situation where the reality of cold fusion is in doubt. Too many of the required questions have been answered and too many studies from which the main errors have been removed have been reported. I'm in the process of examining this literature in detail for a book, so I can say with confidence that the claims are true. I'm also aware that most people who do not believe are simply ignorant of this extensive literature, as are many people in the field.

Consequently, when dealing with skeptics, you have to realize you are dealing with someone who has a very limited and selective knowledge. Their attitude of rejecting what you say because you are a believer, hence can not be trusted, is totally illogical. All scientists have basic beliefs based on what they have been taught or have observed in nature. These beliefs do not make them untrustworthy when describing the evidence for these beliefs. ..... The challenge now is to evaluate what is real and what is not real in an effort to understand just how the effect works. We have a mixture of good and bad work, and a mixture of bits and pieces of the total puzzle. The challenge is to sort this collection into pieces that make sense and can advance our understanding about how the amazing process works.

Michel Jullian (M.J.):
Ed to reconcile your two statements above, there must be at least one experiment of which you are 100% sure, which one is that?

E.S.:
Well, aside from my own work :-), I pick the McKubre heat measurements, the Iwamura transmutation studies, the Miles helium studies, and the Claytor tritium studies. I pick these because the work is so well done and described to allow critical evaluation. Many other studies would be considered very good once the CF phenomenon is accepted. All of the radiation studies are important because it is impossible to miss radiation and none should be produced by the low energy CF cells. All of the neutron measurements are useless and irrelevant to the issue. In addition, 185 credible heat measurements, 58 reports of significant tritium, and 67 studies of transmutation are published. Any other field of study would be embarrassed to have rejected this much work by well known and competent scientists.

J.D.:
. . . I have tried to pass the message that the most important thing in the field was the heat measurement and that the interpretation would come later. But every body sticks to the nuclear interpretation.

E.S.:
All of the methods are difficult to make work every time. When the effect is made to occur and the experiment is well designed, any of the methods would be accepted by normal scientists. However, some methods are more complex than the others, the Mizuno method for example. Consequently, this method is more difficult to demonstrate, as you are discovering. The best method is to design a good calorimeter that you can demonstrate is accurate, use it to measure heat by the classic F-P approach, and measure another expected nuclear product at the same time - helium or radiation for example. If you can show a one-one correlation between heat and another nuclear product, the work gains in credibility, but also gains in difficulty. I suggest, no matter how well you do the Mizuno experiment, the apparatus will be too complex to convince the average person. The work needs to be understandable by an average 10 year old for many people in physics to believe the results.

L.K.: (7/18/06):
"..... I suppose that many of the 185 heat measurements, mentioned by Ed, were in electrolytic cells similar to those used by Fleischmann and Pons. As far as I know, excess heat, in highly reproducible experiments, was most often generated at rates below two watts. Is this correct? And the emphasis was to show that excess heat was not an illusion due to experimental errors.

What I would like to see are reports claiming that excess heat was extraordinary. That is the most interesting (and most controversial) part, as far as science is concerned. Like Jacques, I am willing to wait for convincing demonstration that the measured excess heat is nuclear. Showing that it cannot be explained by prosaic effects would already by a big step forward. I am taking it for granted that calorimetry was essentially error-free, and that electric energy supplied to cells was measured properly. But how did the authors of reports convince themselves, and others, that their highly reproducible results could not be attributed to a chemical reaction? Which reports are the most convincing in that respect?

M.J.
Ludwik, I disagree with your comment that calorimetry and input power measurement can be trusted and only chemical heat should be distrusted, we must check carefully every single possible artefact, or the house of cards falls

down. . . .

L.K.:
1) Nothing should be trusted in a single report. But tens of highly qualified scientists reported positive excess heat results. That is why I am confident that excess heat, generated at the rates below 2 W, is not an illusion due to experimental error. Experimental errors would produce as many positive as negative results. My impression was that results above 2 W are not yet reproducible in F&P cells. Please correct me if I am wrong.

E.S.
1) That is correct. [many of the 185 heat measurements, were in electrolytic cells similar to those used by Fleischmann and Pons]. However, several other methods have been used including low energy plasma and exposure of the NAE [nuclear active environment] to ambient gas pressure.

2) [Ludwik wrote]: "As far as I know, excess heat, in highly reproducible experiments, was most often generated at rates below two watts. Is this correct? And the emphasis was to show that excess heat was not an illusion due to experimental errors." A wide range of maximum heating power has been reported. However, the results can only be properly evaluated when the expected error is included. For example, excess power of 5 mW is reported, but this was obtained using a calorimeter accurate to a microwatt. The issue is not the amount of power, because this is determined by the amount of NAE present. The interesting result is how the NAE can be produced.

3) If you study the Miles work about the He-heat relationship and add the 6 other studies that agree with his results, you will see that a nuclear reaction has to be the explanation.

4) Not every study can prove the results are not chemical or are even caused by a nuclear reaction. However, if someone does an experiment and gets the same anomalous result as someone who has shown their anomalous results to have a nuclear source, it is reasonable to conclude that you both are seeing the same phenomenon. After all, when chemists study a chemical reaction, they are not required to prove each time the existence of atoms or the laws of thermodynamics. At some point, people acknowledge the reality of the underlying process.

L.K.:
1) I suppose that demonstrating the non-chemical origin of excess heat generated at the rate of 5 mW would be much more difficult than at 1000 mW.

2) In an earlier message you wrote: "Two issues exist that are frequently confused. The first is whether an anomalous effect has actually been observed. .....The second issue is the process causing the anomalous behaviors." That is true. I am familiar with many reports describing anomalous effects; emission of charged particles and Iwamura's transmutations are good examples. My question was about something very different. I asked for chemical data supporting the anomalous nature of excess heat generated in highly reproducible experiments, such as those reported by McKubre. As I wrote before, I believe that reality of excess heat was demonstrated in these experiments. But what was done to show that excess heat measured could not be attributed to prosaic effects?

3) You also mentioned anomalous helium demonstrated by Miles, and by other researchers. Generation of 4He at the rate of about one atom per 24 MeV of excess heat is indeed a very convincing argument that a nuclear process was taking place. You are correct that this automatically rules out chemical explanations. Even ten times lower rate would exceed the expected chemical rate by six orders of magnitude (MeV versus eV). I wish we were sufficiently equipped to demonstrate the unusually high rate of accumulation of reaction products in Colorado2. But we were not. The only method available to us, if we want to demonstrate the anomalous nature of excess heat, is chemical analysis of reaction products, as argued by Peter Gluck. Our manuscript would have no chance of being published without an appendix with arguments against trivial origin of excess heat. Do you agree?

E.S.:
1)all of the F-P cells use the same material, the same chemical arguments apply to all of them, as above.
2) [Concerning "our manuscript would have no chance of being published . . "] The Mizuno cell is more complex chemically than the F-P cell. Consequently, it requires more discussion. As I suggested before, the best defense is to

prevent anything from leaving or entering the cell. This way, chemical effects can be easily ruled out.

Mitchell Swartz (M.S.):
Referring to F&P cells Ed wrote that “everything is in its lowest chemical state.” Actually this is not correct. There is energy given off by the loading of palladium by the deuterons which we have been measuring for years with our sensitive calorimeters. That heat given off with loading ranges from circa 50 to several hundred joules or so, but in any case the heat given off is DWARFED by both the excess energy during the experiment and the "heat after death" (when the systems are correctly operated at their optimal operating points), and is recovered when deloading occurs. However, this demonstrates that they are not in their "lowest chemical state" at t=0+.

Also, since the Gibbs free energy involves BOTH enthalpy and entropy, I do not believe all other materials are in their lowest chemical state during the run. For example, I reported that both gold, palladium, and platinum anodes decompose very slightly producing an overlay on the cathode which is capable of, in some cases of palladium with heavy water (and certain other cases) of producing slight excess heat (as I discussed at LENR-2 Texas, which you attended, and thereafter termed "crud"). FWIW that slight excess heat is DWARFED by the excess heat achieved when the reactions are correctly carried out.

In addition, there appear contamination issues arising from the containers (etc.) which are an entropic effect also demonstrating that the systems are not in their "lowest chemical state". However, again, although the contamination markedly lowers the excess heat, as we demonstrated at ICCF-10 (2), and although the energy involved is DWARFED by the excess heat achieved when the reactions are correctly carried out, it is not strictly accurate to make the claim that all materials are in their "lowest chemical state" at t=0+.

The bottom line is that careful calorimetry with full controls, waveform reconstruction, and time integration, and with monitoring of loading energy, etc. is required to prove excess heat. Handwaving alone is probably not sufficient.

E.S.:
Actually, formation of PdD produces energy but the need to decompose D2O to get the deuterium results in a loss of energy, i.e. the net effect is an endothermic reaction.

M.J.:
. . . We don't need tens nor thousands of experiments, we need a single one that anyone could trust 100%, agreed? Do we have it?

E.S.
Actually, five criteria determine what is accepted as reality in science.

1. As you say, a perfect experiment would be nice. Unfortunately these are very rare in all fields of science. Clever people can always imagine alternative explanations. Nevertheless, we have several that are close.

2. A collection of measurements that all show the same patterns of behavior. For example, everyone who makes the necessary measurements sees that greater heat is associated with a greater D/Pd ratio.

3. Finding measurements that give values in agreement with other independent studies. For example, the measured He atom/watt-sec agrees with energy values calculated from mass defect.

4. The measurement agrees with accepted theory.

5. 100% reproducibility is possible.

Criteria #2 and #3 have been met by several different types of behavior. We are working toward the last two. No observation ever starts out meeting all five criteria, yet novel observations are frequently accepted and studied until all five criteria are met. Why should cold fusion be different?

L.K.:
. . . Fleischmann's papers show no evidence of analytical studies of reactants and all products (before versus after). Was such analysis perform for at least one McKubre's experiment ? You referred to them as highly reliable. Perhaps Mike will tell us something about this.

Mike McKubre (M.M.):
Our experiments were designed so that the issue of potential chemical energy sources could be very easily bounded and a complete (or sufficient) chemical balance was attained in every case of reported excess heat. I discussed this many times in tedious detail in 1989-92 but let me summarize here.

The SRI heat producing cells were thermodynamically closed, physically sealed, and contained only Pt (anode and wiring), Pd (cathode), D2O + LI (electrolyte), fused silica and PTFE (walls and inner construction). Sometimes there were known trace additions of deliberate additives (most commonly Al and Si, occasionally B and Be - the last I would not advise). The recombiner catalyst was Pt (or Pd) on alumina. Cells were precharged with D2 gas in an amount calculated to leave a positive gas pressure (sometimes large - mostly small) after full D/Pd loading.

It is standard calorimetric procedure to ensure that final state = initial state. This was done by deloading the Pd and checking that the electrolyte concentration (directly reflected in the conductivity) is the same at the end as the beginning. With these constraints it is easy to show that the sum of all chemical reactions is VERY small compared to the two elephants: the integrated input IV and any excess heat. I have often stated publicly that the ratio of excess energy we observed to the sum of all conceivable chemical sources is 100 - 1000 (or more). A shorthand way of understanding this is that we have measured excess energy corresponding to more than 1000 eV / Pd atom* [footnote below].

Both Ed & Mitch have spoken about the transient enthalpy of D loading (then unloading) in Pd. In our scheme the net enthalpy in both directions is very nearly zero. When D is derived from D2 the loading process is at first exothermic (the partial molar enthalpy negative). That is, the D prefers to be inside the Pd until a loading of D/Pd~0.725 (I am working from memory here). At this point the sign reverses and it becomes increasingly more difficult (endothermic) to insert each D atom** [second footnote]. At a loading D/Pd ~ 0.95 (or maybe a little higher) the integral enthalpy is zero. Independent of sign the one way enthalpy is (as Mitch stated) DWARFED by input and excess enthalpies. In

the method that Ed described where cells do not operate with excess D2, all loaded D must come from D2O (H2O) and Ed is correct that the net enthalpy of D (and H) absorption is always negative.

Each experiment needs to be evaluated separately and no general rule should be assumed to apply. Even as (presumably) competent electrochemists with colleagues who are (presumably) competent analytical chemists we chose at the outset to make our lives easier by designing simple experiments with few moving (i.e. reacting) parts. The analytical difficulties of open cells, particularly those designed (or permitted) to have carbonate electrolytes are much more severe. Without direct experience I don't feel qualified to discuss them.

* Our maximum is >2000 eV per Pd atom - Energetics have recorded over twice this number.

** This was a point discussed by Fleischmann & Preparata at ICCF5

M.J.:
Could we try and concentrate the _whole group_'s brain power on achieving 1/, see if together with all the collective know-how and creativity and mutual criticism we are capable of unleashing we can design this irrefutable excess heat experiment we all need? It seems to me we already have some great building blocks waiting to be assembled.

Ok, depending on the original contributions which will be actually used (which can only be determined when the job's done) the author list may end up several tens of names long (alphabetical order obviously), and the Nobel prize podium may be overcrowded, so what?

E.S.:
The problem with your idea, Michel, is that two problems need to be solved. One problem is to design an experiment without significant error. This is the problem you are addressing and the one that can be and has been largely solved. The other problem is the creation of the nuclear active environment. This is presently produced by nature when she is in a good mood, which is not very often. No one knows how to make this material on purpose, although some methods are more successful than others. Anyone who figures this out will have caught the brass ring and will obtain a patent before discussing the method. Consequently, your suggestion will not be followed.

L.K. (7/19/06):
1) I still think that this "irrefutable excess heat experiment" might be based on a Mizuno-type cell. Why? Because 50-100 W is very impressive. The most challenging task, for the moment, is to convince ourselves, and others, that excess heat cannot possibly be due to well known chemical reactions.

2) I would be happy to see Mizuno alone on that podium. Or Fleischmann+ Pons, or anyone else who made an essential contribution. The most important thing is to end the unjustified discrimination against the CMNS field. We are not pseudo-scientists; our motivation is to contribute to scientific and technological progress.

M.J.:
I too think the magnitude of the effect makes GDPE the best candidate, but Ed doesn't, mainly because, as often discussed here, it is difficult/dangerous to close the system as would be required for a total chemical balance. . . .

E.S.: (7/20/06)
Michel, I have been designing experiments in an attempt to eliminate significant error for the last 17 years in this field. I have designed and built most of the calorimeter types used in this field. Even if I say so myself, I probably know more about calorimeter error than anyone in the field, except perhaps Mike McKubre. I now have two very sensitive and very error-free Seebeck calorimeters. So, your suggestion has been implemented. The problem is to find a sample that actually makes heat.

L.K (not posted).;
Why is this a problem? If I had a working F&P-type cell I would certainly bring it to you. Most researchers would probably be very happy to cooperate with you.

E.S.:
1) [L.K., referring to W/cm^3] asked: “Does this mean that arguments presented by Bockris and his coworkers (in the paper you recommended) should now be rejected?” The use of the term W/cm3 and the Bockris arguments have no relationship to each other. W/cm3 is a method to normalize the power to the volume of the sample, as I said. The Bockris arguments apply to the energy being produced by chemical processes.

2) [L.K. wrote about eV/atom.] “ . . . The ratio turns out to be much larger than 1000 eV/atom. What is wrong with saying "a chemical reaction cannot possibly produce such result?"

You are assuming there is a relationship between the amount of metal removed from the cathode and the amount of energy produced. In fact, the energy was produced by a nuclear reaction and material was lost by a chemical-mechanical process that is completely independent of the nuclear reaction. The absolute amount of energy is the only important value.

L.K.
1) OK, I understand E.S.. Division by a constant number does not change the ratio of two heats (chemical/excess). The answer is in the ratio, not in power densities.

2) Concerning “The absolute amount of energy is the only important value.” That depends on the context. My purpose was to rule out a possibility that excess heat might be chemical. In that context I assumed that tungsten is a chemical fuel. This assumption cannot possibly be defended because the eV/atom are too high. What is wrong with this method of reasoning? Yes, I know the same should be done for any other chemical substance whose mass was reduced considerably during the experiment. Chemists in Paris will probably do this. I suspect that eV per atom of consumed potassium would also not be consistent that K is a chemical fuel. W and K are probably the only substances whose masses are reduced significantly when excess heat is measured. But that must be verified by chemists. Our Colorado2 appendix would be sufficiently convincing if masses lost are determined and if eV/atom are shown to be excessive for every potential chemical fuel. Will this be done in Fauvarque's lab? I hope so.

J.D.
Gentlemen, there is obviously something wrong in your calculation of the energy of reaction per atom. I assume the cathode is palladium (atomic weight : 106,42). So the number of mole involved is 5/106,42 = 0,047 mole. This gives an enthalpy of reaction of some 50000/0,047 = 1064000 J/mole (1064 kJ/mole which is close to the upper limit for chemical reactions). If you want the figure in eV per atom, then number of atom 0,047*6*1E23 = 2.82*1E23. Energy en eV = 50000/1.6*1E-19 Hence energy in eV per atom : 11,08 eV.

L.K.
I wrote: ". . . Assume that 15 grams of the cathodic metal is found at the bottom of the cell. That would mean that only 5 grams of the cathode reacted. " I have no idea how much metallic W was really found at the bottom of the cell by Pierre. 5 grams was purely hypothetical. **I am sorry for not making this clear.** The only numerical calculation performed was 20-15=5. The rest was speculation.

If 5 grams leads to 11 eV/atom, as calculated by Jacques, then 0.05 grams would lead to 1100 eV/atom. According to Mizuno, if my memory can be trusted, 99.99% of lost tungsten was recovered as metal, at the bottom of the cell. The number 1000 eV/atom was posted by Mike; that is why I wrote that 1000 eV/atom would be highly convincing. The main point was to show that we do have ammunition to argue that the COP = 1.24 was not due to chemical processes. It is a matter of measuring, or estimating, masses of lost chemical substances. I hope this path will be followed.

E.S.
Ludwik Kowalski wrote: “That depends on the context. My purpose was to rule out a possibility that excess heat might be chemical.” Yes, I understand the purpose. You need to show that the TOTAL amount of energy is greater than the sum TOTAL of all possible chemical reactions producing heat. This means you need to identify all chemical reactants and products, and determine their quantity. This is relatively easy because only a few reactants are present and their reaction products are well known, or at least can be easily determined. You don't even need to speculate about what is made. This is normal, well understood chemistry. Forget about eV/atom. This has no meaning unless it is associated

with a demonstrated chemical reaction. For example, you might make a little WO3 and when this is divided into a lot of heat the result is a big ev/atom value for that particular ratio. But this means nothing because the actual heat producing reaction might generate many atoms you have not identified.

L.K. (not posted):
I still think that the only chemical substances to be considered, for the eV/atom, are those that were present before the experiment, and whose masses were reduced considerably. The WO_3 is the intermediate product. But all this makes sense only in the context of ruling out chemical origin of excess heat. Heats of combustion of most fuels are below 5 eV per atom, or per molecule. That is why numbers like 1000 eV/at should be convincing.

Let me show another exchange of messages that appeared on the CMNS yesterday. They show that list members are aware of people who might be tempted to exploit the existing controversy and promote nonscientific agendas. Most CMNS researchers do not want to be associated with such agendas.

L.K.:
Am I the only person to receive this message? It came this morning.

Dear Sir,

Glad to see your article. Now we have some news and I hope you'll be interested. Our web site is <http://www.faraday.ru>

Moller and Naudin are wrong way. Best regards, Alexander V. Frolov Faraday Lab Ltd.

Who is Frolov? I do not remember communicating with him before. But I clicked on the above link and read about two commercially available products. Very impressive, if true. Comments and information will be appreciated.

M.J.
I heard of Frolov in the field of "Lifters" (there was talk of a "Frolov hat" device supposedly exhibiting "reactionless" forces or something of the kind), as far as I can tell he is at least as much "wrong way" as the competitors he denigrates. I suggest to wait until he actually delivers what he promises before buying any "fuel less" electricity generator from him :) You could also try a Google search . . .

William Beaty (W.B.):
A. Frolov is a longtime member of the fringe science community. In Russia in ?1996? he organized a conference on CF, antigravity, "torsion" and other fringe physics. My overall impression: he is not a scientist, he lacks the brutal self-honesty required.

Re. the products. The one on the left looks suspiciously like the "Potapov device," a water heater based upon a pump driven by an electric motor. It was claimed to put out more thermal watts than the motor watts input. Potapov brought one to the USA for informal testing, and it only gave normal results with no anomalous excess output. Yet his company was selling them in Russia without being able to support their claims that it was better than a simple electric water heater. We never decided if Potapov was running a scam, or if he'd fallen into "pathological science" and was honestly fooling himself. And that Frolov is selling a perhaps-fradulent device doesn't surprise me. . . .

305) Science or Proto-science ?

Ludwik Kowalski; 7/28/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Results from interesting experiments were recently described in Physical Review Letters (PRL **96,** 034301, January, 2006). The paper, "Nuclear Emissions During Self-Nucleated Acoustic Cavitation;" was published by R. P. Taleyarkhan et al. The six authors, affiliated with four institutions, observed nuclear particles emitted from a small jar with a liquid. They believe that what was observed was ordinary hot fusion; the main argument for this was emission of 2.45 MeV neutrons, gamma rays and generation of tritium. The neutron emission rate is reported as between 5000 and 7000 per second. That is indeed much more than in the normal background due to cosmic rays.

The fact that hot fusion can be induced in a small jar, as opposed to a large tokamac, is indeed remarkable. But the jar was not an electrolytic cell, the authors do not claim that what they studied was cold fusion. They think that stellar temperatures are created in tiny cavitational bubbles containing deuterons. The test cell -- height ~15 cm and diameter ~8 cm -- contained carefully selected mixtures of liquid, such as deuterated benzene or deuterated acetone. A standing ultrasonic wave (maximum amplitude of 15 bars) was established in the jar by using a lead-zirconate-titanate piezoelectric driver ring. A small amount of natural uranium nitrate was dissolved in the liquid to induce generation of desirable bubbles. Nuclear products were observed in liquids containing deuterium but not in liquids containing common hydrogen.

Here is how this was described in the paper: "Results of control experiments with a C_6 H_6-C_2Cl_4-C_3H $_6$O-UN mixture indicated [9] that there was no statistically significant net change in counts between cavitation on and off. In contrast, the results of experiments with a deuterated C_6D_6-C $_2Cl_4$-C_3D_6O-UN mixture produced a significant increase (400%) in neutron counts and 100% increase of ray counts as seen in Fig. 2 and in Table I. [UN stands for the uranium nitrate.] Based on the calibrated detector efficiency, the neutron emission rate was estimated to be 5000–7000 per second." Experiments with H_2O and D_2O liquids, containing UN, showed no sign of unexpected nuclear activity under otherwise identical conditions.

Similar conclusion was reached by using the CR-39 detectors. One year ago, while working on the Oriani effect, I did place CR-39 detectors close to a Pu-Be neutron source. And I saw smaller tracks due to recoiling protons and occasional two to three times larger tracks, probably due to alpha particles from the (n,a) reactions in the CR-39. I also noticed that the number of tracks increased with etching time. My interpretation of this effect was simple, most latent tracks due neutrons do not begin at the surface, as latent tracks due to external alpha particles. The longer one etches, up to a limit, the more latent tracks are exposed to the etching fluid. That should rule out a possibility that tracks are due to a surface contamination, for example, from fingers that were in contact with a liquid containing uranium nitrate.

Implosion of tiny spherical bubbles are accompanied by emission of intense pulses light; for that reason the phenomenon has been named sono-luminnecsence (SL). How reproducible are SL experiments? That question was answered in another publication of Taleyarkhan et al. -- " Supplement (E-PRLTAO-96-019605) to 'Nuclear Emissions During Self Nucleated Acoustic Cavitation')." They wrote: "

Nuclear emissions with cavitation for a deuterated liquid can vary significantly and it is not uncommon to get null

results on a given day if the test cell produced non-spherical and comet-like bubble clusters. The precise reasons behind the absence of recorded nuclear emissions is unknown at present but, as mentioned before, it appears to be closely tied with the behavior of the bubble clusters themselves. Spherical cluster implosions tend to result in nuclear emissions, whereas, non-spherical clusters (especially those tending to comet-like shapes) do not. Nevertheless, nuclear emissions were never noted for control experiments (i.e., with non-deuterated liquids) and also for experiments with water. For unsuccessful campaigns on any given day the test cell operation would result in comet-like bubble streamer formations which would tend to persist despite operation for several hours. This required dismantling of the test reactor to seal leakage pathways, and to filter the test liquid for impurities, or, for persistent problems it was necessary to use a new batch of freshly-drawn test liquids."

That is another similarity between the SL and CMNS; the first similarity being generation of nuclear reactions in a small jar. The issue of reproducibility in CMNS has often been addressed by Ed. Storms. He thinks that the so-called "Nuclear Active Environment" (NAE) has not yet been identified. Here is how this was expressed a message Storms posted at the CMNS list (7/23/06). It was a reply to a message asking which CMNS is the most reproducible.

Ed. Storms wrote:
"As I have been harping on for sometime, the method is not as important as being able to form the NAE on the cathode surface. All of the methods have produced heat on occasion. X1 has claimed co-deposition is completely reproducible, but I have not found this to be true. X2 claims use of a PdB alloy is very reproducible, but this alloy is not available. x3 claims palladium Type A is reproducible, but this is not available and its characteristics are unknown. X4 claims his method is very reproducible, but it has not been described in enough detail to be duplicated. X5 claims Ti is very reproducible, but I have not found this to be true. He also claims placing Ti in the electrolyte improves the behavior of Pd, which I have not found to be true. I have found methods to form a NAE that work on occasion, but then fail to work for unknown reasons. In other words, Scott, you are asking the wrong question. The proper question is, how can the NAE be formed with reproducible results? The answer is, we do no yet know. Whatever you try will suffer the random consequences as experienced by everyone else. If any of us know the solution to this problem, we would be running successful experiments, making demonstrations, and getting rich."

Ludwik Kowalski wrote:
In my opinion, a field of research that does not offer a single truly reproducible demonstration cannot be called scientific. That is why think that the CMNS, and SL are examples of proto-science. My immediate reply to the above was "In other words, CMNS should be replaced by CMNP, where P stands for proto-science. Right or wrong?" Then I added: Here is the excerpt from:

http://en.wikipedia.org/wiki/Protoscience#Historical_perspective

"Proto-science is a word with two meanings. It may mean an unscientific field of study which later becomes a science (e.g., astrology becoming astronomy and alchemy becoming chemistry). Or, it may mean a field of study which appears to conform to the scientific method but is either not falsifiable, or if it is, its predictions and principles have not yet been accepted as science or verified by a consensus of scientists."

By my own definition: an experimental field is proto-scientific when scientific methodology of validation is applied but reproducible experiments are not available. I believe that a single reproducible-on-demand demo will turn CMNS into science. That is what Michel Jullian and Scott Little are asking for. Right? And here is an excerpt about pseuo-science, from

http://en.wikipedia.org/wiki/Pseudoscience#Introduction

"What is pseudo-scince? **Pseudoscience** is a term applied to a body of knowledge, methodology, or practice that diverges from the usual standards required for scientific work, or which is unsupported by sufficient, substantial or verifiable scientific evidence and research .....The standards for determining whether a body of alleged knowledge, methodology, field, belief, or practice is truly scientific can vary from field to field, but involve agreed-on principles including reproducibility and intersubjective verifiability. ....."

Scott Little wrote:
"At this point, we would be delighted to simply have the cold fusion "experience". With one good, solid excess heat experiment under our belt, it would change the whole landscape for us. We've been monitoring the cold fusion field every since its inception. I had my first cold fusion experiment running within an month of the original F&P announcement. I attended the first cold fusion conference held in Santa Fe NM and met Ed Storms there for the first time. Over the years, we've constructed a dozen different calorimeter systems for cold fusion research. We've tried a variety of experiment including many of the newsworthy cold fusion ideas that have surfaced, like the Patterson beads, the Case experiment, Stringham's sonofusion, Mizuno, etc. 'Proof' is too much to ask for right now. We just want to observe the excess heat effect."

Ed Storms wrote:
"I want to make sure no one thinks I believe Szpak, Dash, etc. are untruthful and I'm amazed Swartz would come to this conclusion. What I said was that I have not been able to duplicate the claims. This problem is universal in the field and is an accepted part of the experience without hinting that someone did something wrong. We simply do not know enough to replicate the claims. . . .

Steven Krivit wrote:
We could eliminate many arguments and unfortunate misunderstandings within this community and external to this community if we can agree to, and rigorously apply the distinction between REPEATABLE and REPRODUCIBLE.

REPEATABLE: Researcher A can obtain the expected result from his or her experiment every time he or she makes an attempt.
REPRODUCIBLE: Researcher B can obtain the same result from his or her replication of researcher A's experiment.

Ludwik Kowalski wrote:
To be useful an experiment must be reproducible; repeatability would not turn CMNS proto-science into science. A simple experiment cannot remain repeatable-but-not-reproducible for a long time, unless secrecy is involved. Sooner or later A will teach B how to be successful, or B will convince A that something is wrong. An author publishing experimental results tells others "do what I did and you will get similar results." Is this not the main purpose of publishing?

My suggestion for Scott is to replicate excess heat in a Dash-type cell. It was demonstrated by John's students at ICCF10 and everyone could repeat the experiment. Do you still believe that results are reproducible, John? Would you be willing to supply Scott with the recipe, or send him a ready-to-test cell? Scott's MOAC seems to be ideal for measuring excess heat from your kind of cell. If I had such cell I would bring it to Texas and assist Scott -- to be sure that all is done properly. The entire CMNS community would be interested in our result. John's cell was similar to that used by F&P. Therefore, ruling out a prosaic effect would be much easier than in Mizuno-type cell, as emphasized by Ed. I am recommending this because Dash-type instrument was the only low-voltage cell that I that saw delivering excess heat.

Ed Storms wrote:
[Ludwik wrote:] "In other words, CMNS should be replaced by CMNP, where P stands for proto-science. Right or wrong?"

"The problem is one of ignorance. We do not yet know enough to make the effect work every time. This has nothing to do with science. Science is the method by which ignorance is overcome. We are using science to gradually learn what it takes to solve this problem. Someone someday will discover what the NAE looks like and will apply a layer of it to an inert metal substrate, and suddenly huge amounts of heat will be produced and the issue of reproducibly will disappear."

John Dash wrote:
"Ed, Thanks for trying to reproduce our results. Possible reasons why you were not successful may be caused by differences in the details of our protocol vs. yours. In addition, We work at sea level and you work far above sea level. Does that make any difference?

In order to reply correctly, I need to have the recipe which you used in your attempt to reproduce our results. I need to know every detail from the beginning to the end of the experiment (vendor of the cathode and anode materials and recombination catalyst and and the chemicals used to make the electrolyte, including lot numbers and chemical analyses, thickness or diameter of the anode and cathode materials; also include composition of the cell body and pH of the electrolyte). I need to know the initial condition of the cathode (cold rolled, including %reduction in thickness, annealed, including temperature, time, and environment, etc.), temperature of the electrolyte at steady state, data from an experiment, and your analysis of the data. Was there any deformation of the cathode during the experiment ? Was there any difference in the surface composition of the cathode after electrolysis compared with the composition before electrolysis ? Please send me these details of your attempts to reproduce our results."

Ed. Storms wrote:
Dear John, Here is a summary of what I did to replicate the use of Ti to initiate CF using Pd and D2SO4. An electrolyte of 3 ml D2SO4(concentrated) and 30 ml D2O was used. Titanium was used as the cathode and Pt as the anode. This was electrolyzed in a closed cell using the Seebeck calorimeter as follows:

```
0.048A  for  178 min
0.100A       199
0.200A       200
0.500A        79
```

At the end of this treatment the Ti had lost about 3 mg and had turned black. The electrolyte had turned yellow. No excess energy was observed during this time. A palladium cathode was put in the cell. This was made by rolling a piece of palladium to a thickness of 0.082 mm and cleaning with acetone. No further treatment was used. This was electrolyzed as follows:

```
0.047 A for   89 min
0.500A       149
1.00A        258
1.50A        109
2.00A        109
2.5A         639
```

No excess energy was observed within ±10 mW of zero. The sample surface was examined using the SEM and was found to contain no Ti. The absence of Ti is consistent with Ti not plating from such a solution, as expected. If some aspect of this procedure is not right to make it work, please let me know and I will try again - once I finish the book.

Akito Takahashi wrote:
[Mitch] Thank you for teaching your model. Maybe we need to read your papers which are not available in downloadable e-data, on lenr.canr site and your sites. Where are downloadable ones available? One primitive comment back: We know that the biding energy (strong interaction) of deuteron is 2.22 MeV against the breaking-up to neutron plus proton. How is the so high energy excited state as 21 MeV of deuteron possible?

Ed. Storms wrote:
It has come to my attention that a comment I made about being unable to replicate the claims if Szpak and Dash has been misrepresented. I want it clearly known that my failure to make these replications in no way means that I believe Szpak or Dash are dishonest or in any way misrepresented their work. I believe these gentleman are honest and are examples of the highest integrity in the profession. Failure to replicate claims is common in this field and in no way indicates a lack of honesty or skill.

John Dash wrote:
Dear Ed, Thanks for the fast response. My comments are:
1. We use H2SO4, not D2SO4, in the electrolyte.
2. We also use a Seebeck calorimeter, and we detect excess heat from cells with Ti cathodes and also from cells using Pd cathodes.
3. The currents given are not meaningful. We need to know the current density.
4. Our Ti cathodes never turned black, nor did the electrolyte turn yellow.
4. We need to know the % reduction in thickness of the Pd.

5. I don't understand why you did not find Ti on a Ti cathode after electrolysis.

So, there are many differences in our experiments, compared with your attempts to replicate. When you finish your book, I will be pleased to work with you in another attempt at replication.

Ludwik wrote:
Ed and John recognized that the disagreement resulted from not performing the same experiment. They decided to work together to either confirm or refute reality of excess heat in John's setup. Is this not a good way of solving the controversy? What else should be done when mistakes are made in such difficult situations?

Let me return to protoscience. The concept of NAE -- nuclear active environment -- invented by Ed Storms (and by others, under different names?) -- is very peculiar. Does it belong to theories or does it belong to experiments? Theories (models of reality) are invented to explain facts. Facts are discovered via experiments activities. NAE is an unknown form of matter, it is something to be discovered in the future, perhaps a new nano structure or a new catalyst. Things that may possibly be discovered in the future should not be counted as experimental facts.

Does it mean that the concept of NAE belongs to the realm of physical science theories? I do not think so. Theoretical predictions are made either on the basis of deduction or on the basis of induction. Neither of these are part of NAE, as far as I know. Existence of NAE is based on faith in results of the not-yet-reproducible experiments. Such experiments, performed by recognized experts, are too numerous to be dismissed. Should this kind of attitude be called a physical science theory? I do not think so. NAE is not such theory. In my opinion it is an empty name, a placeholder for something that remains to be discovered.

Unlike in mathematics, a theory in a physical science is validated by showing that it agrees with valid experimental findings, that it has predictive ability, and that it is experimentally falsifiable. The NAE “theory” does not refer to particular findings, it does not have predictive abilities, and it is not falsifiable. The only prediction of the NAE “theory” is that some experimental results will become reproducible, sooner or later. And what about being falsifiable; how can the only NAE prediction shown to be wrong? Suppose that results remain irreproducible for another century. That would certainly not be a proof that the "theory" is wrong. Next suppose that a claim, for example, excess heat accompanied by accumulation of 4He, becomes verifiable on demand. That would possibly validate NAE. But that is not what is needed now, if one wants to elevate NAE to the level of a scientific theory. I cannot think of an experiment capable to falsify validity of the only NAE prediction.

I see nothing wrong with believing in NAE; but importance of this attitude should not be overemphasized. Our rules of validation are not different from those used by mainstream scientists. Like all of them, we know that being patient is a virtue. We should emphasize what our protoscience has in common with science, not what makes it unique. Overemphasizing NAE can hurt our reputation.

In principle, CMNS can remain protoscience for another century or longer. But in practice it will not survive without injection of new resources (young scientists and some financial support). It might disappear in ten or twenty years and reappear naturally much later. In that respect CMNS is not different from other protosciences.

Jim Giles discusses reproducibility in the most recent issue of Nature (July 27, 2006). But that is about science, not protoscience. Here is his opening statement: “The idea that readers should be able to replicate published scientific results is seen as the bedrock of modern science. But what if replication proves difficult or impossible? ” How should editors of leading journals, and referees, deal with undesirable consequences of irreproducibility? That was followed by an explanation of why failures to replicate are unavoidable, even in physical sciences. Several suggestions for dealing with this problem are made by the author. Unfortunately, due to discrimination, CMNS publications are deprived the scrutiny of the refereed journals.

Edmund Storms wrote:
The NAE is neither a theory nor an experiment, but the recognition that for the CF reactions to occur, a novel structure is required. This fact has been supported by every attempt to produce CF. This same concept is applied to many phenomenon, such as superconductivity. For a material to be a superconductor, a special structure is required. This

idea says nothing about what that structure must be. The idea is important in discussing the phenomenon because without this concept, many theories have been applied to the normal structure of PdD. Naturally t hese theories have no value because the normal PdD structure can not support nuclear reactions, as the skeptics are quick to point out. The concept forces people to look at special structures to find an environment that can support CF.

Ludwik Kowalski (not posted):
If NAE is neither a theory nor an experiment then what is it? In our present situation it seems to be a substitution for a recognized theory. How can a recognized theory emerge when not a single CMNS demo is reproducible on demand? Most researchers are aware that what they know is always a small fraction of what can possibly be known. That is part of general philosophy. It goes together with believes that laws of nature exist, that physical science theories are idealized models of reality, and that models should be validated by empirical evidence.

In my opinion NAE is a substitution for a recognized theory. The role of theories in science and technology is essential. We want to understand nature; collecting unrelated empirical facts is not sufficient. Several CMNS theories have been suggested but, as far as I know, none of them was declared to be a winner. So when someone asks for an explanation of a particular CMNS effect; we say it is due to a hidden effect (HE), such as NAE that must be discovered. Our protoscience will become science what its HE, such as NAE, new chemistry, etc. is discovered.

In static electricity, for example, the HE was humidity. In humid air dielectric surfaces are often covered with thin conducing layers through which discharging is much more rapid than it is when the layers are not present. Physics teachers are advised to keep electrostatic demonstration apparatus in dry environments (hotboxes). In that way they can be sure of high reproducibility. Hot air from a blow-dryer is often used to remove undesirable layers on dielectric surfaces.

Post Scriptum:
On a list for physics teachers I posted this message: “When was the the effect of humidity recognized as a factor influencing electrostatic demonstrations? I suspect that Ben Franklin was already familiar with the effect of humidity. But I am not sure. Who was the first to write about this?” Here is a reply from one teacher: “Probably Desaguliers [1683=> 1744]. However, Wm. Watson [1715=>1787], ... explained more clearly than Desaguliers had done, that atmospheric moisture destroyed electricity by conduction " I couldn't find the reference, only the quote above. “The leak derives primarily through surface conductivity promoted by the moisture, not from loss to the air, a point not understood until the end of the 19th century.” Ref: Conduction of Electricity through Gasses I", the Thomsons, Cambridge 1928. Quoted: Electricity in the 17th and 18th Centuries, Heilbron, J. L. UC Press (1979)

Another teacher responded: I believe this [see above] quote is from: A Collection of the Electrical Expeririments Communicated to the Royal Society by Wm. Watson, F. R. S. Read at Several Meetings between October 29. 1747. and Jan. 21. Following William Watson Philosophical Transactions (1683-1775), Vol. 45. (1748), pp. 49-120.

Ed. Storms wrote (referring to Giles’ article in Nature):
This is a very interesting article, but it does not address the situation we face in the CF field. The CF or LENR phenomenon has been replicated many times by laboratories all over the world. By the standards described in the article, CF should have been accepted years ago. The problem we have is the difficulty in making the effect work every time and in a predictable way. This is entirely different from the problem of replication. By continuing to describe the problem as being one of replication, we keep the skeptical attitude alive by using their vocabulary. We should call the problem what it is, i.e. a difficulty in making the effect easy to produce.

Ludwik Kowalski (not posted):
How does the ‘problem of replication’ differ from the ‘difficulty in making the effect easy to produce’?” According to the article, problems of replications result from the limited ability to describe experimental protocols in refereed journals. Our difficulty in making the effect easy to produce, on the other hand, is due to not having the protocol. That is how I understand the last message of Ed (see above). I do not share his opinion that avoiding the term replication, in favor of difficultiy, will help us. Replication -- the bedrock of science, is expected from us and we should keep trying to deliver it. Nobody is asking at high precision at this stage.

The underlying assumption of science is that macroscopic phenomena are reproducible, under identical conditions. But conditions are never exactly the same. That is why very precise replications are impossible. The best one can do to overcome precision limitations, in any laboratory, is to calculate averages and to assume that they are close enough to true values. Limited precision did not interfere with scientific progress, or with technological applications of science. The problem has to do with unpredictable, and large, fluctuations of accuracy, not precision. By the way, the term accuracy usually refers to systematic errors while the term precision refers to random errors. I am imagining an instrument whose calibration constant is significantly influenced by solar flares or by coincidences of other rare events. Using such instrument would be like trying to win in a game designed to tease losers. Expecting reproducibility of CMNS effects would not be consistent with chaotic fluctuations of essential parameters.

Michel Jullian wrote:
Michael, if the difficulty of replication is too many unknown unknowns, which makes sense, couldn't the _complete_ original working cell, or at least one replicated by researcher A himself, be lent to researcher B to save time?

Mike McKubre wrote (7/29/06):
That is how we usually begin; the original equipment set up and operated by the original experimenter(s). In this first Phase we just provide technical and plumbing support. When the experiment is running to the satisfaction of the originator - and we believe we understand what is being done - we invite the originator to leave operation to us. Even at this stage it is quite usual for us to seek further help. Only when the experiment is running for us in the same way as for the originator do we allow ourselves to succumb to the siren urge to "improve".

In terms of unknown unknowns it is interesting that recent discussion in this thread has centered on Huggins and Mengoli. At the time of their successes both of these men were at the top of their respective professions (material science and electrochemistry). They knew more than (I would timidly suggest) anyone who attempted their replication - that is, fewer things were unknown to them. At least one of these things might have been important.

As an example look at Huggins repeat melting that Charles started us with, and the issue of lithium (and beating). Ed assumed in his attempt that Huggins' repeat melting was to remove Li. This is not what I recall from my discussions with Bob at the time, but who knows? My point is that we don't know what we don't know. This applies to the originator as well. So you must start with the same equipment, the same procedures in the same hands. This is the beginning of replication.

Ed. Storms wrote:
What was your understanding, Mike, about what Huggins intended to do? My understanding was that the crucible was the only piece if Pd Huggins had easily available. They arc melted it to get it into a form they could use and to purify it. Arc melting will remove any volatile such as Li, C and O. He pounded the button onto a flat sheet because an arc melted button does no have much area and is hard to use, as we discovered. At that time, I don't believe anyone knew what would work best. As you and others discovered, annealing is beneficial, but Huggins did not do this.

As for replicating exactly what a person has done, I find that replicating exactly what I have done in the past does not always result in success. Obviously variables are present about which we have no knowledge and over which we have no control. On the other hand, when I successfully replicated the Letts laser experiment, I prepared my Pd in an entirely different way. It turns out that the nature of the Pd is not important. What is important is the nature of the gold plate. It turns out gold can plate in many different ways depending on subtle conditions, most of which Dennis did not control or even know about. Consequently, he and I were both lucky to make the effect work at all, something neither of us has been able to do again. We are chasing ghosts until someone identifies the important variables and the important conditions that must be present.

Ludwik Kowalski (not posted):
The debate started in 1989 is going on. On what basis are the authors of these messages accused of being pseudo-scientists? They are addressing a difficult problem. In my opinion their methods of validation are 100% scientific. They perform experiments, they discuss results and they develop theories, like in other areas of physical science. But our scientific establishment is practicing an unfair discrimination against the CMNS field. When will this end? Yes, it

is not the first time that I am asking this question. Discrimination against honest and dedicated scientists is totally unjustified.

Ludwik Kowalski (7/30/06 in a thread about systematic errors):
1) I agree with a possibility of that kind of error. One way to check the reliability of the sampling method would be to use a bomb calorimeter, as suggested by Jed. Instead of a Mizuno-type cell (which is expected to produce excess heat) one could use a sparking current interrupter, as in an old door bell, or in a Tesla coil. This setup is not expected to generate excess energy and electrical power is expected to be exactly the same as thermal power.

Suppose the heat capacity of the calorimeter is 1000 J/deg. Suppose the experiment lasted 300 s and the calorimeter temperature increased by 30 C. Then we would know that thermal energy was 1000*30=30000 J, and that the mean thermal power was 30000/300=100 W. The sampling method, used at the same time, should confirm this result. But suppose that the sampling method gives 50 W, instead of 100W, as speculated by Michel. That would show that he is correct; the electric power obtained by sampling would be declared to be strongly underestimated (by the factor of two in this illustration). . . .

2)Scott's attempts to replicate Mizuno's GDPE results are significant in the context of this discussion. His COPs were consistently very close to 1.00. That can be explained by saying that Scott's cells had no NAE in them. Are his results not indicative that the method of sampling is reliable for Mizuno-type cell frequencies? Yes, I know that the COP=1.00 can be purely coincidental. For example, a little bit of NAE perfectly masked by a systematic error in measuring electric energy. But i do not believe that this was the case.

Ed. Storms wrote:
May I suggest you all are beating a dead horse. Eliminating errors in measuring applied power is easy and can be solved three different ways. The first, as observed by Ludwik, if some cells produce a COP of 1.0, this is a good indication that applied power is correct. Although not all cells are identical, they won't be different in this regard if the same power supply and detection equipment are used. Second, if you sample using a low rate, then use a high rate and see no difference, the values can be taken as correct. This can be checked at any time. Third, if calibration is made using a dead cathode, the sampling errors will cancel out and be eliminated as an issue. With too much emphases on trivial issues, the real issues are overlooked. The real question is, what does it take to form the NAE?

Ludwik Kowalski:
1) I like the idea of using “dead cathodes” in control experiments. But this does not apply in Mizuno-type experiments. In these experiments cathodes are destroyed. Solid tungsten rods are turned into tiny metallic particles or compounds (?).

2) I do not think we are beating a dead horse. If submitted, the Colorado2 paper will be scrutinized in terms of possibilities of experimental errors, not in terms something that might possibly be discovered later. We do not speculate about the mechanism by which excess heat is generated in a Mizuno-type cell. We only argue that the COP>1 is not due to a systematic error, or to a well known effect. Even this seems to be more difficult than I expected.

3) May I suggest that the term Nuclear Active Environment be replaced by something more acceptable to mainstream scientists. Suppose we say that NAE stands for New Active Environment or Not Anticipated Environment (or something like this but better -- please suggest better alternatives). Such replacement would be needed for Mizuno-type cells; we have no evidence that their excess heat is due to a nuclear process. A paragraph about NAE (but without the word “nuclear”) is worth adding at the end of our paper.

Ed. Storms wrote:
. . . .You [Ludwik] are playing into the attitude of the skeptics here. We need to stop doing this. Cold fusion is based on initiating nuclear reactions. This fact can not be hidden. If the Mizuno cell does not make nuclear energy, then it is not cold fusion and it does not involve the NAE. Why confuse the issue just to satisfy a few skeptics who will not be influenced no matter what you call the effect.

Ludwik Kowalski (7/31/06, not posted):
Ed wrote: "Cold fusion is based on initiating nuclear reactions. This fact can not be hidden." It is not a fact; it is a statment what cold fusion is. The rest of the message is also not acceptable. The main point is that Mizuno does seem to produce excess enegy. But we have no evidence that a nuclear process is involved. It can be something else very interesting. That is why the word "nuclear" is not appropriate, at least at this time. And I do not believe that all skeptics are dishonest.

Appended later

Several short messages about NAE were posted today (8/10/06) on the CMNS list. I think they are worth adding. The concept of NAE is interesting but strange. Nobody knows what NAE is but the concept is used as if reality of NAE has already been established. When something unexplained is discovered we know that it can be explained, sooner or later, in terms of something else. That something else is a cause of the event. In my opinion NAE (Nuclear Active Environment) is nothing else but a synonym for the word "cause." Believing that NAE exists is like believing that a cause exists for an unexplained phenomenon.

Peter Gluck:
The secret of NAE is -- probably -- in such studies:
http://www.gatech.edu/news-room/release.php?id=1078

Ludwik Kowalski
What is the basis for such expectation? Is it because distances between ions become shorter? Is it because screening is expected to be much stronger? My understanding is that NAE is a word invented in anticipation of something totally different from what is known.

Edmund Storms:
I agree, the features of nanostructures and their subtle methods of formation would fit the experience of trying to make CF work. As for NAE, the concept is only used to describe a general condition, both known and unknown. This is used just like the word "tree" is used as a general concept, which is applied to many different items of the same general type.

Peter Gluck:
I think that Les Case's method- was the most promising CMNS achievement- in a form very adequate for a real energy technology, but it was not studied and developed with sufficient forces and ideas. It was poisoned and forgotten. Nanotechnology is the key- but this is only a slogan today. CMNS is a special form of catalysis- I bet, therefore this paper is valuable.

Ed. Storms:
I worked very hard trying to duplicate the Case method. I understand even Case can not replicate what he had done. Formation of the naoometer-sized particles on carbon is the problem. This was done using the conventional methods for making chemical catalysts. We need methods to achieve the same end, but without the many variables associated with the catalytic method. Some day money and interest will be available to allow a marriage between CF and the many methods now being developed to apply small particles. The child of such a marriage will save the world.

Ed Storms:
Well Peter, I have identified 9 possible candidates for the NAE. With sufficient money, these possibilities could be easily explored and the real NAE identified. The tools and knowledge are available. All that is lacking is the will and the money.

Ludwik Kowalski (referring to Ed.'s first message above):
"Tree" is probably not the best analogy for the "NAE." What about the "EOL" (Elixer of Life). It also was a word reserved for something to be discovered much later. I am thinking about antibiotics and other effective drugs. Ancients believed that such substance will be found, sooner or later.

Ed. Storms:
I agree, EOL is a better analogy. However, we already know a NAE exists. We just don't know what it looks like.

Peret Gluck
The ideal solution would be a palladiumless NAE, made from cheap and abundant materials, delivering "high currency" energy -- hot steam and not warm water.

Jean Paul Biberian:
NAE is very similar to catalysis where people talk about "active sites". After years and years of research with many scientists and lot of money we still don't know exactly what it is. We know how to manufacture catalysts that work, but without knowing precisely how they work.

Cold fusion is very similar to catalysis, in both cases thermodynamics is favorable, the only obstacle is the energy barrier. The only difference is the many orders of magnitude larger barrier height for cold fusion. In catalysis as well as in Cold Fusion we don't know if the active site is localized or de-localized? What is the role of impurities? What kills the catalyst? I am pretty sure that soon enough we'll discover ways to have a reliable device, however, the understanding of the phenomenon might take lot longer.

By the way, Arata's system: a mixture of nano-particles of palladium embedded in zirconium oxide seems promising and reproducible. SRI has duplicated the experiment years ago with the double cathode system. His new design with gas loading alone is even more convincing.

Peter Gluck:
Do you think that we still do not have sufficient experimental and theoretical data in order to develop a strategy for trying to discover the secret of NAE? If yes, what is actually missing?

Peter Gluck:
I think EOL is a "metaphor too far" NAE describes the new function -- triggering nuclear reactions via a special electronic environment. Simple logic says this is possible only via neutral entities- not by forcing nuclei through the Coulomb Barrier but this is the job of theorists. I am convinced that (excuse me for using the old name of our field): "Hot Fusion is force brute, while Cold Fusion is a very smart nuclear ju-jitsu" It seems tooooo smart!

Jacques Dufour:
I fully agree with you. I worked on catalysts for ten years and I can tell you that the basic principles on how a catalyst works are perfectly well known. What is still a kind of an art is : how can you design a multifunction catalytic system (for instance find an hydrogenation catalyst that can at the same time withdraw nitrogen compounds while standing unaffected in the presence of sulfur (I worked 4 year on that kind of system!). The only problem is that these systems involve too many parameters to be correctly modelized and trial and error experiments are needed. Moreover the detailed reaction paths of certain systems would be too long to be studied scientifically and an empiric approach is more efficient from an industrial point of view.I also worked during my carrier in ore separation by flottation and the situation is exactly the same.In both domains the relevant phenomena underlying the industrial realisation are perfectly known and understood.

Ludwik, I suggest a new acronym for NAE. I propose NYUP for Not Yet Uncovered Phenomenon. As long as this new phenomenon is not indentified and scientifically studied, all the rest is just mondaine discussion (not to use the term bla-bla !). Trying to persuade people, that making so call CF work, is only a question of money and number of people working in the field, is not far from being borderline to intellectual dishonesty.

Ed. Storms:
I find this debate about what to call the environment in which CF occurs a distraction from the important idea. It makes no difference what the environment is called. The only idea of importance is the recognition that such a special environment exists. This idea is in contrast to the original thought of F&P that the entire palladium cathode was involved, being limited only by the amount of deuterium present. The word does not imply any thing about the

environment, either known or unknown. It does not imply that the effect occurs on the surface or in the bulk. It does not imply that the mechanism involves resonance or magic. You are free to say that the NAE is unknown, unexplored, unknowable and anything you like. The word only allows a person to speak about a concept, just like the word "tree" allows a person to speak about a concept without saying anything about the kind of tree. As for my suggestion that more money and people are needed to solve the problem, I ask Jacques what he thinks is needed that would not be dishonest?

Jacques Dufour (8/13/06):
The name is very important and not distraction. When you say NAE (standing, as I understand for Nuclear Active Environment), you say, with no possible discussion, contradiction, confrontation, that the phenomenon is nuclear. As far as I am concerned, the certitudes I have are :

1/ there is something in the field and the main phenomenon is thermal (anomalous enthalpy of reaction in certain systems metal/hydrides)
2/ some very weak nuclear signatures are observed (tritium, neutrons, helium4) but they don't explain the bulk of the phenomenon

Hence, the strategy for me is to present an experiment that a physicist will accept (small, with minimum matter, using the more robust equipment you can imagine, eliminating all energy storage problems, measurement problems and so on). In short a really irrefutable experiments (by the way, this was suggested by some reviwer of the DOE survey). At that stage a potential industrial application is of no interrest .It is better to have Pout/Pin=110% with an irrefutable experiment and a few mg of matter, than Pout/pin = 130% with hundred watts, that a physicist can easily prove doubtfull. A working hypothesis can also be presented, with the objective of being confronted to experiments and to all theoretical knowledge available to day (I am speaking of theoretical knowledge of the main stream physicists, not of those who completely mis-interpret something as basic as the Mossbauer effect).

Then I came to intellectual dishonesty. My reaction was triggered by what Jean-Paul [Biberian] wrote about catalysis. Having worked for some 15 years in the field (see my answer to Ludwik), I can tell you that the basic principles are fully understood. Trying to establish a parallel between what is presented as an empirical art only i.e catalysis (which is far from being the case) and the need for money an manpower to generate NAE based on a very controversial interpretation of what I think is a real phenomenon, is not only really exagerated but also very likely to be counterproductive, in terms of getting this new phenomenon accepted and its research financed (which I hope is our common goal).

So, sorry Ed, but I think it very important to name NYUP [not yet uncovered phenomenon] what we are studying, even if the phenomenon occurs as you think (and I think you are right) not in the bulk but in special sites. And we have to fight on the ground of anomalous enthalpies of reaction and not on the ground of very hypothetical nuclear reactions.

I hope we can discuss all that soon and pardon me to have use the term dishonesty (but we clearly have to challenge each other in this community and accept all contradictions : otherwise we shall be worse than what we criticize in the main scientific community ...)

Ed. Storms:
Jacques DUFOUR wrote: “The name is very important and not distraction. When you say NAE . . . but they don't explain the bulk of the phenomenon” Here we have a difference of opinion. My opinion is based on my complete study of the literature and the arguments I have made in the past and will make in greater detail in my book. Consequently, I'm looking for a NAE. If you are looking for something else, then you will have to call it something else and justify the name as I have done with the NAE.
[He also wrote] “Hence, the strategy for me is . . . as the Mossbauer effect).” I agree this is needed. However, from my reading of the literature such experiments have been done as well as they can be done using the tools presently available. Nevertheless, I wish you success.
[He also wrote] “Then I came to intellectual dishonesty. ..... our common goal)” Please do not confuse your personal opinion about what is happening with universal reality. I agree, you are seeing a real behavior. The issue is whether it has any relationship to what other people are seeing, which is called cold fusion. Please try to avoid making your

experience apply to every other observation. You may be observing an entirely different effect.
[He also wrote] “So, sorry Ed, but I think . . . hypothetical nuclear reactions.“ This conclusion would only be true if nuclear reactions were not occurring. However, a huge collection of evidence shows that they are. They may not be occurring in your work, but they do occur in other studies. My definition applies only to conditions where they do occur. You are free to define your studies however you see fit.
[He also wrote] “I hope we can discuss all . . . the main scientific community ...)” No problem. However, we all need to make a clear distinction between dishonesty and a difference of opinion.

Ludwik Kowalski:
My recollection is that only Mizuno reported on presence of transmutation products in GDPE cells. Is this correct? How large would the energy/atom be if the excess energy he measured were due to transmutations he reported? My guess is that it would exceed millions of MeV/atom. Note that that 23 MeV/atom was reported for the F&P-type cells. Unfortunately, I do not have information on the number of atoms produced while excess energy was measured by Mizuno*. I think that N -- in NAE -- is not yet justified, as far as Mizuno-type cells are concerned. Why don't we hear from Mizuno? Is he OK? I know that he was scheduled for an important operation after the ICCF12. Did someone communicate with him this year? I am worrying.

*below 0.00001 MeV/reaction --> chemical
up to 200 MeV/reaction --> known nuclear
above 200 MeV/ reaction --> totally unknown

Talbot Chubb:
Biberian writes, "By the way, Arata's system . . . “ : I call Arata and Zhang's ZrO2 + nano-palladium powder an "oxide-coated nano-metal composite". The NAE in this process would seem to be either the nano-metal Pd crystals or the interface layers between ZrO2 crystal and the Pd metal.

A-Z have shown that oxide-coated ZrO2, nano-Pd composites absorb hydrogen so as to create the remarkably hydrogen rich hydride PdH3, using what appears to be equilibrium chemistry at 100 bar. Their 2002 electrolysis test run produced ~ 10 W of excess heat continuously for over 20 days using a few grams of Pd. This technology seems to solve the damaging problem of nano-crystal growth, which occurs when metal nano-crystals make contact with each other. The A-Z ICCF12 paper suggests cold fusion heat production at 200 deg C without electrolysis.

Scott Little (8/16/06): Is it possible to formulate the hypothesis for cold fusion as a falsifiable one? The concept of falsifiable hypotheses was emphasized by Karl Popper who claimed that unless a hypothesis was falsifiable, it was not a scientific hypothesis. Not everyone shares his viewpoint (see Criticism section in this article)
http://en.wikipedia.org/wiki/Falsifiability

but, as an experimentalist, I find it rather attractive. The simple hypothesis I have been assuming for cold fusion goes something like this: "Nuclear reactions can occur in an electrolysis cell." Clearly this hypothesis is not falsifiable. Only an infinite number of null experiments will falsify it. Can anyone formulate the cold fusion hypothesis so that it is falsifiable?

Ludwik Kowalski:
It is important to emphasize that the concept of falsifiability was develop for theories. The corresponding concept for experimental data is reproducibility. [A hypothesis is often the first step toward a theory. The statement formulated by Scott would become falsifiable if conditions under which a specific nuclear reaction, such as production of alpaha particles, were said to take place under specified conditions in a clearly described kind of cell. But ths is possible only when experiments are reproducible.]

306) How to search my website for something ?

Ludwik Kowalski; 7/31/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I never expected this website to exceed 300 webpages, as it did after about four years. The problem with so may webpages is difficulty to find something. Suppose I want to quickly find what is there about Oriani effect, or about Huizenga, or about the iesiusa company. How to find and to open pages containing such words and phrases? The same question is probably asked by some readers of my pages. The list of titles that appears when one types

http://blake.montclair.edu/~kowalskil/cf/

in the window of an Internet browser was designed to help because each link to a page has a title. But this does not always help. Fortunately, **Google can be used to search for information on a selected server.** The domain name of the server on which my webpages are located is

http://blake.montclair.edu

as indicated in the above URL. Each Internet server has a unique domain name. Suppose I want to find webpages containing the word NAE. By entering this as a keyword of the general Google search I got 12,100,000 hits. But a Google search limited to my server produced only 12 hits -- exactly what I was looking for. To restrict Google searching to a selected server proceed as follows:

a) Using a browser go to www.google.com
b) Click the "advanced search" link. This brings a page with a search box. Type the NAE (or anything else you might be searching for) into the search box.
c) Scroll down to the line labeled "domain." The right side of that line has a box for entering the domain name. Type http://blake.montclair.edu in that box.
d) Then scroll to the top of the window and click the GOOGLE SEARCH button (near the upper right corner).
e) That should produce the widow showing the search results, for example 12 links to webpages containing the desired keyword or phrase.

That is all I have to say. Other convenient restrictions can be imposed on a Google search. But this is not a book about googling.

307) More private messages about Colorado2

Ludwik Kowalski; 8/9/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

I believe that private correspondence described in unit #285 is worth preserving. It refers to Mizuno-type experiments in which I personally participated. It started as Texas1 project, became Colorado1 project, became my ICCF12 report and will possibly be participation in Paris3 project. Unfortunately, I am still not convinced that excess heat, reported in Paris1 and confirmed in Colorado2, is due to some new Physics. It may be due to a prozaic effect, such as presence tiny droplets, and colloidal particles, in wet steam. Or it can be due to errors in measuring the input energy. Will Paris3 finally convince me that what we called excess heat is really excessive? This remains to be seen.

Why do I spend time on cutting and pasting so many private messages? Because I believe that what we are doing is very important, no matter how the controversy will be resolved. Private messages provide details which might not be apparent when published reports are read. Our correspondence will certainly be appreciated by future historians of science. We are not famous scientists but our messages might become as important as private letters of Galileo, Pasteur, Fermi and Einstein. We are a small part of something significant; future generations will probably study all aspects of our activity with great interest.

= =

1) Pierre --> Richard + Ludwik (3/8/06 ?)

Before going by the end of this week with our dewar tests, we have done with Gérard a series of experiments with our traditionnal beaker, just to see if we were able to find again abnormal excess heat.
A long run (30 minutes) at 250 volts: COP between 1.05 to 1.10
2 runs at 300 volts (15 and 20 minutes): COP around 1.10 up to 1.20
2 runs at 350 volts (only 12 and 10 min due to cathode burning) COP 1.15 to 1.32
Of course, we made the usual calibration with our ohmic heater ...
We really think with Gérard that we are now able to get abnormal excess heat on demand, within, of course, a particular optimised geometry (beaker, anode and cathode)...except unknown artefact !

I told you that, as in Boulder, we failed in trying to get automatic constant length for the cathode by using gravity. Our small ceramic cup was pierced and even a second one placed on the first one. Happily, the bottom in Nickel stopped the plasma electrolysis. See on the pictures attached. But, however a good result : this cup bottom gives a very good behavior to the electrolyte (no splashing, no waves, no foam...)

As asked by Scott, you will find a small movie giving, I hope, plasma colour and sound of our CFR running (I think here at 300 volts). We will get by the end of the week the Boulder electrolyte analysis...

= =

2) Pierre --> Richard + Ludwik

We tested yesterday our dewar by beginning the traditionnal calibration with our ohmic heater. We got the following values:

At 600 watts: mean value for thermal losses: 40 watts
At 400 watts: --- --- 40 watts
At 300 watts: ----------29 watts

At 200 watts -----------------------------21 watts

Compared to the same tests with our beaker, these values are about one third of the beaker values...

Then, we replaced the ohmic heater by our usual electrodes and we made one test at 300 volts during 20 minutes. We have obtained COP values around 1.15 from time 5mn to time 15 mn and even 1.30 at the end of the test (Pth was about 386 watts at time 20 mn).

We tried then several tests at 350 volts. We got good COP (even> 1.3), but we had splashing. .. The main reason is that, with a beaker, it is very difficult to adjust the length of the active cathode and to see at what depth you really placed the electrodes. A transparent dewar would be a good answer to this problem...

But anyway, we think with Gérard that we have found same results with the dewar and with the beaker. We prefer the beaker, easier for the setting up, and also better than the dewar because we can place together the electrodes and the ohmic heater, due to larger diameter for the beaker...

Three pictures are joined. I hope by to morrow to have some chemistry analysis...

= =

3) Pierre --> Ludwik
Je viens d'envoyer la note ci-dessous à Richard S. et Ludwik K. comme ultime contribution dans le contexte de ma venue à BOULDER. Ludwik comptait faire de nos travaux une note de synthèse. Je ne sais si c'est toujours son intention, à moins qu'il n'attende une duplication par Scott Little. J'ajoute pour répondre à vos questions que le brouillard qui apparaît au dessus du bécher apparaît de la même façon lorsque seule la résistance est opérationnelle. Par ailleurs, je ne comprend pas le débat sur le CO? pouvant s'échapper du bécher. Le CO? potentiel dans les 27g de CO3K2 mis en place dans l'électrolyte représente 8.6 g (le tiers de la masse en carbonate de K). Or, chaque essai consomme environ 250g de H2O et avant de renouveler l'électrolyte, nous faisons des dizaines d'essais. C'est donc pour moi un faux problème. J'attends cependant les mesures chimiques en cours avec Gérard.

= =
4) Pierre --> Ludwik+Richard+Gerard+ Jean-Francois Fauvarque
Finally, Gérard gives me the following answer (I am not a chemist and I am just trying to translate his note): 1cm3 of electrolyte was mixed with 50 cm3 of distillated water. HCl at 0.05M was used for dosing. You can see the result in the joined curve. First equivalent point for 1.71 cm3 Second equivalent point for 4.91 cm3 that is to say: 4.91-1.71=3.2 cm3

The first point seems to correspond to the neutralisation of a strong base: KOH (0.05x1.71=0.08M) and the second to the neutralisation of the remaining carbonate of potassium (0.05x3.2=0.16M). This electrolyte seems to be a little bit concentrated, but the answer is clear : due to the numerous runs we did with, we have not to be worried by the escape of CO2. !

= =
5) Ludwik --> Gerard+Pierre+Richard+Jean-Francois
I have no idea what is the meaning of the curve sent to us. How does it help us to make the data more trustworthy? Can this curve be used to show that not much water was lost in the form of tiny droplets?

= =
6) Pierre --> Ludwik+Richard+Gerard
My previous mail was not explicit enough. ... One liter of electrolyte contains 27 g of K2CO3. Inside this carbonate, there is about 8 to 9 g of CO2, which may be released by contact with the very hot plasma. This may be a cause of overestimation of the excess heat. This chemical analysis has shown that our Boulder electrolyte contains always 80% of the initial carbonate content in spite of a lot of runs and hundreds grams of evaporated water. Then it is clear that this very small release of CO2 (20% of 8 g, that is 1.6 g) leads to an insignifiant and negligible correction on all the

evaporated water... That's all is said by our chemical analysis (we will do the same with the initial electrolyte, not used). Are you now OK

= =

7) Pierre --> Richard+Ludwik+Gerard
Hi friends, I am to-day at the CNAM Fauvarque lab. and we are preparing with Gérard some experiments Paris2 type to be done on to-morrow friday. The purpose is to answer the questions raised by Ludwik and to help Pr Fauvarque to prepare his appendix on chemical aspects. We are very interested by the projects of Richard, but be careful Richard with the H2 O2 explosions... We plan to do an experiment similar of the CFR of Jean-Louis Naudin within two weeks, we hope. It seems to us that the thermal losses will be smaller and the global analysis simpler... We will see...

= =

8) Ludwik --> CMNS LIST (April 20, 2006):
Colorado2 experiments replicated the COP>1 claim of the Paris-1 team. They showed that by doing the same things we obtain similar results. That was an important step forward. To make Colorado-2 results publishable we must be able to convince honest referees that excess heat cannot be explained in terms of known chemical reactions. That is the main issue. Unfortunately, it has not been addressed by recognized authorities in chemical aspects of high voltage electrolysis. Did Mizuno, or some of his collaborators, publish something along these lines in Japanese?

My understanding was, and still is, that a complete analysis of potentially possible exothermic chemical reactions is now being conducted in Paris. Im I correct? Planning for new setups, ahead of such analysis, does not seem to be productive, at this stage. Writing a paper based on Colorado-2 results also seems to be premature, for the same reason. But we should compare the conductivity of water (from which the electrolyte was made) with conductivity of condensed liquid escaping from the cells (when the COP was measured). In that way we can estimate the percentage of tiny droplets of the electrolyte in the escaping steam. . . .

= =

9) Pierre --> Richard+Ludwik+Gerard+jean-Francois (April 22, 2006)
We are also trying to launch a new experiment "Paris 3" with a loop of ordinary water for cooling our experiment and with presently hand measurements giving water flow and inlet and outlet temperatures. ..I find as a very good idea your choice to take water at 0°C in order to cool the experiment, but of course you must be careful with thermal contributions (instead of thermal losses.). But I do not understand why your electrolyte is not at 100°C (or maybe at 94°C in Erie !). It is easy to do so with an ohmic heater. ..and it seems to me that the experiment analysis is simpler when every data are not all varying (power, temperatures, ...)

You will see in the joined pictures our first experimental set up, here without any heat insulator. Our first tests with the traditionnal ohmic heater show us too large losses of uncondensed steam (easily measured by our balance), about 40% at 400 watts and even more at 550 watts. Due to the fear of H2-O2 explosion, we managed a too large escaping gases area, in spite of screens located in the center in order to deviate steam on the nylon tubes at the peripherical side. We are now writing our chemical appendix... But, Ludwik, don't be too much impatient.. Gerard and Pr Fauvarque are very busy fort the time being.. I will send you soon the summary !

= =

10) Richard --> Pierre + Ludwik+Gerard+Jean-Francois (4/24/2006):
Bonjour Pierre and company, I am also starting up Colorado #3 experiment. I tried a similar set up to what you are showing in your pictures and found that it didn't work very well for me. I ended up putting the condensation coil just above the electrolyte attached to the lid of the cell. This arrangement works well and does a good job of condensing the steam. The lid over the cell only needs a small hole 3.0 cm in the center to let out the accumulated gas. In the pictures you can see that the cathode comes out the hole. I'm able to push the cathode down a little at a time and keep the reaction going for hours. I'm at work right now but I'll send some pictures tonight.

In this new arrangement I am still losing too much water as steam but it's only 50 grams/hour. I'm working on some baffles to force the steam to travel around the coil. I would like to get this down to less than 10 grams/hour. I also need to insulate the lid of the cell. I seem to be loosing a lot of heat to non-evaporated loses and it's almost all though the lid

of the cell.

I understand your concerns about thermal contributions. I have thermistors at the inlet and outlet of the coil to measure the input and output temperatures. I'm using a big ice chest right now for my cooling loop. The ice chest gives me several hours of 1-2degC water for the test.

My initial measurements with this new arrangement look good. I can't claim any excess heat. It looks like with just a few more modification I'll be able to run a test for several hours with continuous measurement of the input and output power. I agree it's very important that we have continuous measurements for several hours showing excess heat.

I think this experiment with little loss of water over the duration of the test and continuous excess heat for several hours will be very convincing. Running the test for several hours and taking the before and after electrolyte samples will gives us ideal data for a paper.

Ludwik, do you want to come to Colorado again and run help run experiment #3? I should be ready with all the new setup in about a week.

= =

11) Richard --> Ludwik (4/25/06):
I'm very encouraged by the results I got last night from my experiment. The heat exchanger is working nicely with good results. I'm seeing a COP of about 1.30 for over 90 minutes at 300 volts and 0.95 amps. I have a constant 3Deg temperature difference in the heat exchanger with a flow of 1.200 liter/minute. The ohmic heater calibration is showing a heat loss due to conductive and radiated of about 40 watts. Even if I only use the heat exchanger values I seen a COP = 1.1. Attached is draft of a paper for Colorado #3. This draft is first a way to make sure that my thought processes for the experiment are correct. I know I'm a long way from publishing anything. Your comments are appreciated.

= =

12) Ludwik --> Richard
See green comments in the attached file.

= =

13) Richard --> Ludwik
Thanks for the comments. Does the experiment sound solid?

= =

14) Ludwik --> Richard
I can judge what you do on the basis of what you write only. The preliminary description is not sufficient to form an opinion. A flow calorimeter seems to be appropriate when excess energy is generated at the rates exceeding ten watts. How accurately do you measure the flow rate? How much liquid does manage to escape? Suppose that the escaping liquid is 50% droplets. Can this alone explain the COP=1.3, for example? These questions must be addressed; devil is in details.

The most important task, for Colorado-2 and Paris-2 experiments is convincing chemical analysis. I am surprised that Fauvarque, who is presumably a top French electrochemist, did not address that issue in describing results of Paris-1 experiments. I hope this has been addressed in 1997 by Ohmori and Mizuno. Otherwise claims of "unexpected heat" cannot be made. Pierre promised Fauvarque's appendix to me but nothing happens.

= =

15) Richard --> Ludwik (4/26/06):
Ice water is feed to the condenser at 1.20 liters/minute.

Starting time 8:10   Ending time 9:20   total time 70 minutes

The delta temperature at the heat exchanger is 5 degree a 10K @ 25c thermistor
The delta temperature of the outlet water from the ice bath compared to the returning water was also 5 degree

These temperature reading are an average of about 15 random data points over the 70 minutes.

Input voltage 355 and input current 1.2 amps == 426 watts
This is also a random average of the input voltage and current.

The initial weight of the vessel was 2123 grams and the final weight was 2033 so losses due to evaporation or disassociation of H20 is 90 grams

Pin = 285
Pout = Pex + Plosses + Pevap
Pex = 5 * 20 *4.178 = 417
Plosses = I'm estimating it at about 25 watts.
Pevap = 2260 * 90 /(70*60) = 50 watts

Pout = 50 + 417 + 25
Pout = 507

COP = 1.18

= =
16) Ludwik --> Richard (4/26/06):
Thanks for numerical information. Congratulation for being able to forge ahead so fast. Can you also describe to me your condenser? Where is it located in the 2 liter container? How is it connected to the water pump, etc.?

= =
17) Richard to Ludwik (4/26/06):
I purchased a 1.5 liter microwave safe plastic container with an air tight lid from the hardware store. I modified the lid to hold a coil of copper tubing 1.5 meters long. There are two pipe fittings on the lid connecting to the coil. Inside these two pipe fittings I have the two thermistors to measure temperature. In the center of the lid is a 3/8 inch hole for letting out steam and H2-02. I also have some baffles below the coil so the steam can not rise straight up but must move in a convoluted way. This prevents any splashing out the hole in the center. I cathode extends out the 3/8" hole so I can just tap it down a little to keep the reaction going. It fits snuggly through the baffles.

I have an ice chest with a submersible pump. I've let the pump fill a 2 liter beaker about 10 times for 30 seconds. The liquid in the beaker was always 0.6 liters. It was right on the 0.6 liter mark. Looks like I can read the beaker to within 0.01 liter easily.

I have plastic hoses going from the ice chest to the beaker lid. These are both covered with pipe insulation. If I fill the ice chest with 20 lbs for ice I can run for about an hour with the inlet coil temperature being at close to 2degC, after that the inlet temperature starts to rise slowly as more of the ice melts. It looks like as longs as the temperature of the water in the ice chest is below about 40C I can still get good data. I'm bidding on several chillers on ebay, just lost the one I really wanted.

I'm really excited about this experimental setup. It really seems to address a lot of the problems with the open beaker. I hope I can get Advance Energy to run the SEM on the electrolye samples and on the cathode.

I would like you to consider helping publish the paper I'm writing and sent you. I should be able to finish up the missing part in the next month. Here is the latest draft I have added some dummy graphs that show what I'm expecting the final data to look like.

= =

18) Ludwik to Richard + Pierre (4/26/06):
I will start writing a draft of the paper after receiving two essential items:

a) An appendix written by Fauvarque (showing that known chemical reactions cannot possibly be responsible for the COP=1.24 (st. dev. 0.13) that was measured. I take it for granted that he is considered to be a recognized authority in electrochemistry. When should I expect his input. My experience with publishing is a rule: "the longer one waits the more difficult is to write." Sometimes motivation for writing goes away.

b) An estimate of the percentage of tiny droplets, based on some kind of experimental data. If the answer is ~5% then the accuracy with which the number is determined does not have to be excessive. But the open cell approach will be disqualified if the answer turns out to be close to 20%.

I am happy that you are making progress with Colorado-3 and Paris-2 experiments. Does it mean you no longer want to publish the Colorado-2 results in a separate paper? I would go along with your decisions.

= =
19) Ludwik to Richard:
Sounds like a big step forward. I wish I could assist you again. But not now. After you stop improving the setup you should perform about ten measurments of COP at each voltage. In that way mean values and standard deviations will help to resolve the pending issue. As you know, according to Paris-1 the COP goes up with voltage. But this was not confirmed by Colorado-2 experiments. That contribution alone will be a good reason for publishing an additional paper. On the other hand, considering the problem with droplets, perhaps your new results should be included into the paper we anticipated with Pierre. Just mussing, as you say.

20) Richard --> Ludwik (4/26/06):
I've got a few more things to do and I should be able to start collecting a lot of data for statistical analysis. Like you say we need about 10 runs per voltage level for good stats. This is why I don't understand what Michel is doing or not doing. You've got to have a way to get enough data without taking months.

I have got get some sort of circulating chiller. I keep running out of ice. I'm making a little printed circuit board that will have the 250Mhz AD835 multiplier chip. This will end once and for all the input power measurment controversy. I'm going to change the type of thermistor I'm currently using. I can get a different value that will give 0.1 resolution on the temperature. Repeatable is even better at 0.01.

If I can get AE to do the chemical analysis with their SEM I'll go back and run a couple of test like we did in the Colorado 2 experiment and have them analysis. Apparently they can show a plot with elements as light as carbon. They can't show any kind of consentrations. Hope all is going well with the closing. It's a lot of work to move especailly when your downsizing! Sorry you won't be able to help, but any suggestion on the paper will be appreciated.

= =
21) Pierre --> Richard+Ludwik (4/27/06):
I will be happy to have your pictures of Colorado#3 and of course to know where you are now in this new experiment... I am going now for two weeks of vacation in the south of France and I will finish these holidays by doing Paris1 test in the lab of JP Biberian (at Marseille) ; that will be Marseille1. Jacques Dufour and maybe Michel Jullian will be there. By the way, what about Scott Little ?

= =
22) Richard --> Ludwik (4/27/06):
The attache d file is a sample of the type of report Advance Energy can run for me. I'm going to ask them to do a scan of an electrode.

= =
23) Ludwik --> Richard: (4/27/06):

Information provided in the attached file -- locations of characteristic peaks (in keV) for different elements -- is of no interest to us. This is important before performing the X-ray fluorescence analysis. Once you know which peak (or peaks) to use to identify potassium the information we need is in the heights of peaks. Suppose we are interested in K and we know that it produces a peak at 321 KeV (I am just making it up). First we expose the 1 cc of the original electrolyte to X-rays for 10 seconds. Suppose it produces 10000 counts under that peak. We dilute the electrolyte by the factor of ten and the peak become 1000 counts. We dilute by another factor of ten and this time 1 cc shows a peak close to 100 counts. That is the calibration. It shows that counts under the peak, N, are directly proportional to the molarity, X, of a sample.

X=0.2*N/10000

For example, if N=20000 then X=0.4 M, if N=2000 then X=0.04 M, etc. All this is preparation. Now comes the essential moment. Suppose we take 1 cc of the condensed liquid. Suppose the 321 keV peak has only 2000 counts in 10 seconds. This would mean that the concentration of K ions is about 5 times less than in the original electrolyte. Is it good or bad for us? I think it would mean that about 20% of the lost liquid consists of the droplets of the electrolyte. The COP would be nearly 1.00 if that percentage was taken under consideration. On the other hand, a peak with N=100 would tell us that droplets contributed only ~1% of the lost mass. That is too little to explain the COP>1.2 as an artifact due to droplets.

Scott Little has a setup for that kind of analysis. It took him less that 30 min to demonstrate presence of tungsten in the electrolyte for me. I was planning on asking him to perform the K analysis for us, after you produce a sample of the condensed liquid. My suggestion was to use the cold funnel method. But any other method would be OK. The experiment must be performed in the open cell, as we did when the COP=1.24 was determined. As you know, I prefer to finish Colorado-2 before starting Colorado-3, even when we know that Colorado-3 method is better.

= =

24) Ludwik --> Scott Little, Pierre and Richard (4/28/06):
Hi Scott:
1) As you know, presence of tiny droplets in the lost liquid is one of the possible explanation of the high COP. One way to show that the COP=1.24 for example, less that ~1% of what is in 1 cc of the original electrolyte. On the other hand ~24% would confirm the suspicion of the illusion. Do you agree?

2) I did talk to a chemistry professor at my university but he said they have no instruments to measure K. This weekend Richard will have samples to be analyzed.

3) Your X-ray fluorescence setup is probably ideal for what we need? Am I correct? If so then perhaps you will be able to analyze Richard's samples.

4) How is your gravitational project? Are you still planning to verify Colorado2 results? Pierre wrote to me that a very convincing appendix, written by Fauvarque, will be sent to me soon. It will presumably convince honest skeptics that excess heat cannot possibly be due to known chemical reactions. Not being a chemist I will simply accept this; Fauvarque is a recognized authority in the field of electrochemistry. I do not want to start writing the draft of our paper before receiving the appendix, and before knowing that the mass of droplets was a negligible fraction of the lost mass. Should I also wait for the Texas2 results? I hope the answer will be positive.

5) Jean-Paul Biberian, if I recall correctly, also has a setup to perform the X-rays fluorescence analysis. He and Pierre are planning on a new plasma electrolysis experiment in France.

6) I am going to be busy this summer with downsizing activities (emptying the house, selling the house, buying an apartment, and moving). But this should not prevent me from writing the draft. In my mind those who worked on Paris1, Texas1, Colorado1 (before the ICCF11), Colorado2, Paris2 and Texas2 experiments will be the authors (listed in alphabetical order). Let me know if you do not like this suggestion.

7) Rising gas prices made me think about your home-based project for the agricultural fuel, Scott. Are you making

progress on that front? Most cars in Brasil, I was told, run of fuel made from sugar can.

= =

25) Scott --> Ludwik + Pierre + Richard (4/29/06):

"2). . . On the other hand ~24% would confirm the suspicion of the illusion. Do you agree?" Yes, that seems correct and obvious. To analyze the K content easily, how about just weighing a small amount of the sample (i.e. 1 gram), evaporating to dryness, and weighing the dry salt? Yes I know there is some concern that the K2CO3 will turn into KOH but that won't create a huge error in the results.

"3). . .If so then perhaps you will be able to analyze Richard's samples." Yes, I could probably make a reasonably accurate analysis for elemental K content that way. I need about 15 mL of solution to fill the sample cup properly. Actually if that is a great difficulty, I could probably dilute the samples 10:1 and still attain satisfactory accuracy....so I could use as little as 1.5 mL of sample.

"4) How is your gravitational project?" We've completed construction. Now we are at the hard part: making it work properly. It will be difficult, I'm afraid. "Are you still planning to verify Colorado2 results?" Yes, but I don't know exactly when. The gravity project is out top priority right now and it is not finished.

"Should I also wait for the Texas2 results? ....." That depends upon when you want to complete the paper. Perhaps in another month, I'll get to the Texas-2 project.

"6) In my mind those who worked on Paris1, Texas1, Colorado1 (before the ICCF11), Colorado2, Paris2 and Texas2 experiments will be the authors (listed in alphabetical order). Let me know if you do not like this suggestion." You only need to list me as an author it I actually get around to doing Texas2. If I am still busy with the gravity experiment and you want to get the paper finished, you may just mention the Texas1 experiments without including me as an author."

"7) Rising gas prices made me think about your home-based project for the agricultural fuel, Scott. Are you making progress on that front?" No. Our process does not make sufficiently pure biodiesel and we do not know how to improve it. I, too, am not a chemist and that makes me uncomfortable with this kind of experimentation. I just feel like I have no clue what to try next.

= =

26) Richard --> Ludwik (5/5/06):

I'm not sure how to read this chart but it's suppose to show percent of
wet/dry steam at different pressures and temperatures.

http://www.chemicalogic.com/download/mollier_chart_english.pdf

= =

27) Ludwik --> Richard: (5/5/06):

My understanding is as follows:

1) Suppose we have a long cylinder with a piston. It contains some water, for example, 1 Lb or 1 kg. Space above water is vapor (air was pumped out and a very small amount of vapor accumulated). The system is said to be in equilibrium, at any given temperature, when the rate of evaporation and the rate of condensation become equal.

2) At room temperature the equilibrium is when nearly 0% of water is vapor (stem) and nearly 100% is liquid (water). Suppose we supply heat but keep the pressure constant. To accomplish this the volume must be increased. We do this by pulling the piston out (as much as necessary to keep the pressure gauge at the same reading). By adding heat (enthalpy) we create more vapor and less liquid. That what the numbers 10%, 20%, etc. are above constant P line.

3) Saturated (100% dry) steam, I guess, is along the 100% line (on the right). Saturated liquid, I guess, is the 0% line

(on the left). The distance from the 0% line to the 100% line is the latent heat of evaporation, L, for any chosen P.

4) Instead of plotting P, along the vertical axis, one can plot temperature (P*V=RT for one mole of an ideal gas). That is what is shown in the second figure in:

http://www.spiraxsarco.com/learn/modules/2_15_01.asp

5) I think that steam / liquid percentages (at constant P or T) have nothing do do with what we want to know (% of tiny droplets lost). But the second figure in the above URL reminded me about something I wrote before. Somebody responded that my concern was not valid. But I was not convinced. The figure shows that the latent heat of evaporation (L~2250 j/g) depends on the temperature. It decreases when T becomes higher. This might be responsible for the excess heat we measured. The temperature at which steam is formed (at the surface of the cathode) is very high and not clearly defined. Our system is certainly not at equilibrium. The assumed L=2260 J/g might be wrong. Suppose L=2000 J/g but we are not aware of it. We multiply the mass lost by 2260 and this gives us 10% larger thermal energy than it really is.

I will address this issue at the CMNS list again. Perhaps this time somebody will convince me that using L=2260 is OK.

= =

27) Pierre --> Ludwik + Richard (5/25/06):
Pr Fauvarque gave us yesterday the draft of the "chemical" appendix. We hope to send you this note by the end of the next week. I met the same kind of difficulties for Marseille 1 as in Boulder for Colorado 2 during the first days. As soon as we change a little bit the design (for example a new beaker higher than the old one in order to avoid definitively the droplets problem, we have problem with the COP values (only 1.10 to 1.12). And also the wattmeter instability. I hope that Richard will give us soon better news.

= =

28) Ludwik --> Pierre + Richard (5/26/06):
If taller container gives smaller COP then we must worry about tiny droplets. It is natural to expect less droplets when the container becames taller. In a recent CMNS list posting Michel Jullian wrote: “There was _some_ salted water escaping, by which amount it inflated the COP we don't know yet (among the few excellent qualitative tests performed, . . .) “ What kind of tests were performed and what percentage of droplets was found? I need the answer to this question in order to start drafting our paper. Also how many grams of tungsen is consumed per one kJ of excess heat? I am referring to experiments in which the COP is close to 1.24, as in Colorado2.

Michel also wrote: “Strangely, the addition of a 470µF decoupling capacitor directly across the cell's electrodes in the afternoon yielded sub-unity COP readings (0.8 or so) instead of the over-unity COPs (1.25 or so) which we had obtained in the morning confirming the COPs observed in the previous Fauvarque-ICCF12 type GDPE experiments.” That seems to contradic what Pierre wrote about the COPs in Marseilles -- 1.10 and 1.12. I suppose that the COPs close1.25 were from the original cell, not from the taller cell. I am also puzzled by the effect of the 470µF capacitor on the COP.

How should the last sentence in Pierre’s massage be interpreted? Are we ready to write a paper based on Colorado2 experiment or should we write a paper based on Colorado3 experiment instead?

= =

29) Pierre to Ludwik + Gerard (5/28/06):
Je ne remets pas en cause nos résultats et notamment ceux de Boulder. Je pense seulement que cette expérience est délicate et que certaines conditions n'étaient pas remplies : lueur jaune-orange du plasma, intensité voisine de 1A à 1A.15, alors que nous avions des valeurs trop élevées, proches de 2A. etc.. Il faut donc reprendre cette expérience calmement et ce ne sont pas les droplets qui doivent modifier les résultats. Je suis bien sûr en faveur d'un papier sur Colorado 2 mais j'attends aussi les résultats de Richard sur Colorado 3 avec beaucoup d'intérêt. J'ai tardé à vous répondre car j'ai du participer à des évènements familiaux, loin de Paris. Je suis de retour et pour gagner du temps , je

vous écris en français...

= =

30) Ludwik to Richard+Pierre+Gerard (5/29/06):
Pierre wrote in French (see below) to gain time. He is not questioning validity of Colorado2 results. He thinks that "certain conditions were not met," such as color of plasma and the current of ~ 1 A. Our current was ~2A. "Thus we must reconsider these experiments calmly." Pierre does not think that droplets are responsible for the COPs>1. [But that is not enough; we must have data showing that escaping water contained no potassium. That became the central issue when our results were discussed on the CMNS list. My impression was that Gerard was conducting chemical experiments. What did he measure and how can this help us to rule out the effect of droplets? Pierre is in favor of publishing the paper based on Colorado2 but he is eager to see Richard's Colorado3 results.

I am slightly confused by the "we must reconsider these experiments" phrase. What does it imply in practical terms? What should our time-table be? Should we wait or should we try to publish the Colorado2 results as soon as possible? Either way would be OK with me. Let me add some additional observations.

1) What makes the current lower (~1 A instead ~2 A at 350V)? I think it is the thickness of the plasma envelope and concentration of ions in it. The resistance goes up when the layer becomes and the current becomes lower. The current is also directly proportional to the concentration of ions. To get lower current we must decrease the ion density. But I do not know how to control the the layer thickness and degree of ionization. Perhaps the diameter of the cathode has something to do with this. The resistance of the layer goes up when the cathode diameter goes down, provided the layer thickness remains the same.

2) Our temperature (near the wall of the cell) was 89 C, that is because the two-litter container was too large for power we used. I am assuming that others used smaller vessels and their temperatures were uniformly equal to the boiling point. One might suspect that differences between currents are due to differences in temperature. But I do not think so. After all, what counts is the temperature of the plasma and not the temperature near the walls.

= =

31) Ludwik --> to Pierre + Richard (6/2/06):
1) For some reason I had no replies from you. Perhaps my message was lost; That is why I am pasting it below. . . . .

2) Today is Friday; when should I expect Fauvarque's report?

3) What is happening with our attempts to learn about concentrations of potassium in the escaped water and in the electrolyte? My impression was that this work is in progress -- Richard+Scott in the US and Gerard in France. Where do we stand on this?

4) Most of my draft is ready. I will send it to you very soon. My suggestion is to have Richard as the first author for our Colorado2 paper. The rest of us will be listed alphabetically. For the time being I am listing everyone. But I am not sure about George Luce (who works with Scott). And I do not know if Scott will be willing to be the author.

5) Should Fauvarque be the author of the paper or should he only be the author of the appendix? It does not make any difference to me. I will wait for the input from Pierre about this.

6) We also need a good title. Authors: Richard Slaughter, Pierre Paul Clauzon, Jean-Francois Fauvarque, Ludwik Kowalski, Gerard Jean-Michel Lalleve, Scott Little and George Luce

= =

32) Pierre --> Ludwik+Richard+Gerard (6/5/06):
I thought that I answered you, Ludwik... We are so much submerged by a lot of e--mails (for instance Michel J.) that I do not know where I am with you. First, for us, we should go ahead with the Colorado 2 paper ! The draft of the chemical appendix you are waiting for is on the desk of Pr Fauvarque since three days at least! But he is a very busy man and last week, he was responsible for an chemical meeting of two days and so, inaccessible for almost all the

week ! Today, it is the Monday of Pentecôte, usually a public holliday... and however, we hope to meet with Gérard in the CNAM Lab. ...We will try to definitively give a final answer to Marseille 1 and we hope to get a COP larger than the value of 1.12 we got recently… To my sense, this is only in order to have an other confirmation but this result is not necessary for Colorado 2.

I know that experts in electronics like Michel J. or Jacques Dufour are trying to be sure that the input energy is correctly measured. Jacques Dufour will inspect with his oscillometer our voltage and current signals… We will see, but I am confident with the measurements of Richard and his own expertise. ..Furthermore, I do not think that droplets or tiny droplets are a real problem. When you get the good operating conditions with only about 1 A and the good plasma color, you do not have droplets at all. ..Did I answer you , Ludwik?

= =

33) Pierre to Ludwik ((6/5/06):

The paper joined is just for your personnal information... it is still a draft we have to complete! If you have questions about this note, please write only to me...Thanks in advance...

= =

34) Ludwik --> Pierre (6/5/06):

Thanks for showing Fauvarque's draft. One thing is clear; I do not understand it. And I do not want to be a coauthor of something I do not understand. Therefore, I suggest that Fauvarque is shown to be the author of the appendix in our paper. It often happens that we have to form opinion about something we are not qualified to understand. When this happens I rely of authoritative statements of experts. In this case we should post the appendix (when Fauvarque agrees) on the list and ask for constructive criticism. Do you agree that this would be the best strategy? Is Fauvarque the member of the CMNS list?

= =

35) Richard --> Ludwik + Pierre (6/5/06):

I have not been getting any private message from you. I too think we should go ahead and publish the Colorado report. I have been busy at work and have not done very much on the experiments. The calorimetry is proving to be more difficult than I anticipated. I've had some good results with the ohmic heater showing the correct output power. I just don't get the consistency that is needed. I'll try once again to get the samples to Scott for checking the amount of K2CO3 in the evaporated water.

36) Ludwik --> Richard + Pierre (6/5/06):

= =

You wrote: "I have not been getting any private message from you." That means that at least one of my recent messages was lost. I was worrying that you might be sick or something else serious. You also wrote: " I too think we should go ahead and publish the Colorado report. I have been busy at work and have not done very much on the experiments. The calorimetry is proving to be more difficult than I anticipated. I've had some good results with the ohmic heater showing the correct output power. I just don't get the consistency that is needed."

That is Colorado3. I do not think we should be focusing on that experiment. Except, perhaps at the end, to show preliminary results from "work in progress," if you want. My draft will be about Colorado2 only. You also wrote: " I'll try once again to get the samples to Scott for checking the amount of K2CO3 in the evaporated water."

That is good. I will be waiting for Scott's results, and for the chemical appendix of Fauvarque. He must know how much W is consumed during our typical experiment. Did you give him this information, Pierre? Most of the lost tungsten is probably still pure metal, in the deposit, as in Mizuno experiments. But some of it is probably reacted with something to generate heat. I hope he will show that the total number joules from all possible chemical reactions is no more than 150J in 5 minutes. That would be less than 1% of our mean excess heat. We need the number of joules, and a description of data from which the number was obtained. Also some references, to satisfy chemists. It would take no more than two or three days to incorporate the missing information into my first draft. What each of you think about showing the draft to others on our CMNS list (after discussing it in private)? That would help us to end up with a better manuscript.

= =

37) Pierre --> Ludwik+Richard+Gerard (6/6/06):
Our W cathode is 15 cm long, 13.2 g heavy, and the cross sction diameter is 2.4 mm large. A typical run of 20 to 30 minutes burns about 1.5 cm of the cathode (i.e. 1.32 g). A typical abnormal excess energy is about 60,000 joules (100 w during 10 minutes).

= =

38) Ludwik --> Pierre + Richard + Gerard :(6/6/06):
My suggestion is to collect the residuals (for example, after evaporating water) and to find out how many grams of metallic tungsten it contains. According to Mizuno only a small fraction of lost tungsten participates in chemical reactions. Most of W simply melts away and remains metallic. That means that the amount of tungsten acting as a fuel for chemical heat is actually much less than 13 grams, from each cathode, perhaps less than 0.13 grams. That information will probably be very useful to Fauvarque. How else can he calculate the upper limit of chemical contribution to excess heat? Another suggestion, for the appendix only, is to express things in terms of joules and not in terms of watts. Most people know how to go from joules to eV.

Suppose we report 150 kJ in 25 minutes and that the actually reacted mass of tungsten was 0.13 grams. The 150,000 J translates into 9.4*10^23 eV. The 0.13 grams of tungsten translates into 4.24*10^20 atoms. In other words 9.4*10^23 / 4.24*10^20 = 2217 eV per atom. Such amount of energy per atom is three orders of magnitude higher than what is usually associated with chemistry. Note, however, that the result would be only 22 eV per atom if all the lost tungsten reacted as fuel. That is less dramatic than 2217 eV/atom.

= =

39) Richard --> Ludwik + Pierre + Richard :(6/6/06):
I have not been getting any private message from you. I too think we should go ahead and publish the Colorado report. I have been busy at work and have not done very much on the experiments. The calorimetry is proving to be more difficult than I anticipated. I've had some good results with the ohmic heater showing the correct output power. I just don't get the consistency that is needed. = =

40) Ludwik --> Richard (6/6/06):
Below is the message that you probably did not receive. . . .

= =

Ludwik (in a message posted at the CMNS list) 6/8/06:
. . . My draft describing Colorado2 results will be finished as soon as two missing components are received. I intend to expose it to criticism. And, personally, I would have no objection for not publishing it. Waiting for results from Paris3, Colorado3 and Marseilles1 experiments might indeed be preferable, as suggested by Michel.

= =

41) Ludwik --> Gerard + Richard (6/9/06):
(1) Is it OK to show, in our paper, that Fauvarque is the author of the appendix? Why is Fauvarque not participating in our discussions? I would very much like to read what he thinks about GDPE. He is the only electrochemist among us, as far as I know. His active participation would give me more confidence. I am hesitant to go ahead without his active participation. (2) Since I am totally ignorant in chemistry I would like this appendix to be discussed on our CMNS list? Can I post it today and ask for comments? (3) What should I write about this appendix in the main text of our paper? That text does not expect readers to know chemistry. Please write a paragraph for me. More questions later.

= =

42) Ludwik --> Pierre + Richard (6/10/06):
I asked Gerard some preliminary questions this morning. But he did not reply at once. Perhaps you can answer them. Here they are:..... Meanwhile I had to relearn what "titration" is. This shows how little chemistry I know. I am waiting

for your OK about posting the appendix on our CMNS list. I hope others will say that the appendix is well written and should be very convincing to a chemist.

= =

43) Ludwik --> Jean-Francois (Fauvarque) + Pierre + Richard (6/10/06):
Dear Dr. Fauvarque: I am writing a paper about results of our Colorado2 experiment. The appendix you wrote will be an extremely important part of it. Gerard sent me your appendix yesterday but I am in no position to evaluate it -- I am not a chemist. Our paper would not be worth publishing without convincing arguments that excess heat we measured cannot be due to possible chemical reactions.

Publishing a paper (associated with the controversial field of cold fusion) in a mainstream science paper will not be easy. That is why all possible objections should be anticipated. Our statements should be backed by references and by results of numerical calculations. My first impression was that your appendix is vulnerable to criticism of objective referees. That opinion is probably due to my limited familiarity with chemistry. In the main body of the paper I would like to say something like this: "A possibility of chemical origin of excess heat has been carefully examined by one of us (JFF), as shown in the appendix. The conclusion was that chemical fuels present in the cell could not possibly contribute more than 1% (???) to excess heat measured. We definitely need an upper limit, plus a strong appendix to numerically justify it. The fact that the appendix was produced by a well known electrochemist is essential, as far as i am concerned.

P.S. If the only possible fuel were tungsten, and if most of what was eroded during the electrolysis were found as pure metal at the bottom of the beaker, then the chemical contribution would be much less than 1 %. Here is my recent message to Pierre about this:

On Jun 6, 2006, at 9:09 AM, pierre.clauzon@wanadoo.fr wrote:
Ludwik, our W cathode is 15 cm long, 13.2 g heavy, and the cross sction diameter is 2.4 mm.
A typical run of 20 to 30 minutes burns about 1.5 cm of the cathode (i.e. 1.32 g).
A typical abnormal excess energy is about 60,000 joules (100 w during 10 minutes).

Pierre, my suggestion is to collect the residuals and to find out how many grams of metallic tungsten it contains. According to Mizuno only a small fraction of lost tungsten participates in chemical reactions. Most of W simply melts away and remains metallic. That means that the amount of tungsten acting as a fuel for chemical heat is actually much less than 1.3 grams, in a typical run, perhaps less than 0.013 grams. That information will probably be very useful to Fauvarque. How else can he calculate the upper limit of chemical contribution to excess heat? Another suggestion, for the appendix only, is to express things in terms of joules and not in terms of watts. Most people know how to go from joules to eV.

Suppose we report 150 kJ in 25 minutes and that the actually reacted mass of tungsten was 0.013 grams.
The 150,000 J translates into 9.4*10^23 eV
The 0.013 grams of tungsten translates into 4.24*10^19 atoms.

In other words 9.4*10^23 / 4.24*10^19 = 22200 eV per atom. Such amount of energy per atom is three orders of magnitude higher than what is usually associated with chemistry. Note, however, that the result would be only 222 eV per atom if all the lost tungsten reacted as fuel. That is also impressive, but not as impressive than 22200 eV/atom.

We decided to discuss the draft of the paper among the authors first. Then, after making necessary changes, we want to post it on the restricted CMNS discussion list. There are many highly competent and friendly people on that list; they will probably help us to produce a difficult-to-reject paper. Are you among the CMNS subscribers? I will send you the draft as soon as it is ready. To avoid mistakes made by many, including Fleischmann, our paper should not claim that excess heat is nuclear; we have no evidence for this. Here is the last section of my draft:

Conclusion:
The overall conclusion is that the GDPE thermal-excess energy, discovered in (1), and confirmed by other investigators (9, 10 and 11), seems to be real. Generation of excess heat, at the 0.1 kW level, turned out to be

reproducible. The origin of that energy is not clear to us. Can several cells be used in a battery generating excess heat at a much higher rate? Not having an accepted theory one must rely on empirical investigations. Systematic studies of effects of various parameters (sizes, compositions, distances, etc.), on the performance of Mizuno-type cells, seem to be warranted.

Absence of radioactive byproducts is a clear indication that familiar nuclear reactions cannot possibly be responsible for the amount of excess heat measured. A thermonuclear D-D reaction generating excess heat at the rate of 0.1 kW, for three hours (our total electrolysis time), would produce about 4*10^19 neutrons. That would be sufficient to produce radioactive isotopes in many objects near the cell. A Geiger counter we used showed that the level of radioactivity, near the cell, was not higher than natural background.

= =

44) Ludwik --> Pierre + Richard (6/10/06):
That is OK with me. I just sent an email message to JFF, plus a copy to you and to Richard. That would be a good way to start discussing our paper. Is he a CMNS list subscriber?

= =

45) Pierre -->Ludwik + Richard (6/11/06):
Up to now, JF Fauvarque was not a member of the CMNS list. As I told you, he is a very busy man and I just make for him copies of the most meaningful papers delivered in the CMNS list. We are working together with Gérard, under the leadership of Pr Fauvarque. When I am in the CNAM labs, I use the computer of Gérard for the mails, for example. But, before sending you any mail, I usually ask Gérard for his approval..

46) Richrd --> Ludwik + Pierre (6/11/06):
I think it is a good idea to post Fauvarque’s appendix. I’m sure he knows we intend to publish the appendix with our paper. This way we/he can get some additional feedback. I would add some comments to the paper saying it is not for distribution outside the CMNS group. I suspect Fauvarque is just very busy, still he did work on the paper. I think we should send a personal thank you note of appreciation. Perhaps in this note we could ask how he would like to be credited with the appendix

= =

47) Ludwik --> Jean-Francois + Pierre + Richard (6/11/06):

1) Richard, I agree that we should thank Pr. Fauvarque for willing to help us. This morning I looked at the list of his publications, fetched by Google, and I was very impressed. Our claim that the measured excess energy cannot be due to chemical reactions would not be taken seriously by reviewers and editors without a reputable electrochemist. We are lucky to have him. Perhaps he will find time to communicate with us by email during this final stage -- discussing the draft and strategy for publishing (where, what to say, what not to say, etc.). As you know, publishing a paper on a controversial topic is much more difficult than a paper making a contribution to what has already been published.

2) You also received the draft (as an attached file sent by Gerard) of what he wrote. I am reading that appendix again and formulating comments. But before sharing my comments and questions with coauthors I will wait for the reply from JFF. Pierre prefers to discuss the appendix between the coauthors before posting it on the CMNS list. That what we should do for the next two or three days. If nobody comes with suggestions to modify what was written by Jean Francois then I will post the appendix on the CMNS list.

3) Did you send samples of our electrolyte, and of condensed liquid, to Scott? Using his X-ray fluorescence device he promised to determine the percentage of tiny invisible droplets in the escaping liquid. I will be waiting for his input about the droplets. It is also essential. I am no longer counting on Scott's attempt to replicate our results. My draft cannot be finished unless I know that the percentage of droplets was very small, for example one percent or so. We must be absolutely certain that it not close to 24% -- that would show that the COP=1.24 was an illusion. Was the percentage of droplets measured by Gerard, in Paris2 experiments (immediately after Colorado2)? What was the result and how accurate was it? I would like to say something like --> 2% +/- 0.5%. Anything above ~5% would push us away from the comfortable level of high confidence. (that the COP > 1.0).

4) My notebooks are in boxes that were put into self-storage. That is will probably have some questions to you and to Pierre. For now I want to know the capacity of the 500 V electrolytic capacitor we used at the output of your power supply?

5) I also need information about a test we did not perform. Can one of you perform the following test:

a) Start the experiment as usual (by increasing the voltage and performing the first measurement of COP, the one that should always be rejected).

b) Then turn the voltage off suddenly, disconnect the cables, and measure the voltage between the electrodes. We believe that the voltage will be zero. But this should be checked. It will be useful to describe this test in our paper. If the voltage is nearly zero then we will be able to rule out a possibility of a battery-like effect (storing energy during the preliminary steps and releasing it when the COP is measured). That kind of objection can be made by a reviewer. Our answer, even without the suggested test, would be that stored energy would have to be several times larger than 30 kJ (100 W times 300 seconds case after case.) But reporting that we performed such test will show that such possibility was not ignored.

6) In fact, I would not be surprised to see a small remaining potential between the electrodes. If you observe this then treat the cell as if it were a capacitor and calculate the energy stored. Use a two-trace oscilloscope to see the v(t) and i(t) exponential pulses (slow discharging). That what I would do to find the stored energy. I am 99.9% sure it will be much much less than 30 kJ. Perhaps we will be able to say that stored energy turned out to be 0.01 kJ, or something like this.

= =

48) Ludwik -->Gerard + Jean + Pierre + Richard (6/12/06):
On Jun 9, 2006, at 8:27 AM, gerard.lalleve@laposte.net wrote:

About now the droplets case, we confirm to you that we
have not at all loss of potassium when the experiment
is operated in a right way. In Marseille also, we used
chemical paper to see if the steam was polluted by
very tiny droplets. The result was again negative.

1) What we need are numerical results. Something like "contribution of tiny droplets to the mass of the escaping wet steam was found to be 2.5% (???)." Or something like "less than 1%," if the titration method is not sensitive enough to produce one number. That would appear in the main text; the Appendix-2 is for the methodology used to establish the result.

2) Likewise, the main text would say something like "contribution of known chemical reactions, to the excess heat measured, could not possibly exceed 0.01%" (???). That statement would be justified in the Appendix-3.

3) Note that the (???) indicates wishful thinking; I have no idea what the actual numbers will be. I already wrote Appendix-1; it is about measuring electric energy. In my opinion three short appendices are better than a single long one.

4) Today I will read the long appendix written by JFF again. My general impression was that it does not provide percentages we need to justify the COP=1.2 claim. I would like to know what each of you think about the long appendix. Do you agree that turning it into two shorter appendices is desirable? If so then we should see and discuss them, as soon as possible.

5) Where do we stand on the X-rays fluorescence test of samples, promised by Scott? Where do we stand on the estimation of the fraction of tungsten, lost by the cathod, that remains metallic? According to Mizuno that fraction (found in the deposited residuals) is very large. What remains metallic did not participate in chemical reactions and did not contribute to chemical excess heat. That should probably be taken under consideration in the Appendix-3.
= =

49) Richard --> Ludwik (6/12/06):
I've been very busy at work and just have not had the time and energy to work on CF. I'll try very diligently to get the sample for Scott this week.

= =
50) Ludwik --> Richard (6/12/06):
1) I understand your dilemma perfectly. I had a similar problem before retirement. Work connected with teaching had to be my first priority, no matter how much I wanted to do something else.

2) I am puzzled by silence from Fauvarque. The appendix he wrote (Pierre said he gave it to them about two weeks ago) was not very helpful to me. I hope it will be changed. Otherwise our paper will be in trouble. Any referee will see that it is not qualitative, as far as what we want to know is concerned. Most numbers refer to intermediate results from titration.

3) Scott would most likely provide reliable numbers for the Appendix-2 (percentage of droplets in wet steam). But rebuttal of the idea of chemical origin of excess heat (Appendix-3) must be produced by an electrochemist familiar with exotic hot-plasma ebvironement.

= =
51) Ludwik --> Jean + Richard + Gerard + Pierre (6/13/06):
JFF wrote (in our appendix):
1- Acid-Base titration
5 mL of the initial solution is titrated by HCl 1.0 M. The two successive neutralisations of CO3 2 - at pH 8.5 and of HCO3- at pH 4.5 are clearly visible. As expected, no other neutralisation is detected. The titration gives 1.94 M of K+ (counter ion), the carbonate being initially under the form CO3 2 -. . . .

The molarity of 1.94 seems to be impossible. Our electrolyte was 0.2 M. Assuming nearly 100% ionization of K2CO3 in water I would expect the molarity of K+ to be 0.4, or a little less, but not 1.94. Where am I wrong?

= =
52) Jean --> Ludwik (6/13/06):
I was wrong, it was a writing lapsus, the K+ molarity is 0.388, as expected.

= =

53) Ludwik --> Jean (6/13/06):

Thanks for the quick reply. Suppose "wet steam" is condensed when a measurement of COP is in progress. If the K+ molarity of condensed liquid turns out to be close to 0.008 then we would be able to say that the contribution of tiny droplets of electrolyte, to the lost mass, is about 2%. The rest is pure vapor. That would be a strong argument that the COP determined in that experiment is not an illusion due to tiny droplets. And our Colorado2 results (mean COP=1.24, st.dev. =0.13) will be taken more seriously. Do you agree? If so then please ask for the appropriate measurement (or several measurements to determine the precision) to be made.

= =

54) Ludwik --> Jean + Gerard + Richard + Pierre (6/13/06):

Dear RS, , PC, JFF, LK and GL:

1) These are initials of authors in my draft, in the order shown. For obvious reason, Richard is the main author, the rest of us are listed in alphabetic order, according to last names. Is this OK with everybody. I still do not know what the status of Scott Little will be. It will depend on his promised contributions.

2) I wander if the message sent nearly 40 hours ago was received by everybody. My expectation was that we will start discussing the appendix, as soon as possible. That was the purpose of comments shown below. What does each of you think about my comments?

3) This morning Jean-Francois asked me to replace the 1.94 M by the 0.388 M, in two or three places. I did this in my file and you should do it in yours. In that way we will be discussing identical texts.

Ludwik

2) Likewise, the main text would say something like "contribution of known chemical reactions, to the excess heat measured, could not possibly exceed 0.01%" (???). That statement would be justified in the Appendix-3.

3) Note that the (???) indicates wishful thinking; I have no idea what the actual numbers will be. I already wrote Appendix-1; it is about measuring electric energy. In my opinion three short appendices are better than a single long one.

4) Today I will read the long appendix written by JFF again. My general impression was that it does not provide percentages we need to justify the COP=1.2 claim. I would like to know what each of you thinks about the long appendix. Do you agree that turning it into two shorter appendices is desirable? If so then we should see and discuss them, as soon as possible.

5) Where do we stand on the X-rays fluorescence test of samples, promised by Scott? Where do we stand on the estimation of the fraction of tungsten, lost by the cathod, that remains metallic? According to Mizuno that fraction (found in the deposited residuals) is very large. What remains metallic did not participate in chemical reactions and did not contribute to chemical excess heat. That should probably be taken under consideration in the Appendix-3.

= =

55) Richard --> Ludwik (6/14/06):

I'm glad you are on top of this. It's difficult for me to follow. I've got four samples of condensed liquid tonight. The test when easily but I didn't get any real high COP. The highest was 1.20. I'll send these to Scott tomorrow.I have three samples of the condensed liquid and one sample of the electrolyte from the beaker. That will help keep everyone honest. I'll try for some higher COP this week.

= =
56) Ludwik --. Richard (6/14/06):
1) On 4/29/06 Scott wrote to us: "Yes, I could probably make a reasonably accurate analysis for elemental K content that way. I need about 15 mL of solution to fill the sample cup properly. Actually if that is a great difficulty, I could probably dilute the samples 10:1 and still attain satisfactory accuracy. .. so I could use as little as 1.5 mL of sample."

2) Keep this in mind. My suggestion is to split each of your two sample into two and to send only one half of each to Scott. The others may become very valuable if a serious discrepancy develops between the two results (Scott versus Jean-Francois). In that case we might send the samples to a commercial lab. Many medical and environmental labs are well equipped for the analysis of potassium -- they do this routinely.

= =
57) Richard --> Ludwik + Pierre + Scott (6/15/06):
Scott, I sent you four samples today. Each sample is 10 to 15 grams I hope this is enough. Samples 1 to 3 are of 3 runs that had COP's > 1.1. I was not able to get high COP's but I will try again. I sent you all of the sample I took. So you might want to keep part of the sample after you dilute it for further study. The forth sample is just some of the electrolyte after running the tests. Thanks for the help

= =
58) Pierre --> Ludwik + Richard (6/15/06):
Bonjour Ludwik, Je t'écris du laboratoire de Jacques Dufour, beaucoup mieux équipé que notre ancien laboratoire (enregistrements des mesures, alimentations diverses, etc..). Avec l'accord de nos chefs (Prs Fauvarque et Foos), nous avons lancé l'opération Paris 3 ensemble.

Vous êtes entrés en relations, Fauvarque et toi, pour cette annexe chimique. Après en avoir discuté avec lui, nous pouvons dire qu'à la précision des mesures (0.5 à 1%) nous retrouvons dans l'électrolyte tout le potassium initialement présent. C'est aussi une réponse à la question des « tiny droplets ». Une fois le régime de fonctionnement bien établi, j'estime personnellement qu'il n'y a pas d'entraînement significatif de gouttelettes.(<<1%).

Chaque essai de 20 à 30 minutes fait disparaître environ 1.3 g de Tungstène. Une bonne part tombe au fond du bécher (beaker) , peut-être 50%, sous forme de débris métalliques. Nous n'avons pas conservé ces fonds de bécher, mais, là encore, les résultats d'échauffement en terme de réactions chimiques liées au Tungstène sont négligeables comparés aux échauffements anormaux constatés.

Tu écris, Ludwik : « ne laissons pas le mieux être l'ennemi du bien ». J'ajoute dans le même esprit : « ne coupons pas les cheveux en quatre ! ». Je crois qu'il est temps de publier nos résultats de Colorado 2. Nous espérons pouvoir remplir tous les blancs que tu laisseras dans ton draft. J'espère que cette expérience simple donnera l'idée à des experts de la fusion froide de confirmer nos dires et d'apporter leurs propres améliorations. PS: I hope, Richard, you read the french. ..Sorry, if not !

= =
59) Ludwik --> Pierre and Richard (6/15/06):
1) In my opinion, as I wrote before, our paper is not worth submitting to a mainstream journal. A good appendix, signed by a reputable electrochemist is essential. That appendix must convince other experts that excess heat we measured cannot be attributed to well known chemical reactions. His words will be taken seriously, my words or your words will not.

2) Pierre, why is Fauvarque not one of those to whom your message was sent? Are there any problems with his willingness to be fully responsible for the thermo-chemical Appendix 3? I wander why he did not comment on what I wrote about his appendix. Are we going to have separate appendices for energy and for tiny droplets? Should I interpret this as an OK for posting his appendix on the CMNS list (after replacing 1.94 m by 0.388 M)? My expectation was, and still is, that each of will write about his appendix, before we show it on the list.

3) Richard, Pierre tells us that Paris3 experiments will be conducted by an enlarged team (people from Fauvarque lab and from Dufour lab at CNAM. Dufour lab is much better equipped for that kind of work).

4) Pierre also gives us a conclusion about the invisible droplets -- their contribution to the lost liquid was found to be between 0.5 and 1 %. That is a great news; I will include that sentence into the main text. The methodology used to establish this result must be described. We can do this in his long appendix or in the Appendix 2, as I suggested. Two or three paragraphs, that any chemist will understand, would probably be sufficient. Fauvarque's appendix does not mention the 1% conclusion; perhaps it is hidden somewhere between the lines.

5) Let us hope that Scott's data will confirm the very low percentage of droplets. Being familiar with his instrument I will add a paragraph or two about the second method to the Appendix 2 (or two Fauvarque's appendix) .

6) No, I am not trying to split a hair, Pierre. We are making an extraordinary claim. Our paper must be nearly nearly perfect in order to have a chance of being published. Please answer as soon as possible; it is frustrating to wait and not being able to finish the draft. I reached the point at which I can do nothing more by myself. I must be satisfied with contributions made by others. And I do not want to share an unfinished draft.

= =

60) Ludwik --> Pierre and Richard (6/15/06):
In reading Pierre's message more carefully I see that he did not say that droplets were 0.5-1%. He said that the contribution of droplets was much less that 1 %. That is better. The 0.5-1% was their maximum possible error in the statement that the "molarity of the remaining electrolyte did not change." That is a much weaker statement than comparing the 0.2 M of the electrolyte with the molarity of the condensed liquid. If the "much less than 1%" is true that the result should be "much less than 0.002 M." A good referee would certainly ask for a better method of determination of the percentage of droplets. He would also ask if the "much less than 1%" is consistent with the "0.5-1%" accuracy. We should anticipate such questions and answer them in the appendix. Do you agree with this? Does Fauvarque agree with this?

= =

61) Ludwik --> Pierre and Richard (6/15/06):
1) Pierre; I am terribly confused for the absence of comments about what I wrote to Fauvarque and to you (in two messages). Should I start discussing his appendix on the CMNS list, as we were going to do after discussing it among ourselves?

2) Meanwhile I prepared a message (see below) which will lead to such discussion. I will post it as soon as you and Richard OK it.

MY MESSAGE WILL SAY THIS:

On Jun 14, 2006, at 11:07 PM, Ludwik Kowalski wrote:

List of successful replications of Mizino-type excess heat:

1) J.L. Naudin see his website --> http://jlnlabs.imars.com/cfr/
2) V. D. Cirillo et al. see their ICCF11 report
3) J.F. Fauvarque et al. see their ICCF12 report
4) R. Slaughter et al. Colorado2 experiment (we are working on the report)
5) J.F. Fauvarque et al. -- Paris2 (preliminary results after Colorado2)
6) University Labs in Japan

Experiments in preparation or in progress:
7) R.Slaugther -- Colorado3 (preliminary observations of excess heat)
8) J.P. Biberian -- Marselles1
9) J.F. Fauvarque et al. + another lab at CNAM -- Paris3

10) S. Little -- Texas2

What about your lab? I am not going to list names; many researchers on this list are highly qualified to replicate Mizuno-type experiments. And some are they are likely to have what is needed. Working on nearly identical experiments, and sharing results from our non-patent-motivated work, we are likely to promote the CMNS field faster than working on separate experiments and keeping things secret. Naturally, one must be aware of possible dangers, as described earlier on this thread. . . .

I am slowly realizing that my suggestion would be acceptable only if we had convincing (indisputable) arguments that the reported excess heat could not be explained by well known chemical reactions. We need a straight forward thermochemical analysis of reactions that are expected to take place in GDPE cells. Potential reactants present are known and chemists, I expected, can calculate excess heats associated with each of them. It would be a matter of adding individual excess heats (some positive others negative, according to existing enthalpy tables and according to amounts of consumed reactants). I assumed that such analysis would show that the net excess heat from known chemical reactions is at least two orders of magnitude smaller than what was actually measured. But I have not seen such arguments, so far.

What I did see, in a Mizuno's paper (see below), was a discussion based on one potential fuel, tungsten. Is it reasonable to assume that the role of other potential fuels can be neglected, in comparison with tungsten? Mizuno seems to be making such assumption. But I am not a chemist and validity of that assumption is not obvious to me. I hope that reputable chemists will provide indisputable evidence that chemical excess heat is too small in comparison with what comes from a Mizuno-type cell containing the K2CO2 electrolyte. By the way, I do not think that reliance on authority of experts is forbidden by the so-called "scientific method." Where would we be if we had to validate everything by ourselves?

Here is how Mizuno et al. addressed the issue (in T. Mizuno, T. Ohmori, K. Azumi, T. Akimoto and A. Takahashi; “Confirmation of heat generation and anomalous element caused by plasma electrolysis in the liquid;” Conference Proceedings Vol. 70, ìICCF8î Società Italiana Di Fisica, Bologna, 2000, p. 75)

1) It is well known that 380 kJ of heat is released when one mole (183.85 grams) of W is consumed to produce H2WO 4.
2) In reality only 0.1 grams of tungsten was lost during a test in which excess heat was measured. That, could produce 0.207 kJ of heat. The amount of excess heat measured, 54.4 kJ, was found to be considerably larger. Thus no more that 0.4% of excess heat measured could be due to chemical consumption of tungsten.
3) This 0.4% fraction, they wrote, is actually an exaggeration because the 0.1 grams of tungsten lost from the cathode was found at the bottom of the cell in the form of pure metallic powder. In other words, tungsten did not react with oxygen, it was simply removed “by hydrogen corrosion as well as heat damage.”
4) Another chemical reaction taking place in the cell, during plasma electrolysis, is “the decomposition of the carbonate in a water solution.” That reaction is said to be endothermic; it removes 274 kJ of heat per mole of K2CO3. Is it true that tungsten is the only well known exothermic reaction that might contribute to excess heat measured in Mizuno-type cells?

By the way, loosing only 0.1 grams of tungsten per experiment is not consistent with what I remember from Colorado2. It is also not consistent with more qualitative results from Paris2 experiments. Referring to these experiments in a private message, Pierre Clauzon wrote: "In each sequence of tests lasting 20 to 30 minutes we loose about 1.3 grams of tungsten. A sizable fraction of it, perhaps 50%, is found as residuals, deposited at the bottom of the beaker..... " Note that 1.3 grams is considerably larger than 0.1 grams reported by Mizuno et al. That seems to indicate that experiments in Colorado2 and Paris2 were substantially different from those described by Mizuno. Perhaps the shapes of electrodes have something to do with the difference.

In any case, what conclusion can be drawn from the information provided by Pierre? Following Mizuno et al., I will assume that tungsten is the dominant chemical fuel during the glow discharge electrolysis. I will also assume that excess heat is generated at the average rate of 50 W. That translates into 90,000 joules of excess energy (or . 5.62*10^24 eV) during 30 minutes. The 1.3 grams of tungsten, on the other hand, translates into 2.54*10^22 atoms. If

100% of these atoms reacted chemically, to generate 90 kJ of heat, then the rate is 121 eV per atom. that is already two orders of magnitude higher than what is usually associated with chemical reactions. If Mizuno is correct that tungsten in the residuals is pure metal, and if Pierre is correct that residuals contain 50% of the lost tungsten, then the number reacted atoms becomes two times larger and rate becomes 2*121=242 eV/atom.

Another way of using Pierre's data is to follow Mizuno's approach. The mass of the lost tungsten was 1.3 grams. This is 0.0071 moles. The expected chemical heat, due to reacting tungsten, is 0.0071*380 = 2.69 kJ. That is only 3% of the actually measured excess heat. The result would be 1.5% if only 50% of tungsten reacted, as estimated by Pierre. But what if the actual measurements showed that 90% of the lost tungsten is metallic, at the bottom of the beaker? That the result would be a small fraction of one percent. I hope the amount of metallic tungsten, in the residuals could be determined with the accuracy of 5% or so. Honest referees would appreciate our effort to do the best we can to show that excess heat we measured is indeed abnormal. Publishing a paper on excess heat makes sense only if the abnormality can be established. Abnormality is the central point of our paper and it has to be established as conclusively as possible. We are in no position to argue about nuclear or hydrino's origin of excess heat. That would call for much more information than we were able to gather. Comments and help would be highly appreciated.

= =

62) Pierre to Ludwik (6/17/06):
I did receive your last e-mails about our absence of comments, Fauvarque and me. I will do my best this w.e. and I will try to get the same from Fauvarque next week. Fauvarque was at the end of this week in Tunisia, for university exams and contracts . He is a quite busy man and please, accept our apology !

= =

63) Ludwik --> Pierre + Richard (6/17/06):
1) Thanks for the quick reply, Pierre. OK, I will wait. Did Fauvarque talk with you about my comments?
2) Does he agree with the suggestion to have two shorter appendices, one about chemical excess heat and one about tiny droplets?
3) Did he say that he will calculate for us excess heats of chemical reactions (how many kJ each) on the basis of known amounts of reactants, and on the basis of enthalpy tables used by chemists?
4) I will not start discussing his appendix on the CMNS list. But what do you think about the massage I sent you yesterday. Fauvarque is not mentioned in it; I only quote what you wrote about tungsten. Can I post that message today? It might generate helpful comments.

= =

64) Richard --> Scott (6/17/06):
Ludwik, said you can do X-ray fluorescence on the samples to find out if there is any K2C03 or just K in the samples. We are trying to rule out the possibility of droplets or mist being part of the reason for the over unity COP. Sample 4 is just the electrolyte so it should have 0.2 M K2C03.

= =

65) Ludwik --> Richard (6/17/06):
Just relative heights of potassium peaks (in condensed liquid versus original electrolyte) would probably be enough, provided the geometries are identical. Also an error bar on the ratio. Scott might suggested something else; he knows exactly about the context. (P.S. Actually, this would be true only if the ratio was 0.1 or more. For a much lower ratio, which we hope for, Scott will probably dilute to original electrolyte, for example, by a factor of ten, in order to minimize the error.

= =

66) Scott --> Richard + Ludwik (6/17/06):
It may be next Friday before I get a chance to go see the XRF system. It's not at my lab anymore. .. but it's at the place my daughter works. Meanwhile, I want you to calculate what K concentration in these condensate samples would it take to negate, say, a 1.10 COP. That value will give me something to "shoot for". It will tell me whether this is an easy analysis where I have plenty of sensitivity, a borderline analysis where I have to optimize the excitation conditions and use long count times to get the necessary accuracy, or a hopeless analysis where I cannot even detect an

important (to this experiment) amount of K.

= =

67) Ludwik --> Scott + Richard +Jean + Gerard (6/18/06):
Let me try to answer your question. In the draft of his appendix Fauvarque reported the molarity of K+ ions as 0.388 -- determined by the method of the HCL titration. That is only slightly less than the ideal 0.4 M for our totally ionized K2CO3. To prepare the 0.2 M solution of that salt Richard probably used 26 grams per liter or 26 mg/ml. His condensed liquid samples were from experiments that yielded the COP of 1.1.

If such COP were an illusion due to tiny droplets then the concentration of K+ in samples of condensed liquid would be close to 2.6 mg/ml. To negate the illusion, the condensation would have to be below 0.3, hopefully 0.1 or less. Is the 0.1 mg/ml too low for your instrument? My expectation is that Fauvarque will improve the appendix, and that it will be posted on the CMNS list, probably in several days, after we have a chance to discuss it privately.

= =

68) Scott --> Ludwik (6/17/06):
0.1 mg/mL is about 0.1 mg/gm = 0.0001 gm/gm = 100 ppm. No, that's not too low. I should be able to get a detection limit down below that somewhere, maybe 20 ppm or so. Thanks. I will need to make a more dilute known standard. I'll probably make up a 2500 ppm standard. No problem. I'll get back to you guys later. BTW, XRF measures total K in the sample, regardless of ionization state, etc.

= =

69) Ludwik --> Richard, Pierre, Gerard, Jean (6/17/06):
Forwarding the above message from Scott.

= =

70) Richard --> Ludwik (6/20/06):
This is the first real data from Colorado #3. This is about one hour of continuous data. The voltage and current are normalized using 300volts and 1.333 amps. This just so all the info is on a single plot. The sharp increases in current are where I had to push the cathode down because it had burned away. At about data point 1100 I increased the voltage from 300 volts to 320 because the COP was low. I'm not sure what to make of point 1280 where the current suddenly drops and the COP jumps 1.35. You can ponder the graph like I'm doing and let me know what you think.

= =

71) Ludwik --> Richard (6/20/06):
The fact that you can run for one hour is very impressive. But the main COP is about 1.05. It is too early to comment on this, or to worry about this. I am trying to finish our Colorado2 paper. My suggestion is to include Scott in the list of authors; his XRF result will be a significant contribution. If he refuses then we will simply thank him for help, at the end of the paper. I would prefer him to be a coauthor. But neither you nor Pierre responded to this. Does it mean you have some reservations?

= =

72) Richard --> Ludwik (6/20/06):
It's fine to include Scott as a coauthor. Just give him the chance to decline. I suspect he will be reluctant to be a co-author without having help take the data.

= =

73) Ludwik --> Richard (a comment on a picture he sent me, 6/20/06):
COPs are trying to get up when both powers are going down. Is this significant? Perhaps using lower powers is worth trying. What is the nominal diameter of your cathode?

= =

74) Richard --> Ludwik (6/20/06):
Interesting question! I'm using two 0.040 dia wires twisted together with 1 twist per inch. I had order some wire so I

could have longer lengths this was what they sent as a sample. Using two wires got me closer to the original diameter but gave a lot more surface area.

= =

75) Ludwik to Richard (6/20/06):
I need some information for our Colorado2 paper.

1) About capacitors in parallel with the cell.
a) Was it one or more? How many?
b) Was it 500 V and 470 microF each? If not then how many for each?

2) About the little ac kWh-meter (the one we used for the ohmic heater, when it was also plugged in).
a) What model was it? What manufacturer? Was it from Radio shack?
b) what was the approximate cost?

= =

76) Richard --> Ludwik (6/20/21):
There are two 3100uF 450Volt spraque capacitors
The little plug in watt meter is a Kill A Watt model P4400 designed for seeing how much power household appliance use.
The meter is about $30.00
http://www.spytown.com/kilwatwatkil.html

The other AC watt meter is a DMMetering DRM75A
http://www.dmmetering.com/product_groups/spd.htm#

= =

77) Ludwik --> Pierre + Richard (6/21/06):
Ten days ago I made a suggestion which was forgotten in our subsequent correspondence. I asked about information on a test that was not performed. "Can one of you perform the following test:

a) Start the experiment as usual (by increasing the voltage and performing the first measurement of COP, the one that should always be rejected).

b) Then turn the voltage off suddenly, disconnect the cables, and measure the voltage between the electrodes. We believe that the voltage will be zero. But this should be checked. It will be useful to describe this test in our paper. If the voltage is nearly zero then we will be able to rule out a possibility of a battery-like effect (storing energy during the preliminary steps and releasing it when the COP is measured). That kind of objection can be made by a reviewer. Our answer, even without the suggested test, would be that stored energy would have to be several times larger than 30 kJ (100 W times 300 seconds case after case.) But reporting that we performed the test will show that such possibility was not ignored.

In fact, I would not be surprised to see a small remaining potential between the electrodes. If you observe this then treat the cell as if it were a capacitor and calculate the energy stored. Use a two-trace oscilloscope to see the v(t) and i(t) exponential pulses (slow discharging). That what I would do to find the stored energy. I am 99.9% sure it will be much much less than 30 kJ. Perhaps we will be able to say that stored energy turned out to be 0.01 kJ, or something like this."

What do you think about this suggestion? In my opinion our Colorado2 paper would be more difficult to reject if we say that an attempt to discover a battery-like effect was made but results were negative," or something like this.

= =

78) Richard --> Ludwik (6/21/06):
Will do.. I'm sure the voltage goes to zero in a very short time but I'll get some real data. I've done this all the time

when I shut down the supply and the voltage always drops immediately.

= =

79) Ludwik --> Richard + Pierre (6/21/06):
On Jun 21, 2006, at 8:20 AM, Richard Slaughter wrote:

1) That is good, Richard. Try to get the energy actually delivered through a battery-like effect, even if it is only 5J, or much less. Numbers are always more convincing than qualitative statements, like "much smaller than ..." If the number is smaller than what can be measured then give the upper possible limit.

2) I do not know why Fauvarque is not replying. Are you giving him all messages as soon as they arrive, Pierre? How is he reacting to my questions and comments? We need to hear from him, the more the better.

3) Other electrochemists on the CMNS list, like McKubre, Oriani, Szpak, Mizuno, Biberian, Zhilov, etc. are also not responding. Why is it so? The same is true for material scientists, like Storms and Dash. I am not comfortable in such unexpected situation.

= =

80) Ludwik --> Pierre + Richard (6/22/06):
1) Pierre, did you receive the message I sent you yesterday? In that message I asked why Fauvarque is not replying to my comments and questions about the appendix. Now you are not replying. Did my questions create some problems? Were they really so silly that JFF decided to ignore them?

2) According to the appendix only 1 gram, out of 18 grams lost in a typical experiment, was in the form of droplets. That is 5.6%. Can I say, in the main text that due to droplets the mass lost m must be reduced by 5.6 +/- 1 percent? That will lead to the about 5% correction of COP (1.17 instead of 1.24). The 1% error is based on this sentence from the appendix: "The precision of the titration can be estimated to be roughly 1%" Am I interpreting this sentence correctly? If not then what should the bar of errors be for the 5.6% ?

Why am not certain about the 1%? Because a pH value is x, from the 10^x. Was the 1% an error for x or was it an error for pH? A one percent change of x would produce a much larger change in pH. That is why I am not sure that the 5.6 +/- 1 is a correct interpreation of JFF's sentence. Not being a chemist I need an error on the percentage of droplets, not an error on some intermediate result from which the percentage of droplets was calculated.

3) Scott will probably measure the content of K (in condensed liquid) tomorrow. Will his result confirm the 5.6%? If so then the issue of tiny droplets being responsible for the big part of our excess heat will be put to rest.

4) The only remaining issue will be to convincingly show that corrections to the COP due to chemical heat (positive and negative contributions combined) are also very small, probably much less that 1%. Where do we stand on this issue?

= =

81) Pierre --> Ludwik (6/23/06)
Bonjour Ludwik, Je retransmets à JFF tous les e-mails le concernant... Mais c'est une véritable étoile filante en ce moment ! Il est en ce moment en Russie. Lundi, j'essaierai de le voir le matin, car dès l'après-midi, il repart pour Grenoble pour plusieurs jours ! Nous sommes en pleine période d'examens en ce moment.

Je t'envoie un peu plus tard mes réponses plus détaillées à tes questions. Mais dès à présent, je peux te dire que lors d'une expérience avec Dufour hier Jeudi, on a mis un papier chimique dans la vapeur pour vérifier s'il y avait des tiny droplets d'électrolyte. Je persiste à te dire que c'est très très faible et que les valeurs que tu tires du papier de JFF sont des bornes très supérieures! Pour ma part, ce problème est inexistant !

= =

82) Ludwik --> Richard +Pierre (6/23/06):

1) Richard, Pierre forwards all relevant messages to JFF, who is now in Russia. He will try to see him on Monday morning. On Monday afternoon JFF will leave for a several-days-long visit to Grenoble. It is an exams period in France. Pierre will comment on what I wrote a little later. He wrote: "But I can tell you one thing immediately. The experiment with Dufour [Paris3] started yesterday. We placed a chemical paper into the escaping steam and did not observe any droplets of the electrolyte." Pierre is strongly convinced that the number I extracted from the JFF's appendix are highly exagerated. As far as he is concerned, tiny droplets is not something that we should worry about.

2) But a referee will have right to ask for numbers. What I saw in the appendix was 0.005 M translated into 14 grams of electrolyte. Yes, it was given as an upper limit. But that did not tell me that I should replace 14 grams by 0.14 or 0.014 grams. The upper limit usually refers to what was possible to measure with a given method. Telling the referee that droplets represented much much less than 14 grams of the liquid will not be sufficient. The answers will be "how do you know that it should be 0.14 or 0.014?" or "how do you know it was not 13 grams?"

3) Pierre, what is the realistic limit of detection of tiny droplets when chemical paper is used, as you did yesterday?

4) My suggestion is to design an experiment in which the percentage of the electrolyte in the escaping liquid, for example 1%, is known in advance but not to the person performing the measurements. Measuring the same thing several times (to get the mean value and the standard deviation) would be one way to convince the referee.

5) No, I have no idea how to design an experiment in which the percentage of tiny droplets escaping from the beaker can be controlled. Some kind of a sprayer of pure electrolyte, injecting droplets into steam from pure water, would have to be invented.

6) Yes, I know that most often referees do not ask for numerical data about everything. But we are making an extraordinary claim in a paper that should be "difficult to reject." That is why extraordinary efforts are necessary. Do you agree, Pierre?

= =

83) Ludwik --> Scott + Richard + Pierre (6/23/06):
1) Scott, I hope other things did not delay you. When you do perform the XFR experiment please try to measure the concentration several times. This will give us not only the mean value but the standard deviation (random error) as well. Also try to estimate the systematic error. We are making an extraordinary claim and referees are expected to ask a lot of unusual questions. In my opinion, your contribution deserves a separate short appendix. Please write if for me.

2) Fauvarque is too busy now to answer questions about the appendix. I am not very happy about this. He will probably give us full attention after the exams in France are over, probably in a week or so.

= =

84) Richard --> Ludwik (6/23/06):
Hopefully we will be getting numbers from Scott. His detection is less than 20ppm range. Don’t you think this is sufficient with added comments about the chemical paper? We should be able to get a spec on the paper for detectable limits.

= =

85) Ludwik --> Richard (6/23/06):
Yes, but having a conclusion based on two independant methods would be better. Let us wait and see what will be found by Scott.

= =

86) Scott --> Ludwik + Richard + Pierre (6/23/06):
I have not found the time to go visit my XRF analyzer yet. However, I have a nice Mettler balance so I conducted a simple dissolved solids test on the samples you sent. First I weighed 4 Al weighing cups. Then I dispensed some of each sample into each cups. I used a new disposable pipette for each sample to prevent contamination. Then I weighed the wet cups. Then I gently dried the samples in a 70C oven for 4 hours This gentle drying should leave the

salt as K2CO3+1.5H2O. I recorded the first set of dry weights. Then I returned the samples to the 70C oven for another 8 hours. I recorded a 2nd set of dry weights. Here are the results:

[I am extracting from Scott's large table: The mass of solid deposit from each cc of condensed wet steam was 1.68 mg. That was the mean for the samples #1, 2 and 3, after 12 hours in the oven. Individual results were 2.06, 1.15 and 1.84. This leads to the standard deviation of 0.47. For the sample #4 (the original electrolyte) the mass of the solid deposit was 27.4 mg per cc. What does this mean? Let me begin with the original electrolyte. The 27.4 mg/ml translates into 27.4 g/liter. This is in very good agreement with 26.5 grams of K2CO3 that was put into distilled water to make the 0.2 M solution.

Each cc of the solution is essentially 1 gram. That solution was supposed to be from pure steam. Finding 1.68 mg of silid deposit, per one gram of condensed liquid, is significant because 1.68 is 6.13% of 27.4. In other word, our evaporative losses were exaggerated by 6.13 %.This 2.45 times larger than the upper limit in Fauvarque's appendix. And, according to last Thursday test in Paris3, the upper limit should be changed to a much lower number. What is the new upper limit?]

For the mg/mL column, I assumed that the solution density was 1.000 (same for the molarity calculations) As you can see, the condensate samples are NOT very free of dissolved solids. Ludwik calculated that 2.6 mg/mL would "erase" the apparent excess heat and these samples range up to 2 mg/mL. Note that the stock solution came out very close to 0.2M in this analysis.These results make it even more important to go to the XRF analyzer to confirm that this is actually K in the samples. I'll do that sometime this weekend.

= =

87) Ludwik --> Scott + Richard + Pierre (6/23/06):
Scott wrote: "These results make it even more important to go to the XRF analyzer to confirm that this is actually K in the samples. I'll do that sometime this weekend." Yes, indeed. I suspect that some of the net mass is tungsten. The original solution comes as expected (0.2 M) because it does not contain tungsten. If that suspicion is correct then tungsten peaks will appear in the XRF spectra. Knowing concentration of tungsten might help us to deal with the issue of "chemical contributions to excess heat." According to JFF only ~50% tungsten lost by the cathode is recovered as metallic particles at the bottom of the cell. Where is the rest? You might be able to answer this question, Scott.

= =

88) Ludwik --> Scott + Richard + Pierre (6/24/06):
1) Yesterday, responding to the above, I speculated that solid deposits (samples 1, 2 and 3) might consist of mostly tungsten rather than potassium. Thinking about this again I realized that this would be equally bad for our excess heat conclusion. It would show that the measured lost mass m, that we used to calculate evaporative losses, was not pure water only. The m was overestimated by a significant fraction.

2) My suggestion is to collect samples of condensed steam in Paris3 experiments (now in progress) and to measure the mass of solid deposits in them, like Scott did. The mass of the solid deposit would be zero for pure steam. Richard's scale is sensitive enough, I think, to measure the mass of solid deposits from condensed steam. Measuring the mass with 10% accuracy would be sufficient to confirm Scott's preliminary results. Is the mystery going to be solved in such disappointing way? That remains to be seen; perhaps some kind of mistake was made by Scott. He is a great experimentalist, but no one is perfect.

3) The XRF analysis will also be an independent confirmation. It might also be very useful in the context "chemical excess heat" corrections.

4) Suppose we become convinced that the COP=1.24 (st.dev. 0.13) was mostly an illusion. What should then be done? In my opinion it will be our obligation to publish the result, for example, at the upcoming conference in Italy. Would you be willing to present the paper there, Pierre? Trying to publish a paper on "unexplained excess energy" in a mainstream journal would be out of question.

5) I hope that other researchers: Mizuno, Naudin, Iori, etc., will also reexamine their results. After all, it would not be

difficult for them to do what Richard and Scott did. We should have performed similar analysis before collecting data on the COP. Please share your reflections on that subject.

= =

89) Scott --> Ludwik + Richard + Pierre (6/24/06):
Agreed [about "tungsten rather than potassium"]. BTW, in one of my Mizuno runs seven years ago I did measure W in the electrolyte and in the swarf (particles on the bottom of the cell) and observed that only 5% of the W lost by the cathode ended up as swarf. 95% of the lost W went into solution. See:

http://www.earthtech.org/experiments/Inc-W/2ndtry/run6.html

[L.K. wrote "but no one is perfect."] Indeed I am not perfect. The list of my own past measurement errors is a mile long. The dry solids measurement does have a few peculiarities. You saw the difference between the 4 hrs and 12 hrs of oven time. All of the sample were HEAVIER after 12 hours than after 4 hours. That may be due to further chemical reactions in the oven involving the Al weighing cups. Each of the Al cups now has a dark stain on it where the solution dried out. ..some sort of oxidation caused by the basic solution, I suppose. I don't expect these stains to be very significant. We'll see when I get the K analyses done (looks like Monday is my earliest opportunity to go see the XRF analyzer). [L.K. also wrote about "our obligation to publish the result."] .But, of course.

= =

90) Ludwik --> Scott + Richard + Pierre (6/24/06):
Perhaps it would be better to dry samples at room temperature. Doing this under the vacuum (or in a desiccator filled with clean air) would also reduce a chance that something from air reacts with Al and contributes to the net mass difference. Perhaps Al was not the best choice. Just speculating.

= =

91) Richard --> Ludwik + Scott (6/24/06):
It will be very disappointing if W in the steam turns out to be the cause of the excess heat and of course we should still publish the results. The original Mizuno experiment was a mostly closed cell with little evaporated losses. My initial Colorado #3 experiment is encouraging but very inconclusive. Scott you did not see any white deposits in the evaporated test? At least it did not look like K2C03 deposits? Scott thanks for all the extra effort!

= =

92) Scott --> Richard + Ludwik (6/24/06):
I am afraid it does look like K2CO3, Richard. Here's the four Al weigh boats in the dried condition. You can see the darkening of the Al but around the outside there is a definite white deposit. [The jpg file attached] The real white one is #4, the stock solution. The boats are about 4cm in diameter.

BTW, I weighed them again just now after about 48 hours at 70C (I stored them in my oven which is left on at 70C normally) and they were all within 0.1 mg of the "after 12 hours" weight....except for #4 which was 0.4 mg heavier. It should be noted that these samples begin gaining weight as soon as you remove them from the oven. I measured the rate on one of the samples and it was about 0.4 mg/minute. I suppose that's water vapor attaching itself to the Al surface and to the K2CO3 as things cool off.

= =

93) Pierre --> Ludwik + Richard (6/24/06):
I will not add any remarks on what I have already said to Ludwik about the tiny droplets. I hope to see to-morrow Pr Fauvarque for that and may-be other points. ..Do not hesitate, Ludwik, to recall me what are your main concerns.

I would like now to draw your attention on the following question : storage and un-storage of energy, due to the transient between two levels of energy. I was not aware of this effect, because of our lack of registered measurements before. Of course, we have to take into account this effect in analysing the results.. or at least to wait a sufficient time (for us about 5 minutes) before taking into account the values obtained. It is easy, Richard, to see what I mean. You have just to make an experiment with only the ohmic heater and you choose various levels of power between 200 and

800 w for example. At least 15 to 20 minutes for each level, and you plot the COP values (in theory = 1.0). You go of course up and down. What surprises me is that it seems contradictory with the fact that the thermal losses are quite constant on this energy domain...

= =

94) Ludwik --> Pierre + Richard (6/24/06):
The only thing I would like to have, as soon as possible is the new upper limit on the percentage of droplets based on the Thursday experiment. It would be desirable to know this before we hear the results of Scott measurement of the concentration of K+. On Friday you wrote that the new upper limit was much much less that 1%.

My main concerns were enumerated in messages about the JFF's appendix. You wrote that all of them were forwarded to him. Can I be certain that he really read them carefully before deleting? I would be happy to send these messages again, if you think that this might help. And here is my comment about your "two levels of energy" idea. Anticipating that a referee might also think about a possibility of some kind of storage we should address the issue in our paper. I think I will write something like this: "The possibility of significant short-time storages and releases of energy can be ruled out the basis of high reproducibility. The mean COP of 1.24 and the standard deviation of 0.13, from 41 tests, would not be possible if such mechanism played a significant role."

= =

95) Richard --> Pierre + Ludwik (6/25/06):
You are seeing the same problem that I'm working. What is your heat loss? I removed all my insulation so that the time lag as the input or output power changed would be less about 2 minutes without the insulation and about 5 minutes with insulation. I found that from 300 watts to 800 watts the heat loss is directly proportional to the delta temperature of the heat exchanger. Lowering the Input power below 275 watts you really see the stored heat energy in the electrolyte and it takes a long time to dissipate. I'm looking into ways to greatly reduce the amount of electrolyte used this should improve the response. Is this a problem with all calorimeter that has a heat storage mechanism?

= =

96) Pierre --> Richard + Ludwik (6/25/06):
We got a small heat loss of about only 43 watts due, I suppose, to a very good insulator (glass wool). This heat loss seems constant between 250 w to 800 w.I think that we must try to have longer and quite constant power runs by trying to keep the cathode length as constant as possible by motoring it. So this storage effect will no longer be a real problem.You can see our insulated long beaker in the joined picture and the way we choose for diminushing the weigth of the apparatus in order to be able to use our balance ...

= =

97) Richare --> Pierre + Ludwik (6/25/06):
This all sounds good. You are doing the same things that I'm trying. I making a screw device so I can screw the cathode down into the electrolyte. The screw will let be control how much cathode is lower into the electrolyte.

98) Pierre --> Ludwik + Richard + Jean + Gerard (6/26/06):
I just saw Pr Fauvarque coming back yesterday from Russia. As you know, he is very busy and will be free only by mid-July. We discussed however your main concerns. I noted the following points: (a) The value of 1% is classical for a chemical titration. Nothing to see with the amount of lost electrolyte in tiny droplets. As you know, my own opinion is that tiny droplets are of a negligible amount in the evaporated water, but we were not able to measure it accurately. What is the point of view of Richard on this point? (b) You have participated to the Boulder experiments (Colorado 2). They have confirmed the Paris 1 conclusions and this was a good second step. We have no more to add at this time in our conclusions than you may have to add for the Boulder experiments case. (c) To answer with a great accuracy your demands needs to do again at least one month of tests. We do not have the material and financial means to do so at this time in our laboratory. I am not very pleased to send you this uncompleted e-mail. But, I hope that the Scott tests will give you the answers you are waiting for...
= =

99) Ludwik --> Pierre + Jean + Richard + Gerard (6/26/06):

1) I am also not very pleased. Should the first section of the appendix be eliminated from the draft we received? I counted on two independent determinations of the percentage of droplets. Now we have to rely on Scott only.
2) What about the second issue -- contributions of chemical heat to our COP=1.24? This seems to be a theoretical question based on thermochemistry of dominant chemical reactions. Should I expect this kind of input from Pr. Fauvarque in July? A delay of three weeks is not a big deal, my draft will have to wait. I am convinced that a paper about excess heat must contain statements that what we measured was not due to well known chemical reactions, or to droplets. The manuscript would certainly be rejected without quantitative information about this.

= =

100) Ludwik --> Richar + Pierre (6/26/06):
Here is a paragraph I just composed for my anticipated draft. The ??? will be replaced by the number provided by Richard. I also believe that the number will be very small, but a paper "difficult to reject' needs numbers. Anything else I can add on this topic?

"Can excess heat measured be atributed to some kind of energy accumulation process? To answer this question we considered a possibility that our cell acted as a recheargeable electric battery. In a control test the cell, after being connected to the power supply for several hours, was suddenly disconnected and discharged through a resistor. The amount of stored energy turned out to be ??? J. That is a small fraction of one percent of the excess heat measured in a typical test. We concluded that the battery-like effect, if any, had a negligible effect on the reported value of COP. Another possibility considered was short-time accumulations and releases of thermal energy. That hypothesis was ruled out the basis of high reproducibility. The mean COP of 1.24, and the standard deviation of 0.13, from 41 tests, would not be possible if such mechanism played a significant role. Furthermore, significant random thermal accumulations and releases would be associated with significant temperature fluctuations during consecutive tests. The actually observed temperature fluctuations, about one degree or so, indicated some thermal instability. It probably contributed to the size of the standard deviation."

= =

101) Ludwik --> Richard + Pierre (6/26/06):
I suspect the resistor is too small. Your two parallel capacitors have 6200 microfarads. Discharging them through a 500-ohms resistor should take slightly less than 10 seconds (R*C=3 seconds).
= =

102) Scott --> Richard + Ludwik (6/26/06):
I got to the XRF machine today. As usual, the story is not as clear as we would like it to be. So that you can join in the fun, I have attached Excel spreadsheets that contain the raw spectra I obtained today along with some crude calculations (this XRF machine does not have fancy software). The two sheets are K.xls and W.xls for potassium and tungsten analysis, respectively. For K analysis, I used no filter in front of the x-ray tube (so that the softer x-rays would get to the sample) and 10 kV on the anode. Unfortunately, this spectrometer has an air path from the tube to sample to detector so Ar x-rays interfere with the K analysis. In fact, the Ar K-beta is right under the K K-alpha...the most intense K x-ray. So, in fact, I used the Ar K-alpha as a measure of the background under the K peak.

Important: the data show about half as much K in the stock solution than I expected from the 0.2M preparation. And this is based upon a known standard that I prepared today, gravimetrically. More about this later. Despite this setback, there is decent agreement on the ratio of K in the condensate samples to K in the stock solution and the corresponding ratio of % solids in the condensate and % solids in the stock soln.

And then there is the W analysis. As you can see, there are large W peaks in sample #4 which tells me that sample #4 is not virgin stock electrolyte but USED stock electrolyte. At the moment, I do not have any quantitative results for the W but I did calculate the ratio of W in the condensate samples to W in the stock soln. The values match the other two ratios mentioned above pretty well. All three sets of ratios can be found in colored fields in K.xls on the "calculations" worksheet.

I now suspect that the %solids result we got that matched the expected 0.2M so well was a coincidence. The solids I'm weighing must be about half K and half W. Hmmmm..that's a LOT of W dissolved in there. .. I wonder if that's

possible? Maybe there's another component to the solids I'm seeing when I evaporate these samples. And there's still the possibility that I've done something wrong with the K analysis... I'll continue to work on it. If I'm right, though, how did the stock solution lose so much K? Maybe it went out in the mist droplets. Did you guys use this solution for several runs, making up to the same volume each time with pure water? If so, that could explain the reduced K content I am seeing.

A small point that we need to straighten out: Is 70C hot enough to make the K2CO3 anhydrous? It's supposed to be KCO3+1.5H2O when just dried from solution but, of course, there is some point at which it loses all its water and becomes K2CO3. Richard, did you use anhydrous K2CO3 in your preparations? If not, did you calculate so that the solution came out 0.2M K2CO3 and not 0.2M K2CO3+1.5H2O?

= =

103) Ludwik --> Scott + Richard (6/26/06):
For the time being I will take Scott's numbers on their face values.

1) The mean and standard deviations from three samples (for K) are 0.073 and 0.015. That translates into 7.3% droplets based on K alone.

2) The mean and standard deviations from three samples (for W) are 0.070 and 0.014. That translates into 7.0% droplets based on W alone.

3) Assuming nothing else is present in the samples of electrolyte one would conclude, on the basis of these preliminary results, that the percentage of droplets was 14.3 %. In other words, this seems to be the lower limit. Right? Standard deviations are about 18% of the mean values. In other words the percentage of droplets would be reported as 14% +/- 2.5%.

104) Scott --> Ludwik + Richard (6/26/06):
No, I don't think these two 7's should be added. Instead they just support each other. Each one is an independent measure that says that about 7% of the condensate is due to droplets. And the same goes for my oven-drying tests. ..they also show around 7% (with considerable variation).

= =

105) Richard --> Scott + Ludwik (6/26/06):
I did not use anhydrous K2CO3 but K2C03*1.5H20. I did not understand why my bottle of K2C03 was different from Pierre until just now when you used the term anhydrous and it dawn on me..... So it is 26.7 grams of K2C03*1.5H20 in one liter of H20.

The solution was a fresh solution but had been about 10 run adding about 50 grams of fresh water for each run. It took this many runs to get positive COP's and enough condensate from a single run. [P.S.So sample #4 is the final electrolyte after all the test.]

I would estimate about 4-5 inchs of W 3/32 dia rod used during the tests to get the condensate.

= =

106) Scott --> Richard + Ludwik (6/26/06):
At 10:01 PM 6/26/2006, Richard Slaughter wrote:
[1) You wrote ”..... So it is 26.7 grams of K2C03*1.5H20 in one liter of H20]. OK, that's good to know....your K content was a bit low to start with, then. You should have used 0.2 * 165.2 = 33 grams of your hydrated salt to get 0.2M K2CO3.
[2) You wrote “ many runs to get positive COP's and enough condensate from a single run.”] Very interesting. so, with a steady loss of K via droplets, your final K concentration could easily be significantly lower than your initial K concentration.

[3) You wrote: “I would estimate about 4-5 inchs of W 3/32 dia rod.”] OK, I just weighed a new, 6" rod and got 14.46 grams. That's 2.41 grams/inch (excuse us, Ludwik, while we wallow miserably in this American morass of mixed unit systems...:). If 4.5" was used, that's 10.8 grams of W, most of which went into solution according to the seven year old measurements I referenced recently. That's at least comparable to the K content. sortof.

= =

107) Ludwik --> Richard + Scott (6/27/06):
My recollection is that you mentioned the COP's close to 1.10 for runs during which samples were collected. Is this correct? At the time I did not consider this to be important (10% of excess heat would also be spectacular if the contribution from droplets were below 1%). But now this fact might become essential. You probably did not use the same vessel and the same geometry as that used when we worked together.

= =

108) Ludwik --> Pierre + Richard + Scott (6/27/06):
Pierre:
1) Preliminary results from the XFR analysis seem to confirm what Scott reported last Friday. I expect his conclusions to be sent to us today or tomorrow.

2) Meanwhile I would like to share with you the very beginning of my draft. I no longer think that it will become a publishable manuscript very soon. But I do want to send it to the CMNS library. It will be preserved there for posterity. This will be done after the appendix is revised, if necessary, by JFF.

3) Please confirm that nobody who contributed to our work was forgotten. Naturally, I will show you the entire piece when it is finished. We have to wait for JFF to be available again.

4) I really think that what Scott did by simple mass analysis should be done independently in Paris and in Bolder. Too much is at stake, Scott's conclusion must be confirmed before we finalize its validity.

5) Are you planning to go to Italy, Pierre? I suggest that we inform the meeting about the status of our work, especially, if we are no longer as enthusiastic as we were a week or two ago. Would you be willing to do this in the name of all of us, Pierre?

Is the unexplained heat during high voltage electrolysis real?

Richard Slaughter, Pierre Paul Clauzon, Jean Francois Fauvarque, Ludwik Kowalski, Gerard Jean-Michel Lalleve, and Scott Little.

= =

109) Richard --> Scott + Ludwik (6/26/06):
The COPs were 1.10, 1.15 and 1.20. You are correct the vessel and geometry were different. I will work on confirming Scott’s weight measurements. I think I will let the steam saturate a piece of filter paper and then weight the paper after it dries. Scott if I sent a piece of filter paper saturated from the steam is that a large enough sample for the XRF machine? It would be sent wet. Could you soak and/or rinse it to collect the sample? I can also collect samples of electrolyte after each steam sample. These results are important that we should run a second test to confirm these results.

= =

110) Scott --> Richard + Ludwik (6/27/06):
Richard, I need to know the total volume of electrolyte in your cell. I am working on getting actual W concentration results from the XRF data and I need to see if they make sense with the quantity of W you eroded into solution.....[A paper filter] does not sound like an ideal sample, Richard. A thin layer like that can be analyzed via XRF but with overall reduced sensitivity for the analyte. I need about 15 mL of liquid to fill up the sample cups we use. .. so rinsing and collecting the sample from a filter paper would likely result in a significant dilution of the sample. That would not

be good as we are already working at low concentrations. I need bulk liquid samples, at least 15 mL of each.

= =

111) Richard --> Scott + Ludwik (6/27/06):
Ok, I was just thinking that I could hang the filter paper above the cell and let if absorb the liquid from the steam. This way I don't have to worry about contamination from the plastic bottles used to collect the electrolyte. I did clean the bottles and interesting I didn't see any signs of electrolyte on the bottles after they dried. There were lots of water droplets on bottles after collected the condensate. The amount of electrolyte I was using was very close to 1 liter. I always started with 1 liter and as the electrolyte evaporated would add more up to the 1.0 or 1.1 liter mark. I know I used only one W rod for all the test collecting the condensate. The 4 inches I mentioned would be the absolute max. The absolute min would be 2.5 inches.

= =

112) Ludwik --> CMNS list (6/27/06):

1) Due to unforeseen delays, the draft of the paper I was working on could not yet be posted. But what I can do, while waiting for additional input, is to show the beginning of my draft. Details and modified conclusions must wait; they will probably be different from what I anticipated when the introduction shown below was written. Here it is, followed by the list of references. . .

2) Nuances often escape our attention when we quickly read or listen to what others have to say. I was thinking about tiny droplets associated with boiling. My conclusion that such effect, or large systematic errors in measuring electric and thermal energies, cannot lead to COP>1.2 was based on the fact that the measured value of L turned out to be very close to 2260 J/g, in Paris1 experiments. But L was measured with an ohmic heater. Somehow I did not pay attention to this.

= =

113) Scott --> Richard + Ludwik (6/28/06):
Same spreadsheets attached but this time complete.

1. I used Richard's formula for the stock solution to calculate the original K conc in the stock solution. My XRF data shows that about half the K is now gone from the stock solution....! That is consistent with it leaving via the "steam".

2. I used Richard's estimate of 4" of 3/32 W rod consumed to determine that the stock solution should have been about 1% W if nothing had been lost. My XRF analysis shows the stock solution to be only about half that W concentration... again confirming that W was lost from the stock solution.

Both of these observations at least qualitatively support the XRF results that K and W are found in the condensate samples.

3. I added the COP values that Richard put on the sample jars to the spread sheet. There is not a good correlation between them and the K or W concentration in the condensate samples.

4. I computed the 1 sigma standard deviation in the XRF results. In the case of K, it is about 5% relative of the K conc in the condensate samples. In the case of W, it is larger, nearly 10% of the W concentrations we saw. That could be improved with longer count times but I think it is adequate as is.

Note, the non-zero W readings on the two water samples is a reflection of improper background subtraction, not of actual W contamination in the water. I could do a bit better on the W analysis but the results would be quite similar to what you already have.

In conclusion, it looks like approximately 7% of the condensate volume is due to liquid transferred out of the cell. Does that translate linearly to the COP bottom line?...i.e. that 0.07 must be subtracted from the apparent COP's. ..i.e. that a COP of 1.10 turns into 1.03 when this is taken into account?

I think that's the way it works but I could be wrong. Ludwik? Richard?

= =

114) Ludwik --> CMNS list (6/28/06):
I know that Scott, Richard and probably Pierre are busy to verify a tentative conclusion reached so far --> 7% of the lost liquid consisted of the electrolyte droplets. It was based on a simple test performed by Scott. About two weeks ago Richard performed three experiments during which the escaping liquid was condensed outside the cell. The COPs, measured turned out to be 1.2, 1.15 and 1.1. Condensed liquids, plus some amount of the original electrolyte, became samples #1, #2, #3 and #4, respectively. They were sent to Scott Little who has an XRF device able to perform elements analysis.

Note that this approach is very different from that described in JFF's appendix. Titration analysis (Paris2 experiments) was performed on the electrolyte remaining in the cell, not on the re-condensed wet steam. Before performing a sophisticated X-rays analysis, Scott did something much more simple. Here is a message to Richard that I received from Scott last Friday. " I have not found the time to go visit my XRF analyzer yet. However, I have a nice Mettler balance so I conducted a simple dissolved solids test on the samples you sent. First I weighed 4 Al weighing cups. Then I dispensed some of each sample into each cups. I used a new disposable pipette for each sample to prevent contamination. Then I weighed the wet cups. Then I gently dried the samples in a 70C oven for 4 hours This gentle drying should leave the salt as K2CO3+1.5H2O. I recorded the first set of dry weights. Then I returned the samples to the 70C oven for another 8 hours. I recorded a 2nd set of dry weights. Here are the results: [a table with numbers] . . . These results make it even more important to go to the XRF analyzer to confirm that this is actually K in the samples. I'll do that sometime this weekend."

Under ideal conditions sample #4 should show that the mass of the deposit is consistent with the molarity of the initial electrolyte. And samples 1, 2 and 3 should have zero mass, corresponding to 100% dry steam escaping from the cell. But that is not what was discovered by Scott. Masses in samples 1, 2 and 3 were not negligible. Comparing them with the mass in the sample 4 one can conclude that ~7% of the escaping wet steam consisted of pure electrolyte. In my opinion, everyone who is going to study excess heat from a GDPE cell (Glow Discharge Plasma Electrolysis) should first perform a similar dry mass test. I also think that those who reported on excess heat from GDPE cells, especially Mizuno, Naudin, Iorio, Richard, Pierre perform similar tests and report the results. It is prudent not to depend on what has been reported by a single researcher, even a very careful one, like Scott. In fact, I would not be surprised to find out that such tests were performed but were not reported.

Scott, can you please describe your X-rays analysis in the form of an appendix for our draft? I just read what you posted this morning and examined your spectra. They seem to confirm the results based on weights. But, as you indicated, absence of correlation between the percentages of droplets and the roughly determined values of COPs is disturbing. If droplets are responsible for the COPs>1 then samples from experiments with larger COPs must contain more electrolyte than samples from experiments in which the COPs were smaller. That was Richard's comment on what you wrote this morning. Only additional experiments can clarify this matter. My suggestion is to focus on this in Paris3 and Marseilles1 experiments. I am also disturbed by conclusions from Texas1 and Colorado1 experiments. In these experiments the COPs were very close to 1.00. Why were tiny droplets emitted in Colorado2 but not in Colorado1 and Texas1? Is answering this question not a good reason to start Texas2 experiments, Scott? I would very much like to assist you again.

115) Ludwik --> CMNS list (6/28/06):
I am looking at Scott's second table again: The mass of solid deposit from each cc of condensed wet steam was 1.68 mg. That was the mean for the samples #1, 2 and 3, after 12 hours in the oven. Individual results were 2.06, 1.15 and 1.84. This leads to the standard deviation of 0.47. For the sample #4 (the original electrolyte) the mass of the solid deposit was 27.4 mg per cc. What does this mean? Let me begin with the original electrolyte. The 27.4 mg/ml translates into 27.4 g/liter. This is in very good agreement with 26.5 grams of K2CO3 that was put into distilled water to make the 0.2 M solution.

Each cc of the solution is essentially 1 gram. That solution was supposed to be from pure steam. Finding 1.68 mg of

solid deposit, per one gram of condensed liquid, is significant because 1.68 is 6.13% of 27.4. In other word, our evaporative losses were exaggerated by 6.13 %. This 2.45 times larger than the upper limit in Fauvarque's appendix. And, according to last Thursday test in Paris3, the upper limit should be changed to a much lower number. What is the new upper limit?

= =

116) Richard --> CMNS list (6/28/06):
. . . If we POSITIVELY have droplets and/or mist [of electrolyte] then the method of computing excess heat is incorrect and the results of Colorado #2 and Paris #1 are wrong. We still need to validate the presence of electrolyte in the steam. One set of test is not enough and we need test with COP>1.30. . . .

= =

117) Richard --> Scott + Ludwik (6/28/06):
I don't think we can just subtract the mass of the electrolyte from our evaporated mass and recalculate the COP. It seems to me that the presence of the electrolye indicates the presence of droplets. The size and mass of those droplets are unknown. I could see the droplets having at least the mass of the electrolyte. If the presence of the electrolyte is confirmed and we decide that this means the presence of droplets then it seems the open cell GDE is not worth more effort. If we decide to abandoned the open cell I do think we should publish something showing the problems we encounter.

= =

118) Ludwik --> Richard + Scott (6/28/06):
In my mind the term "droplets" stands the "mass lost that is not pure steam." It can be droplets, molecules or tiny crystals. In our context this is not relevant; we just want to be sure that evaporative losses are calculated correctly. In other contexts such details might be of great importance. I like the idea of publishing negative results. In that way what we did will not be totally wasted. But, once again, we need more data. In particular, a correlation between individual COPs and individual "mass corrections" must exist if a large part of COP is an illusion due to the "droplets effect." Data demonstrating the correlation would be a clear demonstration that the droplets effect is real.

= =

119) Ludwik --> Pierre + Richard (7/1/06):
Pierre, I did not hear from you since Scott wrote that, according to his data, about ~6% of the lost liquid was not dry steam. Are you OK? If Scott is right then Colorado2 and Paris1 conclusions must be modified. Do you agree? But his conclusion should be independently verified. Are you and Richard going to perform "dry-deposits" tests on condensed steam samples? We need many tests to check the reproducibility of results, and to get the standard deviation. Then we would correct the initial COP accordingly. Do you both agree that this is a desirable plan? Can this be done in two weeks, before Fauvarque becomes available? I still hope positive COP, such as 1.10, will be worth publishing. But we need numerical data to succeed.

= =

120) Pierre --> Ludwik + Richard (7/2/06):
C'est la FRANCE, Ludwik! Pierre (one of the Colorado 2 team). [That was prompted by what Ludwik mentioned in a messsage posted yesterday at the CMNS list].
= =

121) Ludwik --> Pierre + Richard + Scott (7/2/06):
1) I am glad to hear from you Pierre. I was also happy that France won the game. I started worrying that absence of messages from you might mean you are sick, or something like this.

2) If Scott is right (about the ~6% of the escaping mass being something else than pure water) then Colorado2 and Paris1 conclusions must be modified. Do you agree?

3) But his conclusion should be independently verified. Are you and Richard (and Gerard, Jacques, Naudin, etc.) going to perform "dry-deposits" tests on condensed steam samples? We need many tests to check the reproducibility of

results, and to get standard deviations under different conditions. My hope is that ~6% will not change significantly with conditions, such voltage or geometry. If this is confirmed then we would correct the COP accordingly. Do you both agree that this is a desirable plan? Can this be done in two weeks, before Fauvarque becomes available? I still hope that positive COP, such as 1.18, will be defendable and worth publishing. But we need numerical data to succeed. Hope is good for motivation, not for justification.

4) And what if experimental data show that our claim of COP>1 is not defendable? I agree with Richard that in that case our paper should also be submitted to a mainstream journal. The experimental part, and theoretical appendix about chemical origin of excess heat , do not have to be changed. But the introduction and conclusions will be totally different.

5) How are you Scott? You were also rather silent recently. Are you OK?

= =

122) Scott Little --> Ludwik + Richard +Pierre (7/2/06):
Just fine, thank you. The only thing I have done since the K, W, and gravimetric analyses of Richard's 4 samples is to expose the dried residue from sample #4 to 100% relative humidity air by placing it in a sealed box along with an open container of water. The weight gain was about 2.5 times more than expected if K2CO3 was going to K2CO3+1.5H2O so it appears that there are other hydrate ratios involved here and it also appears that my 70C drying oven probably reduced the salt to the anhydrous form: K2CO3.

What this says to me is that we should focus on K concentrations and ignore the state of hydration....except that will give us some trouble when we try to do a real mass balance as Peter Gluck rightfully suggests.

The main problem with the samples that Richard sent me is the fact that the electrolyte was used over and over again and, according to my analyses, became more and more diluted as salty droplets escaped from the cell while Richard added only pure water to make up the lost volume. Thus the condensate samples I have came from runs whose electrolyte concentration was essentially unknown, except that it was somewhere between the original 0.2M and the final ~0.1M.

For a rigorous approach to this problem we need to perform a series of runs in which a sample of the condensate and a sample of the electrolyte are collected for each run.

= =

123) Pierre --> Ludwik + Jean Francois (7/2/06):

Je crois t'avoir dit que nous travaillons maintenant , Gérard et moi, dans le laboratoire de Jacques Dufour dont les moyens sont plus importants que ceux que nous avions.
Nous avons rencontré cependant les mêmes difficultés que celles rencontrées à Boulder pour reproduire le phénomène. Nous avons dû alors reprendre le même beaker et refaire nos expériences. Tout cela a pris du temps et de plus, nous avons dû regarder le phénomène de stockage-déstockage d'énergie au cours des variations de puissance. Nous étions très préoccupés par ce phénomène qui pouvait remettre en cause tous les résultats acquis sur le CFR....Mes premières conclusions sont que ce phénomène est bien réel, mais que si l'on prend des précautions, par exemple n'enregistrer qu'après au moins 5 minutes de stabilisation et vérifier que les variations de puissance restent modérées pendant l'expérience, il n'y a pas de problème. Le second problème , les "tiny droplets", va être mieux examiné par Jacques dans le cadre du futur Paris 3, mais cela va sans doute prendre du temps...
Pour en revenir à Colorado 2, tu sais que je ne suis pas chimiste et que le temps me manque pour en devenir un. Il faut donc que Jean-François F. te réponde et tu peux compter sur moi pour lui demander de le faire dès la mi-juillet....Ne m'en veux donc pas de ne pas participer aux discussions "chimiques" plus activement... mais je reste cependant persuadé intuitivement que ce problème n'est pas majeur.
Voir dans ton texte ci-dessous quelques réponses en MAJUSCULES.
Amitiés Pierre

= =

124) Ludwik --> Richard + Scott +Pierre (7/2/06):
Hi Richard and Scott:

Pierre replied to me in French. I will try to summarize what he wrote after showing what he wrote in French.

= = = = = = = = = = = = = = = = = = = =
Voir dans ton texte ci-dessous quelques réponses en MAJUSCULES.
Below Pierre is replying to my last message by inserting words in CAPITAL LETTERS.

1) I am glad to hear from you Pierre. I was also happy that France won the game. I started worrying that absence of messages from you might mean you are sick, or something like this.

2) If Scott is right (about the ~6% of the escaping mass being something else than pure water) then Colorado2 and Paris1 conclusions must be modified. Do you agree?
OUI, SI CONFIRME (*)

3) But his conclusion should be independently verified. Are you and Richard (and Gerard, Jacques, Naudin, etc.) going to perform "dry-deposits" tests on condensed steam samples? OUI, MAIS PAS DANS UN DELAI RAPIDE (**) We need many tests to check the reproducibility of results, and to get standard deviations under different conditions. My hope is that ~6% will not change significantly with conditions, such voltage or geometry. If this is confirmed then we would correct the COP accordingly. Do you both agree that this is a desirable plan? Can this be done in two weeks, before Fauvarque becomes available? I DO NOT KNOW. (***) I still hope that positive COP, such as 1.18, will be defendable and worth publishing. But we need numerical data to succeed. Hope is good for motivation, not for justification.

4) And what if experimental data show that our claim of COP>1 is not defendable? I agree with Richard AND ME (****) that in that case our paper should also be submitted to a mainstream journal. The experimental part, and theoretical appendix about chemical origin of excess heat , do not have to be changed. But the introduction and conclusions will be totally different.

5) How are you Scott? You were also rather silent recently. Are you OK?

(*) Pierre agrees with need to correct our COP=1.24 to account for Scott results, if confirmed.
(**) They will perform Little-type tests but not without a delay.
(***) He does not know if such tests will be performed during the next two weeks.
(****) The idea of publishing negative results, if it comes to this, was already discussed by us in Denver and Pierre reminds me that we all agreed on this.
= = = = = = = = = = = = = = =

Ludwik,
Je crois t'avoir dit que nous travaillons maintenant , Gérard et moi, dans le laboratoire de Jacques Dufour dont les moyens sont plus importants que ceux que nous avions.
Nous avons rencontré cependant les mêmes difficultés que celles rencontrées à Boulder pour reproduire le phénomène. Nous avons dû alors reprendre le même beaker et refaire nos expériences. Tout cela a pris du temps et de plus, nous avons dû regarder le phénomène de stockage-déstockage d'énergie au cours des variations de puissance. Nous étions très préoccupés par ce phénomène qui pouvait remettre en cause tous les résultats acquis sur le CFR... Mes premières conclusions sont que ce phénomène est bien réel, mais que si l'on prend des précautions, par exemple n'enregistrer qu'après au moins 5 minutes de stabilisation et vérifier que les variations de puissance restent modérées pendant l'expérience, il n'y a pas de problème. Le second problème , les "tiny droplets", va être mieux examiné par Jacques dans le cadre du futur Paris 3, mais cela va sans doute prendre du temps...
Pour en revenir à Colorado 2, tu sais que je ne suis pas chimiste et que le temps me manque pour en devenir un. Il faut donc que Jean-François F. te réponde et tu peux compter sur moi pour lui demander de le faire dès la mi-juillet... Ne m'en veux donc pas de ne pas participer aux discussions "chimiques" plus activement... mais je reste cependant persuadé intuitivement que ce problème n'est pas majeur. Amitiés Pierre

(a) As you know, Gerard and myself are now working working in Dufour's lab, which is much better equipped.
(b) We also encountered difficulties in reproducing Boulder's results. We had to perform the experiments again in the same beaker. All this took time.
(c) Furthermore, we observed storage and release of energy when consecutive tests are performed at different powers. That was important because the phenomenon could negate our Paris1 conclusions. Fortunately this turned out not to be the case. One must avoid collecting COP data before the temperature of the electrolyte stabilizes. This usually takes more than 5 minutes. Significant electric power changes should be avoided.
(d) The tiny droplets tests will be performed by J. Dufour, in future Paris3 experiments. This will take time.
(e) As you know I am not a chemist. Fauvarque must reply to you and will remind him in two weeks. Now you know why I do not participate in discussing chemical things. Intuition tells me that this is not a major problem.

= =

125) Richard --> Ludwik + Scott + Pierre (7/4/06):
I'm not convinced that the ~6% is a good correction. We are making the assumption that the K2C03 is coming off as particles or a new compound. Is this a valid assumption? I see three other possibilities 1) It is attached to a droplet of water. 2) The K and/or C03 is being vaporized. 3) The K and/or C03 is part of a chemical reaction. All three of these possibilities have different outcomes. Possibility 1 means we have to account for the droplet size. Possibility 2 means we should be adding the (joules) required to vaporization K2 and/or CO3. Possibility 3 might be ok if the deposit are the same as those of the chemical reaction. Does this make sense?

= =

126) Pierre --> Richard + Ludwik +Scott (7/5/06):
We got the same results at the beginning of Paris 3, i.e. COP around 1.0. So, we came back to our usual beaker of Paris 1(small size and no insulation), but then we tried 0.1 M electrolyte in order to get higher voltage without too many amperes...(too high power). And that worked and we got again COP between 1.2 to 1.3. The difficulty is to have a very stabilized power level and then to be sure that we have no storage or release of energy during the change in power... We are planning tests to be sure of that... (we will try to get the same power curve with the ohmic heater and then to see the COP values obtained...)

= =

127) Richard --> Pierre + Ludwik +Scott (7/5/06):
The input power needs to be stable over the same time frame as the measurement of the excess heat. Once the beaker is above room temperature it has stored energy. If I just turn off the input power I will have infinite excess heat until the beaker reaches room temperature ie Power_out/zero. As long as the beaker temperature is substantially above room temperature the electrolyte will still evaporate even without input power. In Colorado #2 just watching the current and voltage the input power seemed to be stable over the 5 minute test period. It is possible that this input power was drifting down and we are measuring some of this stored energy as output power. . . .
= =

128) Ludwik --> Richar + Pierre + Scott (7/5/06):
Ideally one wants to operate under thermal equilibrium, that is when the dm/dt (rate of evaporation) remain constant. The way to accomplish this, in open beaker during the electrolysis, is to use two power supplies, one feeding the electrolysis and another feeding the ohmic heater, immersed in the electrolyte. I am assuming one can measure the electric energy delivered to the cell by each power supply. One would have to add them to calculate the COP.

Suppose the mean dm/dt is evaluated every 3 seconds and the values are plotted value versus time when an experiment is in progress. To keep the dm/dt constant one simply changes the voltage feeding the ohmic heater. If the dm/dt starts going up the voltage is decreased; if the dm/dt starts going down the voltage is increased. I think that keeping the dm/dt constant, within 2 or 3% would not be too difficult.

The temperature-versus-time plot could be useful below the boiling point. Stirring of the electrolyte is probably worth having in all cases. I thing that the last container in Colorado2 was too big for the power of 300-400 W, especially without stirring. One can probably work without stirring, at such wattages, when the beaker is much smaller, for example, one liter. Under such conditions boiling is sufficiently uniform to get a constant temperature within the cell.

= =

129) Ludwik --> Scott + Richard + Pierre (7/7/06):

I hope this will not prevent you from performing the XRF tests on new samples that Richard said will be sent to you soon. These will be from experiments performed as in Colorado2. The initial composition of the electrolyte, before each COP was measured, will be better known this time, I suppose. We should not be surprised, the basis of what you did so far, if the data lead us to a less desirable conclusion. Being able to consistently justify negative results in three different ways (weights, XRF for K and XRF for W) would be very convincing.

Assume we come to a conclusion that the necessary correction of the Richard's COP's leads to the value close to one. We talked about such possibility and agreed that conclusive negative results should be published. A good appendix about the XFR would be needed. Would you also be willing insert a section about your old unsuccessful attempts to replicate Mizuno experiments, Scott? These experiments did not use evaporational calorimetery and this would be important, I think. Another possibility would be to publish two papers at the same time, preferably in the same mainstream journal. One would be about the old Scott's results and another about the Colorado2 results. It is probably not too early to start speculating about these things. But only among four of us, at this time. Right?

= =

130) Ludwik --> Scott _ Richard + Pierre (7/10/06):
I want you to be the first to see unit 302
http://blake.montclair.edu/~kowalskil/cf/302numbers.html
I will post it tomorrow. Comments, as always, will be appreciated.

= =

131) Scott --> Ludwik (7/10/06):
Good Ludwik, I like the honest way in which you discuss the situation. I only wish that Mizuno was an active part of our group.

= =

132) Ludwik --> Pierre + Richard (7/11/06):
I will respect your request for privacy, Pierre. Should I assume that this refers to the second sentence only, and that the problem of storage and release of energy can be openly discussed on the CMNS list? The issue of storage of thermal energy is important. I wanted to quote you on this in unit #302 but decided not to do so.

I hope that unit #302 answered your question about what should be done to make Colorado2 results publishable. Measuring of the COPs, when 5 to 10 samples of condensed liquid are collected would certainly be desirable. But this is not essential when the purpose is to learn about percentages of the electrolyte in the escaping liquid. Just make sure conditions (geometry and voltage) are as close as possible to what we had. Can this be done in your present laboratory

situation? . . .

= =

133) Pierre --> Ludwik + Richard + Gerard (7/11/06):
Of course, the problem of storage and release of energy is important and we have to discuss this point openly in CMNS list. But, what I sent to you was preliminary results and reflects only our point of view, Gérard and myself . That's all. Jacques Dufour was absent from the lab these days.....Now, I am wondering about the wet steam. When we make calibrations curves with the ohmic heater, are we concerned with the tiny droplets of electrolyte? Are your corrections, Ludwik, not already taken care of by the calibration curve made with the electrolyte ? I will try to check that point as soon as possible.

= =

134) Ludwik -->Pierre + Richard + Gerard (7/11/06):
That is a great..... let us hope for the best. Ludwik
P.S. I do not think that the ohmic heater correction automatically corrects for the mass of tiny droplets. To convince myself I am considering an experiment in a thermos. In that case non-evaporative losses tend to become negligible. But droplets escape in the same way as from a beaker of the same size. How can a nearly negligible correction compensate for a non-negligible effect due to tiny droplets? I am thinking about a case in which the "droplets effect" lowers evaporative losses by nearly 10% while the non-evaporative losses are close to 1% of the supplied energy. Do you agree that this would not be possible, Pierre?

You were probably thinking about a situation in which the percentage of droplets in the wet steam during the electrolysis is the same as during the use of the ohmic heater. This remains to be verified experimentally. Let us suppose that an experiment shows that in both cases wet steam contains 5% of the electrolyte. How would you argue that our non-evaporative correction (such as 50 W determined by the use of the ohmic heater) also corrects for the presence of droplets in the wet steam?

= =

135) Richard --> Pierre + Ludwik + Gerard (7/12/06):
In one of my early attempts to collect the steam samples I use the ohmic heater as a test and got very clear water sample. When I switch to the plasma the new sample was obviously contaminated (milky white). Just an observation. Is there an easy test to measure the opaqueness of a sample.

= =

136) Ludwik -->Pierre + Richard + Gerard (7/13/06):

Here is one possibility: Food and drinks are often sold in transparent glass jars or bottles whose walls are flat (not round). Suppose the liquid to be tested for opaqueness is in such container. A beam of light enters the container from the left side and exits from the right side. It falls on a photodiode (from Radio Shack ?). That photodiode, like a thermistor, produces voltage that can be measured; it is proportional to the light intensity. For our purpose opaqueness can be operationally defined as V1/V2, where V1 is the photodiode voltage when the tested liquid is in the jar and V2 is the voltage when the jar is empty.

The experiment should be performed in a darkened room so that most light received by the diode is from the direct beam (not from scattered light, or from other sources in the room). I would place the photodiode into a ~15 cm pipe. A similar pipe would be used on the other side, to collimate the incoming light. A white-light-emitting diode would probably be a sufficient source. If not use a small light bulb, from an old car or a flashlight. The light intensity should match the sensitivity of the photodiode; you might need a dimer.
P.S.
Actually, V1/V2 should be called transparency, not opaqueness. That ratio would change from 0 (not transparent) to 1 (100 % transparent). The V2/V1 could be called opaqueness, if one wanted to use this parameter. Then 1 would stand for the "not opaque at all" and infinity for the 'totally opaque."

= =

137) Pierre --> Richard + Ludwik + Gerard (7/13/06):
I think you are right, Pierre... I looked yesterday to the curves we plotted with the ohmic heater calibrations. I found that the slope of this curves, which must give 2260 j / g , give values very close to 2260 j / g (at + or - 2%). With tiny droplets, these values would have been lower than 2260j/g, I suppose...Your comments, please...

= =
138) Richard --> Pierre + Ludwik + Gerard (7/13/06):
I think it would be very difficult to correct the COP value for the misting. At least in a convincing way to skeptics. The original Mizuno experiment was closed cell very similar to Colorado #3 and Paris #3. I think that is the best approach now.
P.S. Pierre I meant to ask any comments from JL Naudin about the misting. Is he going to try and confirm?
= =
139) Pierre --> Ludwik + Richard (7/15/06):
From mid-July to the end of August, many labs are in holidays in France... I hope that our contributions will not be too delayed... But any way, we will look at yours with interest and pleasure. Cheers

= =
140) Ludwik --> Pierre + Richard (7/15/06):
Should I still be expecting to hear from JFF in July?

= =
141) Pierre --> Ludwik + Richard (7/16/06):

I hope so, Ludwik, and I will tell him to do so. But, anyway, do not hesitate to remind him directly of the answers you are waiting for... Next week, with my family, we plan to go to Russia for a cruise on the Volga between Moscow and St-Petersbourg...(12 d)

= =
142) Ludwik --> Pierre + Richard (7/16/06):
This cruise is on our agenda, perhaps next year. Meanwhile I would like you to take some pictures for me, at a specific location. As you travel toward Volga river, along the famous canal, about 40 miles north of Moscow, there is a village where I lived during the war. It is called "posiolok Dedenievo." There is a railroad station called "Turist" there. Your guide will know the place. Take pictures on both sides of the canal; both before the dock and after the dock. After Dedenievo there was a village "Medviedki," where a railroad bridge goes over the canal. I remember when this bridge was blown up by the Red Army, in late October 1941. The next railroad station is in a place called "Yachroma." And then a town called "Dimitrovo." Germans were in Yachroma for several days when we were hiding in a cellar, under an officially-closed big church. Then German army was pushed away. That was the beginning of their end. Take a picture of the tower of this church from the boat, if you can. Also the picture of the high hill on the right side of the canal, between the dock and the bridge.

= =
143) Pierre --> Richard + Ludwik +Gerard + Jean Francois (8/ ? /06):
Back from vacation in Russia (beautiful cruise from St-Petersburg to Moscow -1800 kms- 4 pictures joined), I went yesterday to our common CNAM laboratory with only Jacques Dufour and his son there. (Gerard, Denis on vacation). Jacques has his own program of experiments using an ice calorimeter, very precise, and his aim is to work on his own theoritical approach to explain cold fusion. Of course, I let him expose his theory in future cold fusion meetings. Jacques has a very long experience on cold fusion experiments. He convinced me to establish the reality of our experimental results by eliminating all the possible artifacts definitively in an irrefutable manner. This is the only way to convince our physicists colleagues, he told me. I think that Ludwik will approve... The tree points we are examining are the following:

1- the measurements of the electric input energy : we protected all the electric wires with external cladding (armoured? I dont' know the american word) and also used of a special circuit with resistance and capacitors to avoid large electrical impulses. I will ask Jacques to give you more details on that, but I can say that we are now very

confident on our measurements.
2- tiny droplets: we have two different approaches with Jacques:
- Jacques will favor the condensation outside of the beaker of all the steam in order to measure both the water produced and the amount of electrolyte eventually carried on (and then the thermal energy produced) .
- Personally, I would prefer to condensate the steam inside the beaker (as Richard has begun with Colorado 3) and measure the cooling flow and his delta T.
We will choose by September the experimental set-up , but of course, this heavy change will take time to fix...
3- Storage and release of energy, with power changes:
I am not as anxious as Jacques is on this item. We made experiments showing that this could be masterized quite easily. But, the way to avoid this problem is to have longer experiments and to try for that to have cathodes moving very slowly in order to maintain constant their active length and then constant the power. Still there, we have to fix the experimental apparatus...

I am confident that we will achieve these goals by the end of this year. Yesterday, we got a COP of 1.3 with our traditional apparatus (analysis by hand to be confirmed). This experiment was to confirm the interest for "armoured" electrical wires... (answer is yes). Richard, where are you on Colorado 3 ?

= =
144) Ludwik --> Pierre (8/5/06):
1) I did not hear from Richard since before your trip to Russia.
2) The Paris3 agenda looks promising. I will probably have some comments later.

= =
145) Ludwik --> Richard + Pierre (8/7/06):
. . . I haven't heard from you since the above question was asked. Is everything OK? By the way, I am also puzzled by Naudin's silence on the CMNS list.

= =
146) Richard --> Ludwik + Pierre (8/7/06):
I've been very busy at work lately. Haven't had time to work on the experiment much. We had a family reunion last weekend it was a lot of fun. Got to see all 11 of the siblings and a lot of the cousins. Attached is a picture of my brothers and sisters. I enjoy your pictures also. I do plan on working on the experiment again soon.

= =
147) Ludwik -->Pierre + Richard +Gerard + Jean Francis (8/8/06)
Pierre: Thanks for information about the upcoming Paris3 experiments. To refresh our memories, let me make some comments and suggestions. I hope they will be useful in planing.

1) Shielded-grounded wires should prevent occasional interference effects observed in the U390 meter. My suggestion is to add a kWh meter on the other side of the power supply. That is what was done in Texas1 and Colorado2. At that level the v(t) and i(t) are sinusoidal and a simple instrument can be used to measure electric energy. I thinking about the instrument Richard used for the ohmic heater. The second kWh meter readings will probably be consistently higher than U390. That should not be a surprise; some electric energy is constantly converted into heat inside the power supply. The rate is probable less than 40 W. An ohmic heater of variable R can be used to learn how this number changes (probably not much) with the wattage readings of the U390.

Suppose that the the difference between two kWh meters is the same fore ohmic heater operating at ~300 W and for the plasma electrolysis cell operating at ~300W. That would be a very convincing argument that no significant errors are made in measuring electric energy supplied to the GDPE cell. Sampling
the v(t) and i(t), for example, 100 times per second, and showing that the sum of v(t)*i(t) agrees with the U390, would be another strong indication that no error was made.

2) Another suggestion is to use fresh electrolyte for each long experiment. Also to measure the amount of tungsten lost by the cathode (to calculate eV of excess heat per removed atom). Large eV/atom, for example, 1000 or more, are

convincing arguments against chemical origin of excess heat. Chemical reactions never produce more than 10 eV/atom (usually less than 5). Note that tungsten that remains metallic does not react chemically with anything. For that reason only a fraction of the W lost by the cathode should be counted when the eV/atom are calculated. It would be essential to measure that fraction. Mizuno wrote that nearly 100% of the W lost by the cathode was in the form of metallic particles at the bottom of the cell. One way to separate metallic tungsten from the less dense solid components would be to agitate the electrolyte and collect what is deposited quickly at the bottom, like in gold panning. By doing this several times one should be able to separate most of the metallic tungsten. A chemist might suggest a better method.

3) Performing the Little-type test (comparing the mass of residuals per cubic cm in the fresh electrolyte with the mass of residuals per cubic cm in the condensed steam) is highly desirable. That seems to be a good method of determining the percentage of tiny liquid droplets, or colloidal particles, in the escaping steam. Scott found that the mg/cm^3 in two samples were not very different. That is alarming. His conclusion, however, was tentative because fresh electrolyte was not used in each experiment. In my opinion Little-type tests should be performed at the very beginning. Hopefully, they will show that the COP>1 is not an illusion due to tiny droplets or particles. Only then should further investigations be made. I suspect that results, such as COP=1.24, would have to be reduced to account tiny particles or droplets in the escaping steam.

4) I agree that establishing "the reality of our experimental results by eliminating all the possible artifacts definitively in an irrefutable manner" is essential at this stage. We already know that results are reproducible. Now we must convince ourselves, and others, that excess heat is not due to a well known effect. Three to five well done experiments, with the maximum amount of information, would probably be more valuable than a much longer sequence of experiments, with the minimum amount of information (only what is needed to calculate the COP).

5) If the purpose of the experiment is to validate conclusions made in Paris1 and Colorado2 then an open cell (favored by Jacques) is preferable. Pierre's preference -- condensing steam inside the cell -- would be more desirable if one wanted to perform better experiments. That is what Richard is planing to do in Colorado3, I suppose. The most desirable outcome would be to show that Paris3 and Colorado3 (and Texas2 ?) results are not very different.

= =

148) Richard --> Pierre + Ludwik + Gerard + Jean Francois + Scott. (8/9/06)

Pierre thanks for sharing what is happening in Paris. I've been busy at work and haven't done much. I finally got the Pinnacle power supply working correctly using 220V and single phase instead of the 3 phases it usually takes. It is doing a nice job of regulating the input power.

I'm also seeing the arc suppression that we never saw during Colorado1. It's very interesting I'm able to slowly increase the power from about 100 Watts to about 1500 W. The plasma starts at about 300 Watts it is a bright red if I keep increasing the power the plasm goes from red to bright white. The two attached pictures show input power at about 500 Watts and 1500 Watts. There is little difference in the beaker between the two power ranges.

I'm also seeing the current drop if I find the operating point, just like we saw for Colorado 2. My biggest problem right now is EMI. I just can't collect the data with computer. The USB data acquisition system keeps going crazy. I'm going to work on that this weekend.

= =

148) Scott -- >Pierre + Ludwik + Richard + Jean Francois + Gerard (8/9/06):
Thanks for the update, Pierre. You are going in the right direction with your rigorous checking of every part of the experiment. One point I would like to make: Seven years ago we studied the fate of the W lost by the cathode and learned that only a small fraction (~5%) of it ends up as swarf at the bottom of the cell. The rest goes into solution, presumably as H2WO4. Our measurements and rationale for this conclusion are presented in this report:

http://www.earthtech.org/experiments/Inc-W/2ndtry/run6.html

This result is also qualitatively confirmed by my recent XRF analysis of Richard's samples. Each of them contained

significant levels of W.

= =

149) Pierre --> Ludwik + Richard + Gerard + Jean Francios (8/26/06):
[Sending us a diagram of a setup for their Paris3 experiments]

150) Ludwik --> Pierre + Richard * Gerard + Jean-Francois (8/26/06):
Thanks for updating, Pierre. I suppose you will have a small pomp forcing water to circulate through the cooling loop. The mass of the water, passing through the cooling loop during a stable run, must be measured accurately. How accurate is your flow-meter? With the new arrangement the input energy, E, is as before but the output energy, Q, is different. The COP is still defined as Q/E but now Q=Q1 + Q2 + Q3. The first two terms are as before (Q1=evaporative loss, Q2=thermal loss) but Q3 = c*m3*dT, where m3 is the mass of water passing through the loop during a run, dT is the constant temperature difference between your two thermocouples, and c is specific heat of water. Am I interpreting your plans correctly?

I suggest you place at least one thermistor (or traditional thermometer) inside the cell, preferably near the wall. The rate of cooling should allow you to control temperatures below the boiling point. Suppose the COP is significantly larger than 1.0 at 80 C. At that temperature Q1 will be negligible and, as you write, the issue of tiny droplets will disappear. My guess is that the COP will not change suddenly between 95 C and 100 C. The temperature of the electrolyte near the wall is not a measure of local temperatures near the cathode.

As you know, optical thermometers (pyrometers) are routinely used by metallurgist to measure temperatures of glowing objects. Eventually one might try to measure the temperature of plasma with an optical thermometer. How does the COP depend on that temperature? But that is a big project. For the time being the main task should be, as for the Colorado2 results, to convince honest referees that COP>1 is not due to well known chemical reactions. I hope these observations will be useful to you.

308) Expected things

Ludwik Kowalski; 9/19/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) About a year ago I asked Steven Jones about progress of his work, especially about high energy alpha particles that he asked me not to write about because it was work in progress (item 124). The reply surprised me; instead of finishing this work Steven simply switched to something that has nothing to do with cold fusion. That is how I learned that he was investigating the conspiracy idea about the collapse of the World Trade Center towers on September 11, 2001. He wrote that the towers were too strong to collapse from the airplane hits alone. He was waiting for samples to be analyzed for the presence of explosives presumably pre-located in critical locations of each building.

In the last ten days two people sent me an article about that investigation of Jones'. It was recently published in Utah's newspaper Desert Morning News. The university seems to punish Steven for this work; they did not allow him to teach (payed leave). The full text of the article can be found at

http://newenergytimes.com/Inthenews/2006Q2-4/Q3/DESERET-BYUPlacesJones.htm

How will this affect reputation of CMNS? Jones and Fleischmann were the most important contributors to that field; the term 'cold fusion" was invented by Jones three years before the 1989 announcement. The effect could not possibly be positive, unless the so-called "conspiracy theory" is confirmed. I do not want to probe into this subject but this unit will have an appendix about possible consequences.

2) Another thing worth mentioning is a new book about CMNS. The author, Edmund Storms, is still working on this book. On August 28 he posted the following message on the restricted Internet list for the CMNS researchers. "Dear Fellow Confusionites, In the process of writing a book, I have come to some conclusion which some people in the CF field might find heretical. In addition, new published information, when viewed in its totality, leads to some conclusions that are in conflict with some major theories. I would like to have these assertions debated in semiprivate before I publish what might be incorrect ideas. So that the debate can be kept focused, I will make each assertion a new link. Of course, ideas in one link will spill over into others, but hopefully the idea will only be applied to the subject dujour. Some people might want to continue a more detailed discussion in private, which is ok, but I do not have time to handle many private discussions. So there goes. (Assertion #1) . . . "

I am not going to quote numerous replies generated by the Assertion #1, and by two subsequent assertions -- #2 and #3. They shows that, contrary to what many think, the CMNS community is far from being a society of mutual admiration. Numerous disagreements, and traces of past disagreements, emerged from the debate. After examining a list of chapters I realized that something very important was missing. This prompted me post the following message. " I suggest that a chapter about promising commercial initiatives that failed is worth adding, for example, between chapters 6 and 7. The most spectacular, as far as I know, was at iESiUSA. Or it can be an appendix. A book without this would not be a total description of what was going in the CMNS field during the last 17 years."

Here is the reply from Ed: "Thanks for the suggestion, Ludwik. I'm afraid I'm not the person to evaluate the commercial aspects. Steve Krivit is doing this. My job is to make sense of the science. Too many of the commercial attempts were not based on science and failed because of human limitations. Such failures will not happen in the future

if and when the science is understood." Another old-timer wrote: "Regarding 'promising commercial initiatives that failed", I'm reminded of Ceti's claim, made in their 1995 Corporate Video that: -- 'Ceti is scaling up the size and efficiency of the cell and expects to produce 1 kW of power as part of a 250 kW array. At ICCF-6 Ceti were claiming they had 40 firm orders for their Rifex demonstration kit. In the event I think only 4 were sold."

I was not aware of this fact. Would it be appropriate to say that the above mentioned corporate video was an axample of a fraudulant manipulation? The same question can be asked about the iesiusa company, as described in units #216, #229, #236, #237, #239, #263 and #279. Assuming the answers are positive one can ask another question. Who is responsible for the fraud, scientists or business people? That question, addressed by S. Krivit (at ICCF12), was asked by Krivit. He said that iesiusa scientists were victims, rather than perpetuators, of fraudulant business activities. I would like to know what Peter Hagelstain thinks about this now. He was deeply involved in the iesiusa situation last fall.

I think that commercially motivated projects are worth describing in a book about CMNS. They were taken seriously in the CMNS community (for example Case presentation at the ICCF10 that I attended) because each project was based on ideas discussed at gatherings of non-commercial researchers. In that sense commercial projects were not different from other projects -- nothing is "based on science" in our area, everything is based on proto-scientific speculations, both theoretical and intuitive. By the way, Case presentation does not appear in the ICFF10 conference proceedings. Why it so? Probably because he failed to submit it before the deadline. I do remember him speaking at the confernce, and showing an impressive metallic setup.

CMNS will remain proto-science until at least one reproducible on demand experiment becomes available. That is why I think that all efforts should be focused on finding such experiment. How many millions of dollars were spent on the CMNS research since 1989 worldwide (including support from Toyota, Mitsibushi and other private benefactors)? Would we still be asking for reproducible on demand demos if all that money was used more rationally? I do not know how to answer these questions. But they should be addressed in a book on cold fusion. Storm and Dash decided to reinvestigate the experiment demonstrated by Dash's students at ICCF10, but not before the book is published. Will this impressive 2002 demo be described in the book? I hope so. This relatively inexpensive setup was enthusiastically described by Eugene Mallove. And, as far as I know, it was not criticized by those who saw the demo. Was it seen by Fleischmann himsef? He was attending the conference but I do not recall seeing him the public demonsration of the experiment. I suppose it was shown to him privately. It would be useful to know his comments.

3) Below is a piece about peer reviewing. It is from Photonics Spectra (April, 2006, page 10). The author, Wendy A. Laurin, is a group publisher of that journal (devoted to applications of optics, lasers, imaging, fiber optics, electro-optics, etc.)

Journals: Advancing Science

As do other qualIty publications, Photonics Spectra uses peer-reviewed journals for news ideas and information on scientific research. Science, Nature, Optics Letters and Applied Physics Letters are a few of the journals we use regularly. They provide not only details on the results of an experiment, but also the technical details of how the experiment was conducted.

Peer-reviewed journals depend on individuals who are willing to commit their time to judge whether submitted papers are suitable for publication and to ask questions if the research is not clear. Most of these people are experts in their field, making them the best ones to perform the initial review.

The accuracy of these journals is now being questioned following the retraction of some articles, including the well-publicized research on cloned human cells and a cancer study from Norway. Some in the general press are asking for more policing of the research that peer-reviewed journals publish.

The reality is that journals do not have the money or time to scrutinize every experiment. Additionally, they do not claim to Investigate each paper. They do, however, ensure that enough information is presented for the experiment to be replicated. Although they have been taking a more proactive approach to the problem, there is no denying that the most powerful means of review are the readers.

Journals are doing their job. They disseminate scientific information to a large group of scientists who can redo the experiments and examine the results in detail. Most highly rated publications will acknowledge that there are some problems with the peer-review process, as evidenced by Science's retraction of a paper. But if the journal had not published the paper, fellow researchers would have had no other way to effectively review the experiment and point out the fallacies.

This is a system that has been productive because peer-reviewed journals rely on their advisers and their readers for feedback. Although there may be individuals who falsify research, in most cases the very act of publication keeps most researchers honest because they know that the work can be thoroughly examined. There is no doubt that the system can be improved, and It has been only in the past few years that some journals have required the authors to report financial interest. But peer-reviewed journals remaIn a powerful way for researchers to communicate with each other.

The power of publication can be shown in other ways as well. A recent editorial in Science magazine states that there are times when an organization or individuals have asked that research by a particular group not be published. Because Science does not believe In censorship, it instead suggests that the would-be suppressors put their thoughts In a technical comment. And therein lies the true job of peer-reviewed journals - putting research in the open for everyone to see.

The upcoming 2007 ACS conference (appended on 10/14/06):
Several days ago someone made a suggestion that papers devoted to CMNS topics should be presented at the next American Chemical Society (ACS) meeting. Such presentayions have been made at recent APS (American Physical Society). But presenting CMNS papers at ACS was not easy, as described below by Mel Miles. Instead of addressing the issues scientifically (during the conference) the organizers tried to block presentations administratvely. What a pity. Is such discrimination justifiable? When will it end? Here is how one 1999 discrimination episode was described, on the CMNS list, by Dr. Miles:

In 1999, my China Lake co-workers were tasked with organizing the ACS Ontario, California Western Regional Meeting, October 6-8. They asked me to organize a battery and cold fusion session which I did. This caused all hell to break loose. The special plenary symposium speaker, Dr. Jerome Karle of NRL, threatened to withdraw from the conference if cold fusion papers were allowed. Others such as Dr. Cotton of Texas A&M threatened to resign from ACS. At one point, ACS proposed a compromise solution where the cold fusion session would be allowed but would not be sponsored by ACS and abstracts would not appear in the ACS Abstract Book. At this point, my China Lake co-workers (Peter Zarras and Erick Erickson) threatened to resign from ACS if the cold fusion session were treated this way. In the end, ACS sponsored our session and allowed our abstracts (For program, see http://www.vidrine.com/paccon/techprogram.html). However, the cold fusion session was separated from the battery presentations and moved to Friday, we were told to keep a low profile, and not to invite any more speakers on cold fusion. Speakers at this cold fusion ACS meeting included Martin Fleischmann, Stan Szpak, Mike McKubre, Talbot Chubb, John Dash, Ed Storms, Robert T. Bush, Ben Bush, Russ George, and myself. I believe that this was the last time that cold fusion papers wee allowed at an ACS meeting except for maybe a few isolated papers that escaped detection. In contrast, APS (Physics) has been allowing cold fusion sessions at their March meetings for years - thanks to Scott Chubb.

I hope my experience with ACS will give Dr. Marwan and others some insight on what to expect when word gets out about these submitted cold fusion papers." In giving me permission to post the above message Dr. Miles added: "I

consulted my notebook before I wrote this, thus it is accurate." Will the 1999 opposition episode be repeated in the spring of 2007? That remains to be seen.

309) What is NAE?

Ludwik Kowalski; 10/1/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Yesterday I posted a message (shown in green below) at a restricted list for CMNS researchers. It was about NAE (Nuclear Active Environment), the concept often used by Ed Storms. I hope my message will generate some discussion. Those who are not familiar with the concept of NAE should refer to two Ed's papers:

a) "A Student's Guide to Cold Fusion" at:

http://www.lenr-canr.org/

b) and "The Nature of the Nuclear Active Environment Required for Nuclear Energy Reactions" at:

http://www.lenr-canr.org/acrobat/StormsEthenatureo.pdf

Here is the concluding part of the Storms'second paper:

"Once the NAE is accepted as being of a small size and made from a complex alloy of various elements, perhaps including palladium, methods required for replicating the effect can be suggested. The most obvious method is to use techniques developed by the microelectronic industry, which can deposit controlled amounts of material onto very small regions. Such methods would allow the particle size to be controlled as well as having the ability to apply known amounts of various elements. Once the range of variables affecting the NAE is understood, a large amount of active material could be easily made. In addition, a correct model for explaining the unique nuclear reactions could be developed based on such knowledge. In the absence of this approach, present efforts are handicapped by having to create the NAE using random processes, which is a very inefficient method. The Iwamura et al. [54] study shows what can be accomplished when suitable tools are applied to the problem."

Here NAE is described in terms of physical parameters: small size, made from a complex alloy, etc. But in other messages NAE is described in terms of what is expected to do. Which one is the definition and which one is the consequence of that definition?

2) Ludwik wrote:
"I am again thinking about Ed's concept of NAE (nuclear active environment). We do not know what NAE is; it is something to be identified in the future. Therefore, I think, that the concept of NAE cannot be used to validate known experimental facts or situations. In science we proceed from what is already known to what is not known. The opposite approach seems to be unscientific; perhaps it should be categorized as philosophical or mathematical. Why mathematical? Because mathematicians begin with propositions and proceed to examine consequences resulting from them. Scientists, on the other hand, begin with experimental facts and proceed toward explanations.

Ed assumes that CMNS phenomena will become demonstrable on demand when NAE is identified in terms of its physical parameters. For the time being he identifies it in terms of desirable effects. But how do we know that such effects will take place? He postulates that. A mathematician should have no trouble with postulating. He would say

that a starting point of a derivation is an axiom (or an already proven theorem); it does not have to be validated (or justified again). A physical scientist, on the other hand, is expected to begin with reproducible experimental facts and to proceed toward deeper understandings.

Yes, science and mathematics benefited greatly from clever thinkers who were frequently changing hats -- from the pointed hat of a mathematician to the pipe hat of a scientist, and vice versa. But that should not prevent us from distinguishing two kinds of thinkers. It should also not prevent us from asking questions about NAE. Why do we need that concept at this stage? For the time being, as far as I can see, NAE is used only as an explanation of failures to produce a convincing reproducible-on-demand demo. Does it validate claims based on not-always-reproducible experiments? Does it help us to make CMNS more acceptable to mainstream scientists? I do not think so."

3) Replying to the above Ed Storms wrote:
"Frankly, I'm at a loss to understand why the concept of NAE is so hard to accept. The concept only acknowledges that the LENR reactions do not occur in ordinary materials, but only in special regions. We need to call these regions something if we wish to communicate about the differences between these regions. The NAE is a description used to distinguish one region from another. We say one region of a material is smooth and another is rough as a means to make a distinction. The idea of NAE is no different. One region can initiate a nuclear reaction and another region can not. What is so difficult to understand about this a pproach? In addition, it is obvious if we were able to make more of this special environment, we would be able to initiate more nuclear activity."

This generated an interesting discussion. The message posted by X reminded us about theoretical physicists who sometimes wear one hat and sometimes the other. A specific illustration was given. But not too many theoreticians are like Fermi who was equally productive under each hat. Most theoretical physicists rely on reported experimental results. Likewise, most experimental physicists rely on conclusions reached through complex theoretical derivations performed by mathematically inclined colleagues.

Ludwik's reply:
a) Regions should be distinguished in terms of physical parameters, not in terms of desirable effects. That was my main point.

b) The last sentence is an example of circular reasoning. First we define NAE in terms of desirable effects and then we say, "it is obvious" that such effects will take place in NAE.

c) Will the concept of NAE help us to make CMNS more acceptable to mainstream scientists? I do not think so.

4) Ed's reply:
a) "[You wrote:] Regions should be distinguished in terms of physical parameters, not in terms of desirable effects. That was my main point." Since when? A region can be beautiful, soft, or bright. A person can be desirable, intelligent, handsome. All are terms used to distinguish one region or person from another. No physical parameters are involved. In order to discuss anything, we need words to distinguish one idea from another. NAE distinguishes those regions that do not allow nuclear reactions to be initiated from regions where such reactions are possible. Only later will the characteristics be defined. It is like the word "tree" which distinguished an item from a flower, for example, without say what kind of tree or what kind of flower. You are making this much too complicated.

b) "[You also wrote:] The last sentence is an example of circular reasoning. First we define NAE in terms of desirable effects and then we say, "it is obvious" that such effects will take place in NAE." I don't think you will understand what I'm saying if you don't read what I wrote. You are not quoting my statement accurately. The analogy to what I said about NAE is, if you have more money, you can buy more things. This is a very simple statement requiring no additional interpretation

c) "[You also wrote:] Will the concept of NAE help us to make CMNS more acceptable to mainstream scientists? I do not think so." If the concept helps those of us who understand the concept make progress in defining the NAE, then the field will advance and it will be accepted."

5) Ludwik's reply:
Circular reasoning is the practice of assuming something, in order to prove the very thing that you assumed. Why do I think that your message about NAE (see below) is an example of circular reasoning? You wrote:

> The concept [NAE] only acknowledges that the LENR reactions
> do not occur in ordinary materials, but only in special regions.

In other words, you are **defining** NAE as an environment in which LENR reactions occur. Then you wrote:

> . . . it is obvious if we were able to make more of this special
> environment, we would be able to initiate more nuclear activity.

Yes, it is obvious because NAE was **defined** as an environment supporting nuclear reactions. To remove circularity of reasoning one would have to define NAE differently. One possibility, for example, would be to say that NAE consists of regions in which average distances between atoms are shorter that 100 F. Or it can be defined in terms of local temperature higher than 10^6 K, etc. That what I had in mind by "physical parameters."

It is possible that you already defined NAE in terms of physical parameters but I am not aware of this. In that case ability to generate CMNS reactions would no longer be 'by definition," it would be a logical consequence of a definition. And your statement above would no longer be an example of circular reasoning. In that case, however, one has to explain why such environment should produce such and such consequences. That is what theoretical physicists do.

6) A comment from Y:
NAE is defined by Y as a region of space in which a chain reaction of some kind can propagate, from atom to atom. He argues that a region containing BEC (Bose Einstein Condensate) should have the ability to sustain a chain reaction. (By the way, I am not quoting what X and Y wrote because I do not want to waste time on asking for permissions. Ed, on the other hand, and several other researchers, gave me blank permissions to be quote what they post on CMNS list. I really appreciate this.)

7) Ed's reply to Y:
"Well, Y, I see you understand the need to accept the concept of NAE. Once a NAE is acknowledged, we can talk about what it is made of and what mechanisms operate in its unique structure, mechanisms not possible anywhere else. This restriction immediately forces theory to take a different approach. For example, some theories assume the basic requirement of the NAE is a large D/Pd ratio. Unfortunately, nuclear activity is observed when the D/Pd ratio is low. Some assume high voltage gradients are necessary. Unfortunately, nuclear activity is seen in the absence of applied voltage. Quantum effects are proposed to cause charge shielding when the lattice is perfect. Unfortunately, the lattice is never perfect anywhere. Each assumed ideal condition is shot down by nature. I suggest theoreticians must start thinking in new directions. I also suggest, hydrino formation is the only mechanism not in conflict with observation. We have the irony of one outlawed idea being an explanation for another outlawed idea."

8) Ludwik's comment:
In reading Ed's reply to Y I see that he also believes that NAE must be defined by models (to which I referred to as material parameters) and not by desirable effects. This opens the path toward noncircular arguments about validity of each model. Desirable effects of NAE must now be explained; they are no longer "obvious" by definition. I hope that readers of Ed's anticipated book will have no reason to think that circular reasoning is allowed by CMNS researchers.

9) Storms' comment:
Several additional researchers contributed to this thread. One of them also thinks that defining NAE in terms of desirable effects amounts to "tautology." In a subsequent message Storms wrote: "For a long time, people assumed the nuclear reactions were occurring throughout the sample. Then attention was focused on the surface of a cathode because this is where the D/Pd ratio is greatest. Theories were based on the properties of PdD as if nothing unique was required. The NAE concept focuses attention on the need to explore some very unique property of matter." In his first reply (see above) Ed wrote: that the concept NAE "only acknowledges that the LENR reactions do not occur in

ordinary materials, but only in special regions." In another message a comparison was made with bacterial colonies which grow in favorable spots, and not uniformly.

10) Ludwik's comment:
Discussion between Z and Ed was interesting. How do we know about bacterial colonies? By observing them through microscopes. Such observations are highly reproducible. And how does Ed know that CMNS reactions cluster in small regions? Is it an experimental fact or is it a theoretical postulate?

a) Suppose it is an experimental fact. In that case the validation criterion is replicability. One must refer to specific reactions and to conditions under which they are clustered. Unfortunately, we still do not have reproducible demonstrations of CMNS reactions.

b) Suppose we say that the existence of NAE is a theoretical statement (which is not a guess). Then the statement must be validated theoretically in terms of what is already known. In that case NAE becomes a model-dependent concept.

Is it not true that scientific concepts are either experimental or theoretical? If so then how should NAE be characterized? I think that Ed would agree that existence of NAE is only a useful educated guess, at this time. Such guesses often contribute to progress in science and technology.

11) Another Storm's comment:
The next day, replying to Z, Storms wrote: "The idea of NAE is very simple - apparently too simple for it to be easily understood. You are reading too much into the idea and making it too complicated. The NAE describes a solid material in which conditions permit a CF reaction to take place. The idea acknowledges the obvious, that the CF reactions are very selective about where they occur. The idea allows people to discuss the difference between ordinary dead material and the special active material. It also encourages focus on finding this unique material rather than trying to explain the effect by QM actions in ordinary material. I do not know what the NAE looks like or what elements it contains, No one knows this yet. The challenge is to determine just what is required of this environment. I propose hydrinos are involved, but so far, there is no proof for this assumption. You are free to propose anything your imagination can support. The whole point is getting people to think about a special condition."

12) Next day Ludwik wrote:
Saying "it describes" is very different from saying "it is." If we do not know what "it is" then how can we know what "it describes?" That is what bothers me when I think about NAE. The concept seems to be very unusual, unless it is recognized as an educated guess.

P.S. (**not posted**):
Ed wrote "the NAE describes a solid material In that sense NAE can be said to be a theory. Theories describe things; things do not describe other things. Why am I focusing on philosophy? Because I am looking for clarity about NAE.

We already have too many unusual things in CMNS; why do we need this one? To improve the status of CMNS in the eyes of mainstream scientists we should emphasize that our methods of validation do not differ from those they use in difficult situations. What we need is at least one reproducible-on-demand demo of a new nuclear effect. That is why I am happy that Storms and Dash plan to produce a convincing demo based on what students of John Dash did at ICCF10. I hope that collaboration will go further than what we did in Colorado. Replicating Paris1 was relatively easy, convincing ourselves that excess heat was not due to a chemical, or other non-nuclear, effect seems to be much harder. Why do we need the concept of NAE to guide us? What we need is a theory.

13) Ludwik wrote (also not posted):
In my opinion educated guesses are likely to be much more productive than random jumping in different directions. In that sense the NAE concept might be very useful. But what is really needed, as often emphasized by Storms, is a theory that has been recognized as successful. A theory becomes successful when it is able to predict a set of conditions under which at least one CMNS reaction, for example, emission of unexplained alpha particles, is experimentally reproducible. Theoreticians create and manipulate conceptual models, experimentalists deal with

physical reality. What will be available first, a successful CMNS model or a truly reproducible CMNS experiment? Both might happen at about the same time. I am thinking about Fisher's model based on polyneutrons and about Oriani's and Lipson's experiments with CR-39 detectors. I do not remember what motivated Lipson but Oriani told me that his CR-39 experiments were undertaken to test Fisher's theory (see item #191 at this website).

14) Z was William Collis; today he gave permission to quote this message:

a) Edmund Storms <storms2@ix.netcom.com> wrote: "We know that the nuclear reactions are difficult to initiate and when they occur, the nuclear products are found in only isolated locations." Agreed.

b) [He also wrote] "We know that clusters of deuterons are involved in the transmutation reactions and probably in heat production as well." Not sure. This is an aspect of some models but perhaps it is not an observation.

c) [He also wrote] "We know that significant gamma radiation is not produced." Agreed. Few gammas, neutrons nor apparent radioactivity.

d) [He also wrote] I propose that for energy to be lost after a nuclear reaction, at least two products must be formed, one of which may be a gamma. The only way this requirement can be avoided is for the energy to be communicated directly to the lattice." Agreed. We also know that Cold Fusion can take place in liquid, gas or solid surface phases which would rule out any lattice bulk mediated effect. Unfortunately there has been little demonstration that the lattice is capable of suppressing gamma radiation. Until such a demonstration occurs we should consider any model that relies on it as unverified conjecture.

e) [He also wrote] "We know energetic particles are emitted, which is in conflict with energy being coupled to the lattice." Energetic particles are quite rare, so I would not class them as a primary observation. If a near surface excited nucleus could transfer energy towards the lattice bulk, we would expect momentum conservation to create an energetic particle directed away from the bulk.

f) [He also wrote] . "I propose that nature resists the concentration of energy. Therefore, for clusters to form or for sufficient energy to be localized to initiate a nuclear reaction, the process must be exothermic." Probably.

g) [He also wrote] "Formation of hydrino's is exothermic. A fully collapsed atom would appear to have very little nuclear charge. Therefore, it might fuse with another element. This idea was suggested by Mills years ago. In addition, hydrinos can form clusters, which is an exothermic process. When these clusters fuse with another nucleus, a logical assumption results. This assumption is that the electrons are spit out of the reaction with high energy, which is the process whereby energy is communicated to the lattice. The faux beta would not be detected outside of the apparatus. However, the weak X-rays have been detected."

Agreed as far as the synthesis of hypothetical hydrinos and their clusters are concerned - no easily detectable X-rays. However I suspect that the rate of fusion in mini molecules will be such that copious hard radiation would be emitted. Using Koonin's formula (See NATURE VOL 339 NO. 6227 PP 690-691, 29 JUNE 1989), a mini PD or D2 molecule a tenth of normal size will have a lifetime of only 10**11 and 10**9 Seconds respectively. As we don't see gammas or neutrons corresponding to these expected fusion rates, that's evidence they don't exist.

I'll concede the above rates are similar to measured excess powers. But I would expect excess power to continue for a time scale appropriate for the lifetime of the mini-molecules - which might be a long time after the experiment is switched off. Heat after death does not last decades!

h) [He also wrote] "So, by simply assuming hydrinos exist, a model for formation of clusters, fusion of clusters, and the transfer of energy is provided." Agreed, apart from the above.

i) [He also wrote] "In addition the difficult and localized process occurs because hydrinos can be produced only where certain catalyst atoms are present in the sample. The obvious test, which most other models lack, is to discover which atoms act as catalysts under CF conditions and put them in a sample. I suggest the CaO used in the Iwamura method is

such a material. If so, the process occurring in the Iwamura sandwich becomes obvious." It doesn't seem obvious to me. Would you agree that any deuterons fuse with Iwamura's 133Cs one at a time! If so, the expected first reactions could be:-

2H +133Cs(100.%)-> 1n (beta-)+134Ba(2.42%) +5.942 MeV
2H +133Cs(100.%)-> 1H (100.%)+134Cs(beta-) +4.667 MeV
2H +133Cs(100.%)-> 4He(100.%)+131Xe(21.2%) +11.050 MeV

Once again, I ask, "Why don't we see neutrons?". I ask the same question also if you assume that multiple deuterons all fuse simultaneously (Takahashi's model). The trouble with all these models is that the deuteron is a very blunt instrument for creating non-radioactive transmutations. Most deuterium reactions are just too energetic. In theory, a deuteron can fuse exothermically with every naturally existing isotope! But it doesn't. This might mean that the basic mechanism is NOT deuterium / protium fusion. Maybe in a further message, we can enumerate other key observations which need explaining.

15) Ed wrote (about the last point above, at the end of a much longer message)**:**
. . . This is a good point that has troubled me as well. We don't know the rules that control such reactions. Apparently, the reactions only favor stable products, with a few exceptions. Nevertheless, I expect once this idea is accepted, someone will find a way to explain how only stable isotopes are produced. It seem intuitive obvious to me that the reaction would want to go to the lowest energy state, hence only a stable product would be favored.

16) Ludwik wrote:
In rereading Storms' paper:

<http://www.lenr-canr.org/acrobat/StormsEthenatureo.pdf>

I see a very important statement; it appears in the introduction. "We will start by making the assumption that most claims for low energy fusion and transmutation are correct. Support for this assumption is readily available in the literature[3-5]." Yes, we can make this assumption, and point to corresponding references. But that does not automatically validate the assumption. At this stage each experimental claim is still questionable, as far as I know. That is why I think that NAE is an educated guess. It amounts to the following:

a) Highly qualified researchers reported experimental facts which seem to conflict with generally accepted theories. However, for unknown reason, experiments are not always reproducible.

b) The reason for irreproducibility is absence of understanding. How can one argue with this? Essential factors determining output of experiments remain unknown.

c) Ed seems to believe that new nuclear reactions will become reproducible on demand in a special kind of environment -- NAE. Here is how he writes about this in the same introduction. "The challenge of this paper is to learn about the environment in which these nuclear reactions occur by assuming that the environment has universal characteristics common to all methods found to produce the effect."

d) The educated guess about universal set of preconditions might be confirmed in the future. Another possibility is that different nuclear reactions will require different sets of preconditions. For example, an environment that makes production of He possible might be very different from an environment in which alpha particles, or neutrons, are emitted.

17) Peter Gluck wrote:
Very good synthesis of the situation, I think. However, the global history of the experimental results show that the problem of reproducibility is or can be an essential information. Why CMNS does NOT work is as important as why it works, when it works. Very few (0.1%) of the experiments give excellent results, some tens of percents of them give very mediocre results and a lot of them give immeasurably low results. (As heat excess). . . .

18) Ed Storms wrote:
. . . I agree, neutron production results from a different environment than heat-helium production. Nevertheless, I do not believe nature has many mechanisms at its disposal. Otherwise, these effects would have been seen more often and in many different types of environments.

19) Ludwik wrote:
Earlier in this thread I wrote: (a) Regions should be distinguished in terms of physical parameters, not in terms of desirable effects. That was my main point. (b) The last sentence is an example of circular reasoning. First we define NAE in terms of desirable effects and then we say, "it is obvious" that such effects will take place in NAE.

I was responding to Ed who wrote: "Frankly, I'm at a loss to understand why the concept of NAE is so hard to accept. The concept only acknowledges that the LENR reactions do not occur in ordinary materials, but only in special regions. We need to call these regions something if we wish to communicate about the differences between these regions. The NAE is a description used to distinguish one region from another. We say one region of a material is smooth and another is rough as a means to make a distinction. The idea of NAE is no different. One region can initiate a nuclear reaction and another region can not. What is so difficult to understand about this approach? In addition, it is obvious if we were able to make more of this special environment, we would be able to initiate more nuclear activity."

What triggered my message was the word "obvious" in the last sentence. The concept is not at all difficult to accept. Ed's educated guess about a special region, named NAE, is reasonable. But the word "obvious" makes sense only if NAE is defined as the cause of CMNS phenomena. Suppose, as Ed wrote many times, that NAE is defined as a region containing X, Y and Z ingredients, or conditions. Then things become much less obvious. First, the ingredients and conditions must be identified, then one must show, either theoretically or experimentally, that CMNS phenomena become reproducible when X, Y, Z are present. Why should this be obvious to us at this stage? It was only the word "obvious" that turned a reasonable guess into tautology. I am sorry for not making this sufficiently clear. Let us hope that things will become obvious in not too distant future.

20) Ed Storms wrote:
What is obvious is that CF needs a special environment. I do not need to define what that special environment is to make this statement. For example, I can say it is obvious that an embryo needs a special environment to grow into a functioning human baby. I do not need to define what that environment needs to be. Of course, if I intend to grow a baby from an embryo, I need to know the details. Even without this knowledge, I can call the special environment the uterus without any argument. Why can't I call the special environment needed for CF a NAE without argument?

21) Ludwik (not posted)**:**
Yes, processes we know need support. Saying this is like saying that every real effect has a cause. But scientific community has not yet recognized reality of a single CMNS process. In other words, it does not agree that the embrio exists. We are still trying to built a reproducibal-on-demand demo. That is why many might think that speculationg about NAE is premature. They have right to ask for at least one reliably reproducible demo before accepting speculations about CMNS phenomena. They are likely to say that what is obvious for an embrio is not necessary obvious for CMNS phenomena. Offering a single reproducible demo seems to be a better step toward recognition than offering educated guesses. But, as expected by Ed, educated guesses might help us to select a path toward a potential success.

310) Alchemy versus CMNS?

Ludwik Kowalski; 10/15/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This unit is an update on what has been described in unit #186.
In what follows I am using blue to quote myself and green to quote others.

Introduction:
On Friday October 13 of 2006, Roberto Monti, an independent alchemy researcher, posted a message on a restricted Internet list. He thinks that some ideas, usually attributed to John Fisher, should be attributed to him. A dispute about priority is not worth discussing unless the idea becomes part of generally accepted science. This message was prompted by Roberto's website that was given as a reference.

http://www.lowenergytransmutations.org/papers.htm

A real alchemist among us
In a subsequent message he wrote "my website has had more than 9000 visitors and more than 22000 pages have been downloaded (since 2004, when we decided to put there a counter)." I went to the website and downloaded his second file. After reading it I posted the following comment on the restricted Internet list for CMNS researchers.

. . . Referring to the method described in (17) Roberto wrote:

We *washed*, following Geber's instructions, 500g of Mercury in *very good Vinegar*, obtained mixing 1/2 liter of Vinegar with 1/2 liter of Acetic Acid for 2 - 3 months. Then we took 100g of the *washed Mercury* from the 500g. Once dissolved in Nitric Acid 1 to 5, the 100g showed 55mg of Gold crystals. After 2 more months 100g of the same lot of 500g, dissolved in Nitric, gave 88mg of Gold crystals. Analyzed by SEM and ICP the Gold crystals showed to be from 100% to 90% Gold. The most beautiful we have ever seen (see photographs) (18).

17) I. Filalete, *Open Entrance to the Closed Palace of the King*. Phoenix, Genova 1987, p.11.
18) R. A. Monti, G. A. Cesarano-Monti, Metallic Transmutations induced by Acetic Acid. J. N. E.

What is not clear to me is who are "we" in the first sentence above. Is it Roberto et al. or is it Filalete et al.? The J.N.E. probably stands for the Journal of New Energy. When was the (18) published? Was it discussed at earlier ICCF gatherings? What did other CF researchers say about it? Roberto also wrote:

On April 1992 John Bockris invited R. A. Monti to join and witness experimental tests suggested by Joe Champion (The Philadelphia Project). The first test showed immediately what was going on: it was clearly an attempt to replicate the *Twelfth Key* of the *dry way to the Philosopher stone* of Basil Valentine (19).

Bockris and Champion knew very little about Alchemy. Fortunately April is *the right season* for Transmutations. Consequently the experiments showed definitely - during April and May - the production of Gold and other Noble

Elements from the ignition of a mixture of Metallic Salts and other Elements (20). In September 1992 the Philadelphia Project finished.

J. Bockris is often described as a leading electrochemist of the past century. Ed, I think that his alchemy experiments, and those described by Roberto, should not be ignored in your upcoming book about cold fusion. These people, like Piantelli, Patterson and Case (mentioned by Peter Gluck this morning), were part of cold fusion history. Let me again suggest that you write a special chapter devoted to their ideas (even if you disagree with them). Likewise, the commercial applications project described at ICCF11 by E. Anderson, or that described at ICCF12 by S. Krivit, should not be ignored. Let me end by quoting Roberto's paper again, for those who found it difficult to download the 52 Mb file.

After ICCF-5 (Monte Carlo, 1995) it was necessary to have similar experiments repeated in independent laboratories for the *validation* of the process . In 1996 an industrial reactor was built in Canada and sent to Italy for a new series of independent tests at ENEA, Saluggia (Italian National Laboratories). In these tests the production of Silver from Lead was used as a driver of the transmutation of Thorium and Uranium. Thorium was reduced by 88% . Uranium by 30% (23).

To make a further demonstration of the reality of these experimental results a new series of tests was carried out on May 21 and May 25 1998. The first experiment (May 21) showed the transmutation of 1.32g (30% of the total) of Uranium (23). The uncertainty declared by the laboratory was between 5 and 10% . To avoid any possibility of error we decided to show the possibility to increase this result through a slight change in the proprietary formula used, suggested by the Alpha Extended Model of the Atom (1), (5). Consequently a second test was carried out on May 25, 1998, with the only addition of 50g of SiO2 (powder) in the same composition used for the test of May 21. The result was the transmutation of 2.07g of Uranium (45% of the total). An increase of 15% (+ 50% compared to the test of May 21). . . .

In 2002 (October 9) we made another demonstration at the Royal Institute of Technology (Stockholm, Sweden). It was the first time we tried a test, with thorium, in the second window of the year. Three ignitions were made (see the videotape and History section). The samples obtained from the first ignition were taken, for analysis, by G. Godowski . The results never returned (disappeared). The samples from the second and the third ignition were taken by J. Coleman and analyzed by R. N. Barnes (26). A very interesting result came out: using the mixture with 50g of SiO2 also the thorium in the slag was destroyed (about 100% of the total). We need, obviously, more tests made in the second window of the year, to verify this experimental result. . . .

A comment:
If highly radioactive wastes from nuclear reactors could be turned into non-radioactive substances then the main objection to nuclear energy from fission reactors would disappear. That would be a totally unexpected, and highly appreciated, gift to mankind from CMNS community. I do not think that this is possible without using highly intense sources of neutrons, as suggested, for example, by Carlo Rubia at CERN. But I would be happy to change my mind. Godowski, who you mentioned, was (is?) deeply committed to Rubia's project.

Replying to the above Dr. Roberto Monti wrote:
Filalete published his book in 1645. Or you are kidding or you show deep ignorance ot the history of alchemy. My website is enough. I do not need any further publicity. There is even too much Information. I know that many of the experiments that I suggested, have already been repeated successfully by many people. The French, in particular, have a peculiar attitude: whenever one of my tests is successful, they put on it: "Classified." My reply: “Yes, I had no idea who Filalete was. What confused me was the date at your reference #17”

Is alchemy part of CMNS?:
Then, addressing Ed Storms, who is writing a book about cold fusion, I wrote: ”I think that his [Bockris'] alchemy experiments, and those described by Roberto, should not be ignored in your upcoming book about cold fusion. These people, like Piantelli, Patterson and Case (mentioned by Peter Gluck this morning), were part of cold fusion history. Let me again suggest that you write a special chapter devoted to their ideas (even if you disagree with them). Likewise, the commercial applications project described at ICCF11 by E. Anderson, or that described at ICCF12 by S.

Krivit, should not be ignored. Why should (or should not) a book about CF inform readers about all aspects of CMNS? Why to focus (or not focus) only on those ideas which, the author beliefs, have a good chance of being accepted? Perhaps someone will answer these questions.

In the immediate reply Ed Storms wrote: " . . . My criteria is to discuss that which is done with sufficient skill and described with sufficient clarity to allow an educated person to make sense of the concept and accept that reality is being described, even when the reality is not understood." Does this apply only to Monti or to Piantelli, Patterson and Case as well? In one of his messages Roberto mentioned that his papers, presented at ICCF11 and ICCF12, were not included in the proceedings. But, as I just verified, Case and Pattreson are also not mentioned in the index of authors of ICCF11 papers. I did hear Case's presentations at ICCF11. I suppose that the issue of publishing or not publishing certain papers was discussed among conference organizers. They probably decided that certain topics had nothing to do with CMNS. Or perhaps they were afraid that publishing alchemy papers would give ammunition to those who claim that all cold fusion researchers are practitioners of voodoo science.

Another voice:
Referring to an experiment performed by a friend, X -- he prefers to remain anonymous -- wrote: "Effectively in 2000 a test of transmutation, according to the protocol of our friend R. Monti has been performed by a friend of mine; he was the chief of a big R&D lab completely devoted in the field of explosives and ammunitions. ..... Two tests have been successful in transmuting Hg into Au. The total of the mixture was in the range of 50 grams. In the best test 0.6 grams of gold were recovered by the classical way of Aqua Regalis. The quality of Au has been tested by a mass spectrometer." Then X described bizarre circumstances under which the report was classified. The alchemically produced gold is now in two wedding rings.

Another comment:
Dr. Monti is apparently not the only one who takes ancient alchemy seriously. In my last contribution to this thread I wrote: "I suspect that most people on this list, like most mainstream scientists, have the same attitude to medieval alchemy as I have. We were educated to think that transmutations of elements by chemical means are not possible. And we all believe in nuclear alchemy. What would I do if I had a simple reproducible-on-demand demo of a chemical transmutation? Taking negative attitude toward old alchemy for granted, I would focus on the demo itself and not on the fact that it is based on what was described long time ago. Any chemist should be able to replicate a procedure that was used in 1645, provided it was properly described. I would say "I do not know why it happens; but it does happen. Please confirm or refute my claim before jumping to a conclusion." That would be more productive than anything else, at least for the time being.

Roberto, I would be happy to make your simple protocol known to science teachers. Please describe it clearly and I will post it on my website. But avoid the case of turning mercury into gold, many people would simply smile instead of performing experiments. You wrote: '. ....A very interesting result came out: using the mixture with 50g of SiO2 also the Thorium in the slag was destroyed (about 100% of the total). We need, obviously, more tests made in the second window of the year, to verify this experimental result.' Please describe the protocol for destroying thorium by a chemical procedure. And do not mention 'the second window of the year.' Most people expect reproducibility at any time.

No matter how strongly one disagrees with Monti it is important to keep in mind that "the proof is in the pudding. " Suppose that a procedure to transform one element into another, by using chemical means, is confirmed by many experimentalists. That would be a proof and we should be able to accept it. The burden of offering the procedure, as always, should be on those who make claims, not on those who are asked to accept claims. Reality, however, is often more complicated. It has to do with prejudice, with money, with conservatism, with fanaticism, etc. etc.. Will I live long enough to witness rehabilitation of old alchemy? Most likely not. For the time being I will accept general belief that non-nuclear alchemy, like astrology, is pseudo-science.

Appended on 10/19/06:
1) This is about alleged discrimination (not publishing Monti's ICCF11 report in the proceedings). Prompted by Roberto, the chairman of the conference, Jean Paul Biberian, wrote: "The reason your paper was not published in the proceedings of ICCF11 is simply that it was not a scientific paper. I was very open to publish papers at the border line

of CMNS: I accepted a paper on alchemy by Pérez Pariente. . . " Yes, many controversial presentations (but not as controversial as making gold from mercury) were published in the proceedings.

2) Gold from mercury or gold in mercury? I know that everything is present in everything, in a traceable amount. Is it possible that tens of milligrams of gold, shown on the photos from Roberto web site, were initially present in mercury, or in the vinegar, used to produce tiny crystals? Why was the question not addressed in his paper? What is obvious to the author is not always obvious to readers.

3) As mentioned in the unit #186, Monti's process of destroying radioactive waste by chemically induced transmutations is at the base of an anticipated commercial project. We know nothing about that project, except that progress is being made. The company wants to keep low profile at this time. This is understandable, they do not want to reveal technological secrets to potential competitors. But there is also a negative aspect in such attitude; discussing scientific aspects with scientists on the CMNS list can be very helpful. That is probably a well known dilemma. Is it possible to discuss purely scientific aspects of a pending application without revealing the "how-to-do-it" details? Assuming that the answer to this question is positive, I want to ask some questions about the proposed transmutations of NORM (Naturally Occurring Radioactive Material). Presumably such materials will be mixed with industrial byproducts (tons of waste?).

(a) Is Roberto's transmutation process selective or does it have about the same efficiency for all NORMs: U, Th, Ra, Po, Rn, etc.? (*) Roberto describes efficiency in terms of the "decrease per ignition." For example, referring to 1998 experiments, he wrote: "The first experiment (May 21) showed the transmutation of 1.32g (30% of the total) of Uranium."

(b) What instruments are used to measure transmutation efficiencies?

(c) How many tests were performed in the last two years? How reproducible are the results?

(d) How certain is Roberto that the decrease in the activity of NORMs is due to transmutations of atomic nuclei rather than to their redistribution (changes in counting geometry)? Or how does he know that the decrease is not due to dispersion of radioactive materials into the environment?

One often hears the old English proverb about proof being in the pudding. But what kind of commercial pudding will convince us that Monti's claims are valid? It has to be a set of reproducible-on-demand experimental data and the discription of the "reactor's" anatomy that most us would consider to be free of artifacts. What else can it be, Roberto?

To make clear what artifacts I would look for, let me describe an ongoing experiment. For nearly 7 weeks I have been measuring radioactivity of a hyperthyroidism patient (my wife) who received 8 microcuries of the I-131. The half-life of that isotope is eight days. But a Geiger counter, situated in the same position with respect to the throat, was showing that the counting rate was decreasing much faster, especially at the beginning. The first measurement was taken about three days after the pill was taken. A naive person might conclude that Linda's body transmuted radioactive iodine into something non-radioactive. But that would be wrong. A more credible explanation is that a significant amount is iodine was biologically removed from the body (dispersion) or that the distribution of the iodine within the body was changing (counting geometry becoming less favorable). The first hypothesis was confirmed by the fact that Linda's saliva, for example, was found to be radioactive. How does Roberto know that dispersion and redistribution were not responsible for what he attributed to pyrolitically induced nuclear transmutations of uranium and thorium?

Scientific papers posted on out web sites should meet standards imposed on papers published in referred journals. Reasonable objections should be anticipated by the authors and addressed in what is published. The same should be true for papers presented at our conferences, as indicated by Jean Paul.

Appended on 10/21/06:
Here is what one reader of the above wrote to me in a private message last night:

". . . Regarding mercury transmuting to gold: Read pages 540-542 in Strong's Procedures in Experimental Physics.

This gives good reasons to be suspicious of claims of "transmutation", especially if one knows nothing about the history of the mercury used in the experiment. Mercury almagamates with many metals (as with silver, used for tooth fillings). The more likely explanation of the "transmutation" is contamination. If the experimenter does not know what is in his mercury before the experiment, then the results of the experiment must obviously be in question. Certainly the mercury of 1645 would be suspect. ....." Yes, this observation is valid. The burden of proof is on Roberto. Perhaps he will share the results of chemical analysis of mercury used in transmutation experiments with other CMNS researchers. Mizuno, who also performed transmutation experiments, was very specific about purity of various materials, including water.

But contamination can no longer play a significant role in experiments during which nearly 50% of the total is transmuted, as in the case of Roberto's May 25, 1998 experiment with uranium (see above). In that case the suspected artifacts are dispersion and changes in the counting geometry. Note that if 45% of uranium (about 2 grams) was transmuted then about 2 grams of something else should have been created. What was it? I suspect that Roberto has no answer to this question. But he is certainly aware that the question is very important -- it is likely to be asked by critical readers. Did you try to demonstrate appearance of about two grams of a new substance, Roberto? That would make your transmutation claim much more credible than it is.

What did John Bockris have to say about contamination in his alchemy experiments? He is a worldwide authority on chemistry and electrochemistry -- a teacher of teachers, as someone wrote. I saw his textbook and I read that Fleischmann was his student. Is it conceivable that Bockris also ignored to address the issue of possible contamination? I do not think so.

Appended on October 24, 2006:
Let me mention that George Washington bridge, admired each day from the balcony of our new apartment, was inaugurated exactly 75 years ago. Was it simply a coincidence that I was born on the same day? An astrologist might think so -- and probably explain the coincidence in terms a stellar configuration .....In a message posted on our restricted list, Bill Collis wrote:

"Your quite right in raising the question of dispersion and also asking about the instrumentation used to measure any transmutation. The two issues are connected. Both Th232 and U238 decay by alpha emmission which penetrate Geiger counters with difficulty or not at all. Some gamma radiation is produced (see PCNUDAT on the ISCMNS CD-ROM/DVD-R) but at low energy and intensity. Put a Geiger counter near thorium or uranium and it buzzes frantically. This is due to gamma radiation from the beta decays of the daughters. You can demonstrate this easily by placing an absorber between the source and the Geiger tube. Elimination of radioactivity by "ignition" probably involves temperatures greater than 1500 degrees. Many of the radioactive daughters of uranium and thorium, such as Radium, Francium, Radon, Astatine, Polonium all boil below these temperatures. Of course we should also realize that the boiling point of their chemical compounds may be different. Nevertheless, the prospects for dispersion into the gas phase look rather high."

That is why a very hot piece of uranium might appear to be less radioactive than the same piece before heating. Was a possibility of such scenario discussed by Roberto? If so then I am not aware of it. Responding to Bill, I wrote: "I would like to know what Roberto thinks about the role of dispersion. Ideally, it should be prevented; less ideally (in a preliminary experiment), it should be accounted for. That is not a simple task. On his website Roberto wrote that nearly 50% of uranium -- about 2 grams -- was transmuted in May of 1998. Such outcome, if possible, would be very desirable. Roberto, what allowed you to conclude that transmutations were real?"

Will he reply to our questions? A well known nuclear scientists once wrote, many years ago, that "researchers have the responsibility to publish their own experimental data. They should be in a position to explain and defend their results to other qualified experts. This is especially true when the reported data are controversial and directly contradict well-established scientific results in the literature. The description of experiments and results should be published in sufficient detail to give the expert reader the possibility of evaluating the significance of the claimed result." How can one disagree with this? Personally, I do not think that Roberto paper contains good arguments for reality of chemically induced nuclear transmutation. And, for some reason, he is not willing to reply. That is not a good sign. Something is not right somewhere.

This birthday card came today, 10/24/2006.

Appended on October 27, 2006:
A long awaited reply from Roberto was posted this morning. He addressed concerns of several CMNS researcher. But my questions (about dispersion and the counting method) were not addressed. Why is it so? In an earlier message Monti asked Bill Collis to translate his Italian papers. Here is the reply from Bill: ". . . As I wrote before, I'm quite happy to discuss your theoretical works privately. However I suspect they will not pass peer review and consequently any translation work will be in vain. I would suggest instead you write an experimental paper, describing transmutation. It should include proper blanks or controls. It should use nuclear instrumentation to verify claimed nuclear effects. Such a scientific paper, if you can write it, should certainly pass peer review. I will be happy to consider translating it, or correcting it, free of charge. But I'm not prepared to discuss translation of any kind, whether free of charge or for a fee, unless I first see the manuscript. I think that's fair isn't it?" I did not know that Roberto is also a theoretician. His paper about Einstein, shown at:

http://www.lowenergytransmutations.org/papers.htm

is just as strange as his experimental report about fabricating gold from mercury. I cannot accept Roberto's conclusion that Einstein goofed on special relativity. We know that equations of that theory have been shown valid many times. High energy accelerators, used in numerous laboratories, were designed with that theory. These complex devices work because the equations are correct. Perhaps someone will post a message evaluating Roberto's theories of transmutations. Let end with the following dead-end speculation about making gold.

It is a well known fact that 10% of natural mercury is the isotope ^{198}Hg. A stable ^{197}Au (common gold) would be created if one proton was emitted from the ^{198}Hg nucleus. What could be more simple than this? Unfortunately, the atomic masses involved in such emission are unfavorable:

^{198}Hg 197.96677 amu
^{197}Au 196.96655 amu
proton 1.00782 amu

The sum of the last two masses, 197.97437 amu, exceeds the mass of the ^{198}Hg by 0.00760 amu. In other words, spontaneous emission of protons from ^{198}Hg is energetically forbidden; the minimum energy needed to emit a proton is $m*c^2 = 0.00760*931.48=7.08$ MeV. Yes, I am using Einstein's famous $E=m*c^2$ equation here. Is it possible that a chemical process can supply a ^{198}Hg nucleus with more than 7.MeV of energy? I do not think so. By the way, the binding energy of a proton in ^{198}Hg, exceeding 7 MeV, is not a wall-like barrier, it is a step-like energy threshold. That is why speculations about catalysts are likely to be fruitless. But what about billions of atoms, each contributing a tiny amount of thermal energy to a single ^{198}Hg nucleus? Something like that would help; if we knew how to concentrate thermal energy of many atoms in a nucleus of one atom.

P.S.
A message posted two days ago (on our restricted Internet list for CMNS researchers) referred to a paper published in the most recent issue of New Scientist. The title of that paper was: "The Cryogenic Model of Nuclear Fusion." Referring to this paper, and to a message about a relevant French patent, Roberto wrote about his much earlier paper on that model. His message contained the following prediction:

". . . They shall have a bigger surprise when they will come to
know that any radioactivity can be easily destroyed in 3 days."

Here is my reply:
1) Are you referring to transmutations induced by neutrons? That can probably be done, but not "easily."
2) Yes, easy destruction of "any radioactivity" will be a big surprise. How soon will we experience this surprise?
3) Will the issues of possible artifacts be addressed?

Efficient destruction of highly radioactive isotopes, in spent fuel from nuclear reactors, would open a new era of nuclear electricity. By the way, rapid turning of radioactive isotopes into stable isotopes will rapidly release usable energy. The process my be able to pay for itself. Let us hope for this.

Roberto, may I have permission to quote the above prediction on my website?

Permission to quote was given but, as before, my questions were not answered. Why is it so? Something is not right somewhere.

Appended on 11/6/06:
Apparently, Roberto decided not to answer my question about dispersing. But messages he did post on the CMNS list indicate that his "Cryogenic Model of Nuclear Fusion" (developed in 1987, two years before the discovery of CF was announced by Fleischmann and Pons) played an important role in subsequent investigations. The word "cryogenic" usually refers to temperatures near absolute zero. Roberto's paper is in Italian but it will be translated into English and posted on his personal website, in a month or so. If I understood posted messages correctly, the model claims that the temperature at the center of the sun is lower than at the surface. The surface temperature, only about 6000K, is certainly too low to allow for generation of hot fusion energy, and for conversion of hydrogen into helium. What will astrophysicists say about this model? Will they conclude, incorrectly, that all CMNS claims are as unrealistic as Roberto's? I hope not.

311) A contribution from A. Alberts

Ludwik Kowalski; 11/xx/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

About two months ago Albert Alberts, from Netherlands, mentioned some observations made by Otto Reifenschweiler. This was on the restricted Internet list for CMNS researchers. Asked for a clarification, Alberts wrote:

"The 'Reifenschweiler effect' is the observation that the beta-decay of tritium half-life 12.5 years is delayed reversibly by about 25-30% when the isotope is absorbed in 15 nm titanium-clusters in a temperature window in between 160-275 C. Remarkably at 360 C the original radioactivity reappears. The effect is absent in bulk metal. Discovered around 1960/1962 at Philips Research Eindhoven, The Netherlands Reifenschweiler extensively discussed his observation with o.a Casimir (the director of research at the time), Kistemaker (ultracentrifuge expert), and although no satisfactory explanation was found, R. was allowed to publish it. At the time a unique example as to how an electronic environment might affect nuclear phenomena."

In a private e-mail message Alberts, who used to be a physics teacher, wrote: "I don't know if that work was replicated, he was invited to, I think, Sandia and later to Los Alamos to demonstrate the effect, instigated by a fellow named Cox. What I do know is that it was replicated in the Philips labs many times, supervised by the eminent Casimir at the time. The beta-rays were detected by Geiger-Mueller counters, at the time Philips had the most advanced evaporation/evacuation techniques possible. Even electron microscopy. The work was criticized by a German fellow, but Reifenschweiler retaliated. That stuff should be in his reprints." He also wrote that he is in contact with Dr. Reifenschweiler (who is quite old) and that he has some old manuscripts. Subsequently I asked Alberts to compose an essay on Reifenschweiler effect. He agreed. His essay will be shown below as soon as it arrives. I think Reifenschweiler himself will assist in writing a good summary. Meanwhile let me mention that a French researcher, Fabrice David, also summarized Reifenschweiler effect in 2004. That was the topic of his presentation at ICCF11 (11th International Conference on Cold Fusion) in Marseilles.

ALBERTS' ESSAY WILL BE PLACED HERE

312) Another kind of beta decay?

Ludwik Kowalski; 10/28/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

What follows is a message I posted on a restricted Internet list for CMNS researchers. It was prompted by a speculation, posted by another researcher, that half lives of radioactive nuclei can be reduced by keeping them at extremely low temperatures. My piece, ironically, is about speeding up the decay of some nuclei at extremely high temperatures.

Here is an idea that preoccupied me more than 25 years ago. It is recorded in a note from an old binder. I expected the half life, in beta-minus decay, to be reduced when atoms are ionized. Some bare radioactive nuclei (atoms without electrons) in very hot plasma, I speculated, would decay faster than nuclei in neutral atoms. This was based on what is known about beta-plus decay, where two decay paths are available (two ways of changing a proton into a neutron): (a) positrons are emitted or (b) orbital K electrons are absorbed by nuclei. The second path is known as EC (electron capture). The half life of a beta-plus decay would become longer if the second path could be prevented, somehow. By how much longer? It would depend on the fraction of nuclei decaying via the EC path. That fraction, by the way, is called branching ratio.

In the beta-minus decay (changing a neutron into a proton) we have only one path -- emission of an electron. The second conceivable path -- placing an electron into an atomic orbit of neutral atom -- is forbidden by Pauli principle. It is not possible to add an electron into an already-occupied orbit. The central idea was that a new path for the beta-minus decay is automatically open when bare nuclei are formed. By opening another decay path one would speed up the decay of some beta-minus radioactive nuclei.

Unfortunately, total ionization of atoms calls for temperatures that are probably too high for practical applications. Why did I not think about this when I first heard Roberto at ICCF11 ? He was talking about a "pyrolytic method" of destroying radioactivity. I do not know what kind of process it is and how high were his temperatures. My old binder shows that I was anticipating two hot plasma experiments. This was discussed with two plasma physicists in Princeton. The experiments never materialized. Here is a note composed on 1/5/1980. ". . . The second experiment in hot plasma has to do with "speeding up" the decay of beta-minus radioactive nuclei by a process that can be called orbit population, OP. In this process the transformation of a neutron into proton is associated with the emission of an antineutrino and with the appearance of an electron on an empty atomic orbital." Branching ratio formulas for the beta-plus decay can be found in many textbooks. Assuming the formulas are applicable not only to EC but also to OP (in fully ionized atoms), I was able to show that changes in half-lives can be very significant. I wrote that according to preliminary calculations, "the half-life of bare ^{106}Ru should be reduced by a factor of 23, as compared with neutral atoms. [That means about two weeks instead one year.] In most cases, however, the reduction factors are not that large." . . .

P.S.

(a) Temperatures T needed to produce nearly total ionization of atoms are high. The values of kT, where k is Boltzmann's constant, are usually expressed in keV (several keV, for light elements and up to about 100 keV for the elements at the end of the periodic chart).

(b) The OP process probably does take place in many stars. I would not be surprised to learn that it is taken under

consideration by nuclear astrophysicists.

Appended on 12/10/06: For some reason, in speculating about the OP process nearly three decades ago, I was not aware that it was discussed by others. The paper of Gareev, presented in 2004 at ICCF11, discusses this topic much better. The title of the article was “Enhancement mechanisms of low-energy nuclear reactions” and the authors were: F.A. Gareev, I.E. Zhidkova and Yu.L. Ratis.

313) Nonscientific aspects of CMNS

Ludwik Kowalski; 11/17/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This morning Peter Gluck started a thread “we are not alone.” That was on the restricted list for CMNS researchers. Referring to two recent publications in Science, he wrote that high temperature superconductivity, like CMNS, is also struggling with explanations of experimental discoveries made many years ago. Several hours later, John Coviello posted the following reply.

“It is interesting how relatively uncontroversial high-temperature superconductivity is compared to cold fusion, considering they are both in the same quandary of lacking an explanation that satisfies mainstream science. What are the differences? Perhaps the fact that cold fusion could destroy a multi-trillion dollar fossil/nuclear fuels industry, while high-temperature superconductivity barely even threatens multibillion dollar communications and power transmission industries is a factors? I say barely because high-temperature superconductivity would not doom the industries, in fact, it would cause a new wave of spending on infrastructure and equipment upgrades and create a lot of business activity, as firms rush to install the latest technology, so perhaps they have nothing to fear at all. Cold fusion would mostly end the financial prospects of the bloody oil trade, dirty coal industry and wasteful nuclear fission industries. Is it any wonder cold fusion enjoys few friends in high places given the implications of its commercialization?”

Three people responded. They pointed out that, unlike in CMNS, experimental observations in the area of high temperature superconductivity turned out to be reasonably reproducible. Here one of the responses; it was posted by Scott Little. He wrote:

“My son and I made some YCBO blocks for his junior high-school science fair project in 1991. around 4 years after their discovery. Following a published recipe, the first batch we made worked well enough to demonstrate the Meissner effect (magnet levitation). I still have these superconductors. They still work. Somehow that doesn't remind me of cold fusion at all. ....)”

“What I would like to know, is whether or not factors mentioned by John played any role in creating the discriminatory attitude toward CF, in early 1990s. The young lady, CF, Ed Storm's mistress, is going to be 18 next spring. That is about time to be treated as adult science. Will Ed's book help? Will confirmations of San Diego results help? Will conformation of Oriani's results help? We will see.” That was my own comment on the list. No one responded so far. John was not the first to point the accusing finger at oil companies. What evidence is available to support such accusations? Perhaps other factors, such as personal animosities, jalousie, and, above all, competition for grant money, should also be blamed for excommunication, if I can use this term, of cold fusion in early 1990s. I hope that others will help us to understand the mechanism of the process of social discrimination of cold fusion. The "nonscientific" aspects of the history of CMNS are interesting; I hope at least some of them will be addressed in the book about cold fusion that Ed Storms is writing. Let me mention that I first saw the word “excommunication” in one of his essays, written several years ago.

Personally I am not convinced that oil companies are behind those who use administrational means (like rejecting papers, not accepting patents, etc.) to discriminate against cold fusion. Big companies would probably be among the

first to invest heavily in CMNS technology, if convinced that it is promising. But blaming of “rich and powerful” is not new. What evidence do we have that oil companies conspired against cold fusion in 1990s?

Appended on 11/23/06

The only reply, so far, was that suppressing an emerging new energy technology (such as electric cars) would be in the interest of oil companies. That is not a proof of conspiratorial manipulations. When Enron executives were accused of such manipulations they were confronted with convincing proofs, I believe. The argument “that would be in their interest” is not sufficient. Being prudent and not investing in the not-yet-demonstrated technology is a virtue. Automatic blaming of rich and powerful for everything bad is not new. Sometimes these “bloodsuckers” are responsible for bad things but sometimes bad things have other causes. I am thinking about hurricanes, epidemics and famines, for example.

The more I think about this the more am I convinced that accusing oil company executives of conspiracy against cold fusion makes no sense. Why would they be less concerned about consequences of pollution and global warming that most of us? Most of them also love their children and grand children. And they always look for opportunities to make money. Replacing declining oil resources by CMNS sources of energy would offer a chance to make money. Therefore, it is only logical, to expect them to sit and wait for opportunities to make money. Some of them are probably watching carefully what is going on in the CMNS fields. Why should they think that CMNS is “ready to deliver” when we still do not have a reproducible-on-demand demo?

Absence of additional comments is a good indication that most CMNS researchers do not blame oil companies for discrimination against cold fusion. This can be contrasted with what one often reads at open websites at which cold fusion is discussed by non-practitioners. At those websites accusations of oil companies are much more frequent.

314) CMNS Research in the US Navy Lab

Ludwik Kowalski; 11/11/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction

1) This unit is prompted by what has just been published by Steven Krivit. He is a journalist who follows CMNS developments and writes about them in the online magazine called New Energy <http://newenergytimes.com >. He also wrote a book devoted to the controversial CMNS field. That book, by the way, can be ordered from the above website. Before reading beyond this introduction, please go to

http://newenergytimes.com/news/2006/NET19.htm

and click the link to item #7, entitled "Extraordinary Evidence." Read the item carefully and then read my comments below. I do not want to repeat what has already been described on the above webpage; I only want to share some observations.

2) Yesterday, in a personal message to me, Steven wrote: "The field of low energy nuclear reactions, historically known as cold fusion, has never had simple physical evidence of the claimed nuclear processes to physically place in the hands of doubters. Until now. Scientists at the U.S. Navy's San Diego SPAWAR Systems Center have produced something unique in the 17-year history of the scientific drama historically known as cold fusion: simple, portable, highly repeatable, unambiguous, and permanent physical evidence of nuclear events using detectors that have a long track record of reliability and acceptance among nuclear physicists. Using a unique experimental method called co-deposition, combined with the application of external electric and magnetic fields, and recording the results with standard nuclear-industry detectors, researchers have produced what may be the most convincing evidence yet in the pursuit of proof of low energy nuclear reactions. "

3) Naturally, I was not the only one to read about Steve's journalistic description of the work in San Diego. The publication was announced on the selected list for CMNS researchers. A scientific paper describing the results was submitted to a refereed journal in September; I hope it will not be rejected. On the same day the following message ws posted by another CMNS researcher, Scott Little. He wrote: "Ludwik, you have considerable experience with CR-39. What is the possibility that these results, despite the controls that have been run, are due to some sort of chemical/electrical/physical interaction and not energetic particles?" Responding to this I wrote:

"Scott, I am glad you asked. As it turns out, in the last several days I was trying to answer the very same question about the new results of Richard Oriani. Last summer he sent me the unpublished paper describing the results. I am considering a possibility of working with Richard again, in the near future. With his permission I am happy to summarize the results. The bottom line is that, according to Oriani, nickel cathodes, after being used in a simple electrolytic cell, emit nuclear particles. His average result for used cathodes, from 32 experiments, was 89 tracks per cm^2 while his average result for virgin cathodes, from 24 experiments, was 20 tracks/cm^2. The electrolysis times and CR-39 exposure times (after cathodes were removed the cell) fluctuated between 2 and 4 days. For the purpose of statistical analysis I assumed that the average electrolysis time was 3 days while the average CR-39 exposure time was 2.5 days.

Richard, please confirm that this is correct, or give me correct times. Actually, the number of post-electrolysis experiments was larger than 32. But I eliminated the Pd cathodes results and one result for the Ni (because the electrolysis time was only 1 day). These eliminated cases were not significantly different from the 32 cases I analyzed statistically. But why should a statistical analysis be done on a mixture of very different cases? I also eliminated one extraordinary case in which the track density, from the used Ni cathode, was about 300 per cm^2. Yes, I know that this might turn out to be the most important case. But textbooks tell us to examine distributions before analyzing them, and to extract outliers. That is why the most favorable case was removed. I wanted to follow a standard statistical protocol. The so-called "null hypothesis" was that two slightly overlapping distributions (32 results 24 controls) were from the same population. The alternate hypothesis, that two distributions are really different, prevailed. My conclusion agrees with what Richard wrote in the draft -- the probability is vanishingly small that the difference 89 and 20 is coincidental. Yes, standard deviations are large, but they were calculated from Richard's data. In other words, random errors were realistically accounted for, to reach the conclusion.

I will provide more details about what I did in another message. And I hope Richard will tell us what the current status of his manuscript is. We are anticipating an experiment in which the CR-39 results will be compared with results obtained by using a silicon detector. The major technical difficulty will the very low counting rate, perhaps only two or three particles per hour. This is slightly above what is said to be possible with a commercially available unit from Erotic. Being an optimist I expect the background to be below 0.5 per hour, when the detection threshold is increased, for example to 4 MeV. Is this realistic? The advantage of using CR-39 is that it allows to work at much lower average counting rates, provided pre-counted CR-39 chips are used, as done by Oriani. . . .

The advantage of an electronic detector is that it will give energies of particles responsible for CR-39 tracks. Just imagine what one would be able to say if the energies turned out to be higher than 8 MeV. That would immediately rule out a possibility that what is being detected is due natural alpha radioactivity of something in our environment. On the other extreme, one may find that the energy histogram is consistent with energies for Rn etc. That would cause us to focus on a possibility of contamination. Another great advantage of electronic detection would be an opportunity to study the time dependance of counting rates. Do they decrease significantly from day to day or do they remain constant? . .

Here are actual Oriani's results;

1) Controls, CR-39 chips, exposure 2 to 3 days

(tracks/cm^2):
18,15,39,23,45,21,27,0,10 0,22 26,36,22,34,14,10,17,10,25,16,21,24,12
24 results, mean value=20.3; standard deviation=11.1

2) Used Ni cathodes, CR-39 chips, exposure 2 to 3 days

(tracks/cm^2):
145,128,116,149,133, 145,63,45,66,118,69,96,180,127,84,115,57,79,65, 71,74,71,41,66,43,81,71,53,56,69,99,80
32 results, mean value=89.2; standard deviation=35.8

= =

This is the end of my introduction.
Please go to the "Extraordinary Evidence" item now, and read it before
reading what I have to say.

http://newenergytimes.com/news/2006/NET19.htm

= =

Appended on 11/15/06:

The ongoing Internet discussion of SPAWAR results, on our restricted list, is going on. I was reading numerous messages and thinking about the best way to summarize them here. Meanwhile, Pamela Boss, who leads the SPAWAR project, wrote to me in private: ". . . Once we've got this Q&A to a mutually satisfying place, we'll review the verbiage and get you a cleaned up version that we feel comfortable with you posting very soon." That is great; what could be better than this? Please read her input below before jumping to my closing comments.

Appended on 11/19/06:

I sort of expected to receive pieces from Pamela and from Steve during this weekend. But nothing was sent to me. I suppose Pamela is very busy with the ongoing experiments. So I should wait. Meanwhile I started speculating about the Frapa -Stanila effect discovered in San Diego. The suggested name seems to be appropriate; it is made from first names of four SPAWAR researchers: Frank, Pamela, Stanislaw and Larry, in the order in which they were introduced in Kriven's report. This temporary name has some melody; perhaps it is appropriate for a folk dance to be created to celebrate the 2006 discovery. But what if Frapa-Stanila refers to something bad or impollite in another language? In that case another name would have to be composed. Why don't I say SPAWAR effect ? Because when I tried to guess what the acronym stands for, the first words that came to my mind were "spaying" and "war." I prefer something more pleasant, for example, an Italian dance, Tarantella. But I will be glad to use the name chosen by those who discovered the effect.

Appended on 11/20/06:

Something interesting was posted this morning on the CMNS list by Krivit. He wants the replications of the Frapa-Stanila effect to be organized and coordinated. The first step, labeled alpha; is to have the effect replicated by selected electrochemists. The second step, labeled beta, will be based by the detailed protocole written by the SPAWAR team and refined by alpha group. Anyone willing to be part of the beta project will receive the protocole. This was described in:

http://www.thegalileoproject.org

I would not mind to participate in the beta phase; but not before confirmations are announced in the alpha phase. The idea of coordinating efforts of several teams, working on the same project at the same time, is worth supporting. Will researchers outside the CMNS list, for example, teachers and students, by invited to participate in the beta phase? I hope so.

Appended on 11/22/06:

What follow is a set of answers to Frequently Asked Questions (FAQ) about the Frapa-Stanila effect. It has just be posted by the New Energy Institute,

http://newenergytimes.com/contact/contact.htm

I expect the FAQ list, grabbed from

http://www.thegalileoproject.org/FAQ.htm

to become longer. Keep in mind that the author, Steven Krivit, is a journalist, who has learned a lot about science since he started investigating cold fusion (the new name is CMNS) several years ago. It would not surprise me to learn that the piece pasted below was actually approved by scientists who are investigating the new effect. Steven assumes that readers are already familiar with his article, "Extraordinary Evidence," published in New Energy Times on Nov. 10, 2006 It is item #7 in:

Q1. Did the researchers consider possible sources of contamination?

A1. The SPAWAR team performed a number of controls that indicated that their observations were not the result of radioactive atoms in the solution.

(a) For example, they immersed a CR-39 detector in the co-deposition solution without performing electrolysis. The detector was immersed for the same amount of time as for their electrolysis experiments. The result was that no tracks were observed on the detector.

(b) They performed electrolysis experiments without the $PdCl_2$ in the solution. Result: No tracks were observed.

(c) They performed co-deposition experiments, in the absence of external electric or magnetic fields. Result: No tracks were observed.

With regard to possible radiological contamination, although CR-39 background studies continue at SPAWAR, the reported CR-39 charged particle density is more than 10,000 times the background track count.

If the tracks are caused by alpha or proton emission, as proposed by the researchers, then this indicates energy levels 1 million times larger than any known chemical source. The absence of tracks, as shown in the control studies performed without the required parameters, rules out internal chemical, and both internal and external radiological, cell contamination as the track source.

Q2. Are the researchers claiming that this is proof of cold fusion?

A2. No. They make no claims of any form of fusion reaction with regard to this experiment. Instead, the evidence reported is suggested as a novel, anomalous low energy nuclear reaction.

Q3. Did the researchers measure heat?

A3. No attempt was made to measure heat in this experiment, it was not a concern of the researchers at the time.

Q4. Di-alkyl carbonate polymers will decompose in the presence of a acid, and especially acid + heat to form lower molecular weight species + CO_2. The acid-degraded lower molecular weight chains become carboxylic acid terminated, and hence are soluble in aqueous base, and can be extracted from the polymer matrix. This could give the appearance of pits (as seen in this article). **Could the CR-39 plastic have degraded due to heat,** and thus become soluble in the aqueous base development step, and thus be the result of a chemical, not a nuclear reaction?

A4. SPAWAR researchers reply: "Each of the wires Au, Ag, and Pt were at the same potential of approximately 2 V or less, and the current was approximately 100 mA or less. It was observed that the number of charged particles varied among the wires, but there was a distinct "shadow" corresponding with the back side of the wires closest to, and in contact with, the CR-39. This “region,” without tracks, directly behind the wire constitutes an insitu “control.” If the proposed localized heating is a function of joule heating, the heat conductivity of the various metals is sufficient to prevent local hot spots against the CR-39. If the proposed localized heating is a function of simply D2O dissociation and Pd loading during, or subsequent to, co-deposition and even if anisotrophic, again, the heat conductivity of the various metals is sufficient to prevent local hot spots against the CR-39. Therefore, if the purported catalytic effect causing depolymerization of the CR-39 was occurring, then it should have occurred directly behind the wire in closest contact with the CR-39. It did not.

In addition, we observed tracks at distances exceeding the diameter of the wire and extending over 1 mm, where there was no contact between the wire and the CR-39. Thus, there was not opportunity for exothermic, Pd-loading generated heat or joule heating to provide the catalytic heating required to depolymerize the CR-39, whether or not a localized

low low pH or insitu acid contamination exists.

I know that the authors are still deeply involved in studying the Frapa-Stanila effect, and in revising the initial manuscript. Their paper will probably be published in two or three months. That would be the best time to ask for additional questions. Their argument (c), against a possibility that tracks might be due to alpha-radioactive substances accumulating on the cathode, is very convincing. But if I were a referee of their paper, I would insist on measuring and reporting activities of alpha-radioactive substances in the used materials. Such activities, or upper limits, can easily be measured by using CR-39 detectors.

The most likely source, in my mind, would be water. i know that alpha radioactive substances, such as uranium, radium, radon, etc., are always present in water. Typical concentrations are 1 to 10 pCi/L, but sometimes much more. Suppose that only ^{222}Rn is present and that its initial concentration is 10 pCi/L. How many alpha particles is emitted each hour? (Hint: One Ci emits 37 billion particles per second.) The answer is 133 particles. How many atoms of ^{222}Rn are initially present in the 0.1 l of water? (Hint: The half-life of ^{222}Rn is 3.8 days.) The answer is 17700 atoms. Suppose all these atoms are rapidly electroplated on the cathode and decay there during a 10-days long experiment. Also suppose that 10% of alpha particles are creating tracks in CR-39 detectors. How many tracks will be recorded? The answer is trivial; it amounts to 1770 tracks.

If the same activity of 10 pCi/L was due to ^{226}Ra, (half-life is 1620 years) then the number of atoms would be much larger. Only a very small fraction of them would produce tracks. The number of tracks, however, would be larger, but not astronomically larger, under identical conditions. More specifically, 133 particles per hour translates into 31920 particles in ten days. Ten percent of this is 3192, or about two times more than for ^{222}Rn . The same result would be obtained for any alpha-radioactive isotopes whose half-life is significantly longer than the duration of the experiment. This includes ^{238}U, ^{235}U, ^{232}Th, etc. etc. Naturally, all this would become irrelevant if the initial activity in the electrolyte was shown to be less than 0.001 pCi/L; I do not know what to expect from distilled, or twice-distilled water. Naturally, all this would become irrelevant if the initial activity in the electrolyte was shown to be less than 0.001 pCi/L; I do not know what to expect from distilled, or twice distilled water.

The reader of a paper should be informed about the initial concentration of alpha radioactivity (pCi/L) in order to be even more convinced that tracks are not due to alpha radioactive substances originally present in the electrolyte. The claimed effect -- a nuclear process triggered by a chemical process -- is so unexpected, according what is known, that a reader (and a referee whose role is to help potential readers) is likely to think about various artifacts. What if electric or magnetic field, imposed from the outside the cell, simply deflect the ions that would otherwise be deposited on the cathode? It is not hard, for a knowledgeable person, to invert scenarios in which observed effects are trivialized, in one way or another. The authors of claims must try to anticipate such attempts and address the issues.

This is very difficult when one has no theory to lean on. Nothing makes sense without an acceptable theory. And experimental results that make no sense are very difficult to promote. I am convinced that experimental facts will be explained, one way or another, in less than one year, after experiments become reproducible on demand. This will be accomplished in small steps, by changing one parameter after another and by discussing the results openly. That is the essence of scientific methodology. Secrecy does not help to promote science.

Appended on 11/24/06:

The New Energy report contains references to papers already published by San Diego team. The authors have investigated several indicators of nuclear activities before focusing on the use of CR-39. One of these papers (3), by Stanislaw Szpk, Pamela A Mosier Boss, Charles Young and Frank Gordon, describes morphological changes in the cathode and production of new elements in presence of an external electrostatic field. After a brief historical introduction the authors mention co-deposited Pd/D electrodes and external electrostatic field. These are essential components of the methodology they used to discover massive tracks in CR-39. I suppose that present setup does not differ drastically from the one used before.

The rectangular cell (2 by 2 by 8 cm) was made from acrylic -- 8 cm refers to the height. The cathode was gold while the anode was platinum. The electrolyte was 0.03M PdCl2 + 0.3M LiCl in D2. Each experiment was perform in three

stages, as specified below:

(a) Preparation: Current 1 mA for 24 hours. Then raising it to 3 mA and waiting till the electrolyte becomes transparent.

(b) Stabilization: Raising the current to about 40 mA for 2-3 hours.

(c) Exposure: Applying the constant difference of potential, 6000 V, to two parallel copper plates glued to outside walls. The anode and the cathode plates were parallel to the cell bottom. The current was raised to 100 mA and above. To explain this the authors wanted the system to be “in far-from-equilibrium condition.” After 48 hours the current was turned off and the cathode was examined. Exposure to external electric field was reported to be responsible for dramatic morphological and chemical changes on cathode surfaces. It is now easy to understand motivation for placing detectors of nuclear particles near the cathode in recent experiments.

It would be interesting to known if similar experiments were performed with the electrolyte based on ordinary water, rather than based on much more expensive heavy water. Note the Oriani effects were discovery with the electrolyte made from ordinary water. I am thinking for experiments to be performed by students and teachers.

315) A new effect or contamination?

Ludwik Kowalski; 11/23/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This unit is based what was described in unit #314. Critics will suspect that what is attributed to a new nuclear effect might be due to presence of alpha radioactive substances in the electrolyte. San Diego team is fully aware of this and the issue has been addressed by them, as reported by Steven Krivit. The strongest argument they presented was the disappearance of emission when an external electric or magnetic field is applied to the cell. This topic is worth thinking and speculating about. It will certainly become an issue after the San Diego paper is published. How easy would it be to show, by using CR-39 chips, that the initial concentration of alpha radioactivity (pCi/L) was indeed too low to produce as many tracks as actually observed? I just realized that the method I was recommending (on the CMNS list) is impractical. In fact, I recommended two methods, as shown below:

"I hope that those who read unit #314 noticed that my numerical examples about alpha activities in the electrolyte were based on the exaggerated initial concentration (10 pCi/L) in the electrolyte. I hope the electrolyte will be shown to be practically non-radioactive. But this might call for keeping a CR-39 suspended in the liquid for two or three months. A faster way to eliminate suspicions (that codeposited radioactivity is responsible for the tracks) would be to run the electrolysis, without an external field, for several hours. Then to remove the cathode and expose it to CR-39. If the initial pCi/L is very small then the number of tracks on the chip should be essentially the same as on a chip, from the same stack, that was kept in a vacuum during the same time. Oriani would probably use a pre-counted CR-39 chip; in that way the answer would be more precise (smaller random error)."

The principle behind the first method is simple. Suspend the CR-39 chip in the liquid whose pCi/L is known and count the number of tracks per cm^2. That would establish a relation between the track density, D1, and the pCi/L. Then suspend another chip in the liquid X and measure the track density D2. If D2=D1, when the exposure times are identical, then both pCi/L are also the same. If D2=0.1*D1, for the same exposure time, then the pCi/L of X is ten times smaller than the known concentration in the standard liquid. The same conclusion would be reached if, in order to obtain D2=D1 the exposure time of the second chip had to be ten times longer. For a much smaller D2, the D2=D1 would be possible only after very long exposures. The numerical illustration below, also posted on the CMNS list, shows why this simple method becomes impractical when concentrations of alpha radioactivity become less than 10 pCi/L.

Let us see if 2 or 3 months was a good guess. I will assume that the CR-39 (area=1cm^2) has already been etched and pre-counted. One side showed 6 preexisting tracks and another showed 4 (due to exposure to cosmic rays during the long storage, etc.). I select the side which has only 4 tracks and expose it to water for 100 days. I will ignore the other side. Suppose that after 100 days in water I find 40 new tracks. What was the radioactivity concentration in pCi/L?

To answer this question approximately I will make the following assumptions:

a) Alpha radioactivity was due to an isotope whose half-life is much longer than 100 days. In other words, the activity is constant.
b) The range of alpha particles in water is 0.05 mm.
c) The layer of water from which alpha particles can reach the detector is 0.05 mm thick. (The rule of thumb is "as

many mg/cm^2 as MeV")
d) From all particles emitted in my layer only 10% produce tracks.

The assumption (d) can be justified as follows. 50% of particles are emitted away for CR-39. About 80 % of the remaining particles will be either absorbed in the 0.05 mm layer or reach the detector at too large angle of incidence. If these assumptions are justified then the following reasoning applies:

e) Since 40 tracks were found then 400 alpha particles were emitted.
f) What was the volume of my layer? It was 1(cm^2)*0.005 (cm)=0.005 cm^3 = 5*10^-6 liters.
g) Activity was 400 decays in 5*10^-6 L. This translates into 8*10^7 decays per liter in 100 days (or 8640000 s) or 9.2 decays per liter per second.
h) By definition, 1 Ci is 3.7*10^10 decays per second. Thus 9.2 translates into 250 pCi.

Conclusion: To produce 40 tracks in 100 days the activity would have to be 250 pCi/L. To detect 2.5 pCi/L, and to get 40 tracks, the CR-39 would have to stay in water for 100*100=10000 days, or about 27 years. . . .

It has already been shown (see above) that the concentration D2=10 pCi/L (for 222Ra, 238U, etc.) could cover the cathode surface with the amount of radioactivity emitting 32000 alpha particles in ten days. The result would be 8000 if D2 were 2.5 pCi/L. Would this be considered negligible in comparison with the number of alpha particles attributed to the San Diego effect? I cannot answer this question because I do not know how to estimate the total number of alpha particles attributed to that effect. It is desirable to have D2<0.25 pCi/L but that would call for exposures longer then 270 years.

And what about my “faster method” suggested above? Only an electrochemist can tell if the basic assumption of that method is realistic? The assumption is that atoms, such as Ra, U, in water are ionized. I think they are. That is why I expected them to migrate to the cathode surface rapidly. Several hours is reasonably short in comparison with ten days. This suggests a way to make the first method practical, even when initial concentrations of alpha-radioactivity are very low. I mention this in
a reply to a message posted on our restricted list this morning.

On Nov 23, 2006, at 5:06 AM, Michel Jullian wrote:

1) "SPAWAR effect" sounds fine, I can't understand why Ludwik dislikes it.

I will stop using the Frapa-Stanila label, at least for a while and see how others refer to the new effect.

2) Ludwik don't you agree any more that Pam's observation of "no external field --> no tracks" rules out the codeposited radioactivity artifact?

I think that the absence of tracks, when the external EM field is removed, is a very powerful argument against alpha radioactive contaminants. But I would very much like to see another, equally powerful argument.

3) It occurred to me that all imaginable artifacts associated with direct contact between the cathode wires and the CR39 material (thermal effects discussed in Steve's Galileo project FAQ, my mechanical puncturing hypothesis..) could be ruled out by interposing a thin layer of waterproof and ultra low density material such as expanded polystyrene: this would be transparent to alphas wouldn't it? (low g/cm3)

I think it is a good idea for arguing that mechanical effect are not responsible for observed tracks. But I saw too many CR-39 chips to worry about this. On the other hand, reporting that such check was actually performed, and showing real numbers, would help to establish credibility.

4) I convinced myself last night, by playing with numbers, that measuring specific alpha-activity in the electrolyte, at the level above 100 pCi/L, is feasible, provided one is willing to wait at least a month or two. Specific alpha-activities of 1 pCi/L, or less, cannot be measured in the same way. But then I realized that there is a way around. Suppose we

place an open 10 L container with water to be tested, into an oven where the temperature is 97 C. How long would it take to reduce the volume of water to 0.1 cm^3? (I am trying to avoid the "escaping droplets" ambiguity we discussed in a different context.) This would increase the initial concentration, for example, from 0.1 pCi/L (that we hope for) to 1000 pCi/L. Measuring 1000 pCi/L is not at all difficult.

Again, I would like to know what chemists think about such evaporative leveraging. I already asked this question here, several days ago, but no one replied. Is it reasonable to assume that most radioactive atoms will remain in water? I believe so, especially when there is no boiling. In any case, reporting that the initial specific alpha-activity was found to be less than 0.1 pCi/L would also add credibility to the discovery of a new nuclear effect. What else can be done, to promote credibility?

5) Suppose we wait till all water is evaporated. Then nearly all (?) radioactive atoms (responsible for 10*1000=10000 pCi) will be in a very thin layer. The 10000 pCi refers to 370 alpha particles per second (or 1330000 per hour). Suppose the area of the source is 100 cm^2. Put a 1 cm^2 chip (or, more preferably, a Si detector) on top of the remaining layer. How many tracks will be formed in each hour? The source activity would be 13300 alphas per hour and the counting rate would be ~13300/10=1330 per hour. The factor of 10 is probably exaggerated, to account for particles that are not intercepted by a 1 cm^2 detector. But it is prudent to be pessimistic in rough estimations.

The situation can be improved considerably. It is silly to throw away 99% of the source area (by using only 1 cm^2). Radioactive atoms, initially distributed over the 100 cm^2 bottom, can probably be forced to move to a much smaller area, for example, 1 cm^2. I am thinking about dissolving the deposits first and then evaporating water in a tiny beaker. That would increase the counting rate to more than 1330*100=133000 per hour. Yes, I know that it is much easier to speculate than to perform experiments. But I do have some experience with such things; and I am trying to be useful.

I hope the reader of this unit would not object if I make a little digression. I want to tell a real story; it should explain why I am so much preoccupied with the issue of contamination. I was working on my doctoral project in Orsay, France. The topic was “Fission induced by protons of 156 MeV.” One day, it was probably in 1961, I received a phone call from our librarian, Mme Vergne. She said she had an American visitor who keeps telling her things she does not understand. It is something about fission. She had other things to do and she wanted me to take Bob Walker, a researcher from General Electric Laboratory, from her. That is how I met the coauthor of the famous book about solid state track detectors. He wanted to show us how tracks, due to fission fragments, could be detected in mica.

Mica was used in the same way in which CR-39 chips are used today, except that it had to be etched in hydrofluoric acid. The CR-39 chips are very useful when one wants to count rare alpha particles in presence of abundant beta and gamma rays. In the same way, mica is an ideal detector when one wants to eliminate the effect of alpha particles and protons. I quickly learned the technique and it was later put to good use. Those who might be interested in details can refer to "Fission and Complete-fusion Probabilities as a Function of Angular Momentum ...", in Physical Review C, 1974, 10, 200. Examining pieces of natural mica, found in different places, I was fascinated by tracks they always display. Tracks in mica are due to spontaneous fission of isotopes of uranium, thorium, etc. Sometimes rivers of tracks could be seen under the microscope, showing how water, containing fissionable isotopes was sipping through the tiny cracks in the crystalline mineral. It was fascinating to think that some of latent tracks were formed hundreds of million years ago, waiting to be etched and observed. I know that water always carry elements like U and Th, in trace concentrations. And I would not be surprized to learn that Pu, and other man-made elements, are also present. OK, that is the end of my personal story.

P.S.

Replying to my request for permission to quote, Michel wrote: “my suggestion was meant to rule out ‘all imaginable artifacts associated with direct contact’, not just mechanical, it could be thermal or electrical or whatever one could come up with.” Hmm, all imaginable? OK, I know what he had in mind. Yes, as many reasonable objections as possible, should be anticipated and addressed. Contamination with alpha-radioactive substances is likely to be one of them. Convincing critical thinkers that chemical processes can occasionally trigger nuclear processes will not be easy, even after the San Diego effect is recognized as universally replicable. Theoretical considerations, based on reproducible data, will become essential ammunition at the next stage.

Appended on 11/27/06

In a message posted on 11/27/06 one CMNS researcher suggested a cell whose bottom would be a very thin metallic foil -- sufficienntly thin to pass alpha particles. That would be a cathode. A detector of particles would be placed below the cathode, rather than in the electrolyte. I think that a foil transparent to alpha particles would not be strong enough to support a column of the electrolyte. That was the essence of my reply. But then I added: “About one year ago, in Oriani's lab, we were performing experiments with a glass cell that had no glass at the bottom, only a Ni foil. That was our cathode; the Pt anode was suspended above the cathode. But the Ni foil was much thicker than the range of alpha particles. The CR-39 chips were placed below the cathode, during the electrolysis. The most surprising was that the number of tracks, accumulated in two two or three days, were larger that the background. Contamination of electrolyte with alpha radioactivity, if any, could not be blamed for the effect. I do not know what was the final verdict; the results have not been published by Oriani.

I tried to replicate his results at home but no definite conclusion was reached. I did observe the effect on several occasions but results were not reproducible. I started to suspect that static charges on CR-39 surfaces (that could possibly be created by removing the protecting plastic) attracted positive alpha-radioactive ions. Such ions are always present in air. I already mentioned that, in most basements, dust removed from a TV screen is alpha radioactive. This can be checked by using a Geiger counter with a sufficiently thin window. Leave the TV on for a week or two and then remove as much dust as you can with a small piece of wet paper towel. This of course does not imply that my results were affected by static charges as large as those on TV screens. But it is better to be prudent; it easy to remove cahrges by squeezing the unwrapped CR-39 chip beween wet fingers.

I shared my suspicion with Oriani and he said that simple precautions will be undertaken to be sure that CR-39 surfaces do not remain charged. Did this eliminate the effect? I do not know. Most recently Oriani was studying cathodes after the electrolysis. CR-39 chips were applied to surfaces that were wet during the electrolysis, as described here in one of his recent messages. Oriani’s results are shown in unit #314 at my CMNS website.”

316) New nuclear processes

Ludwik Kowalski; 11/25/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This unit is inspired by a set of three messages, from the restricted Internet list for CMNS researchers. I think that they are important. Referring to the second FAQ (see above), Brian Josephson, our only Nobel Laureate (so far? ;-) wrote:

"I wonder if that is the most appropriate answer. The usual objection to 'CF' is that LNER is impossible because of the Coulomb barrier. A2 is literally correct, but I would have thought that some mention should be made of the connection. In fact, A2 is puzzling. However, on doing my own puzzling I see that there is a way in which the results could happen without fusion, which is that in some strange way energy from the fields gets focussed on individual particles and accelerates them sufficiently to make tracks in the plastic. That would be interesting in itself. In any event, Q2 deserves a longer answer than A2. In fact, my suggested mechanism (which would seem to be the only way to get tracks without fusion) would *not* be a nuclear reaction as normally understood. Or am I missing something?"

My reply was: "The only change that can help, at this stage, would be to replace the last word "reaction" by "process." in my opinion it was wise not to say more. We want the discussion to be focused on experimental details assuring replications, not on possible interpretations. This will come naturally, as soon as reproducibility on-demand is recognized. ..... I think that the strategy for keeping low profile (in their first publication and in PR activities) is good. They should say something like this: 'we do not claim anything but the fact that something extraordinary was discovered. Please check the reproducibility and help us to make sense of experimental facts.' We do not want to see the repeat of mistakes as those that resulted in the 1989 tragedy."

In the next message Brian added: "Perhaps the thing to do is to get rid of the first two sentences of A2,so that there is no explicit denial of a connection, and then to go on with "all that the experimenters claim is.....[whatever]" and perhaps, as Ludwik suggests, replace reaction by process."

Mike McKubre replied:
"Brian makes a good point. First I am uneasy about any general statement about the claims of ALL cf experimenters ('they'). In 18 years I have heard the most astounding claims: mini black holes, trapped thermal neutrons, electrons clusters at solid densities, polyneutrons, etc. ALL of which would be capable of initiating or catalyzing fusion. NONE of which I can reject from first principles or experimental observation.

Second I (on behalf of my co-workers) do in fact claim evidence of fusion events and fusion products (4He, 3He, tritium, lattice heat at 24 MeV/4He). For years I refused to call the field "cold fusion" (all the while attending ICCF's). It was not until we had evidence well in hand of fusion products that I began openly to use the term cold fusion (without inverted coma's), and using the abbreviation cf.

What we don't claim, what nobody ever has claimed as far as I am aware (but I am sensitive to my first point above) is that the reaction is the same pairwise d-d or d-Li reactions that power the H bomb. It is precisely the relaxing of the 2 body boundary condition that makes what we do possible*. But it is still fusion at one limit of nuclear reaction. Other things seem to be happening as well. *Actually I would add relaxing the particle mindset as well - but I throw that out just to stir up the billiard ball boys."

How can a retired teacher miss an opportunity to elaborate and comment? Brian refers to “some strange way in which energy from the fields gets focussed on individual particles.” And Mike suggests relaxing "the particle mindset." To elaborate on this let me explain why I prefer to use the phrase "nuclear process" instead of "nuclear reaction." A nuclear reactions is always imagined as a collision of two atomic nuclei. The initial stage, when two particles approach each other, is called input channel. It nearly always involves two nuclei (particles); the probability of a multiple collision is extremely small. The number of reaction products (competing output channels) can be larger than two; it is no longer a matter of probability of being in the same place at the same time; it is a matter of available energy (and other conservation laws).

At low energies (less than ~30 MeV) the following model is in good agreement with a very large set of experimental data. The two atomic nuclei either bounce away from each other (scattering) or fuse, forming a compound nucleus. That system is highly unstable and it brakes into two pieces, usually after a very small fraction of a picosecond. One of these pieces might again break into two pieces, etc., till excitation available energy is exhausted (converted into kinetic energies and excitation energies of products, and subsequently into heat.) Suggesting that we should reject the "particle mindset," Mike was probably saying that the entrance channel might be very different from what is commonly associated with the phrase "nuclear reaction." Why should a different kind of entrance channel, perhaps involving billions of nuclei in a crystal, be excluded. Several people speculated about collective behavior of many nuclei in the exit channel (to explain quasi-absence of neutrons and tritium), but I do not recall seeing similar considerations for the input channel.

I do not have any specific model for the "collective input channel." A very general idea is that a chemical process of some kind, under favorable conditions, leads to occasional nuclear events. Each atom might contribute only a small fraction of its kinetic energy (0.025 eV at room temperature), to the emitted particle. All existing models will be discussed after truly reproducible-on-demand demos become available. The main point is that, unlike the phrase "nuclear reaction," the phrase "nuclear process" will free our minds from the traditional interpretation of the input channel. For that reason, I would prefer labels LENP instead of LENR, and CANP instead of CANR, where P would be for "process or processes."
P.S.
Replying to my request for permission to quote, Mike added; “I am happy to see your elaboration. I believe that we are cursed by the apparent simplicity and success of two body, point interaction, scattering / tunneling physics. It will not work for us. We need to expand our discussion and our vision.” The comment Brian made was “It is nice having it all together.” If collective behavior makes sense for the output of a process then it should also make sense for the input. But nothing significant will happen till experiments are recognized as truly reproducible.

Appended on 11/27/06

Here is one crazy model. Consider a parallel plates capacitor with a costant difference of potential 10 volts. The medium is vacuum. Suppose that a H+ ion is released near the anode. It travels toward the cathode gaining 10 eV of kinetic energy. The negative cathode gives it an electron and the ion turns into a neutral atom. That atom bounces elastically from the cathode and arrives to the anode. Its kinetic energy is still 10 eV. Here its electron is given to the anode and the atom turns into a positive ions again. It means it is again accelerated and its kinetic energy increases to 20 eV. Suppose the process is repeated one million times. Then the kinetic energy will become 10 MeV. That is more than enough to produce a nuclear reaction.

I have no idea how to turn this idea into a practical device. But I do not think that conservation laws could be used to show that such process is impossible. A cyclotron is an example of a device in which kilovolts are used to accelerate particles 10 MeV and above through a large number of small steps. The idea occurred to me as I was learning about electrochemical double-layers. Each layer is modeled as a capacitor acharge to make several volts. But the distance between the positive and negative sheets is very small, something like 10^-8 cm. Perhaps the secret of NAE is is double-layer acceleration in a double-layer. Yes, I know that this is not even “physics for poets.” One has to learn more about double layers to produce something serious.

317) About CR-39 detectors

Ludwik Kowalski; 12/1/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction
Unit #314 was devoted to exciting developments in San Diego. The name I invented for the new effect, based on first names of SPAWAR researchers did not catch on; most researchers, on the CMNS list continue using the SPAWAR identifier, as Steven Krivit did in reporting the discovery on 11/10/06. In issue #19 of New Energy Times, at

http://newenergytimes.com/news/2006/NET19.htm

, referring to a recent meeting in Washington D.C., he reported: "The chips that the SPAWAR Systems Center scientists had brought to Washington were slices of CR-39 plastic, a common, transparent polymer that resists fogging and abrasions and is used to make eyeglass lenses, among other things. The researchers had placed the small pieces of plastic inside several of their electrochemical LENR test cells to capture and preserve any fleeting evidence of nuclear events.

"We heard about the use of CR-39 detectors from other LENR researchers at the 11th International Conference on Condensed Matter Nuclear Science in Marseilles, , in 2004," Mosier-Boss said.

She and her colleagues later learned that these same simple detectors have long been used by researchers in inertial confinement fusion (a form of hot fusion) and other areas of nuclear science to record the passage of neutrons, protons, and alpha particles (the two-proton nuclei of helium atoms stripped of their electrons). The traveling particles' charges shatter the bonds linking the plastic's polymers, leaving pits or "tracks" in the plastic.

After a CR-39 detector is exposed to a source of nuclear emissions, the detector is bathed in a sodium hydroxide solution, typically for six or seven hours, at a temperature between 65 and 73 degrees C. .....The bath scours away the collision's debris, and the resulting tracks are visible with a microscope or, if they're present in sufficient densities, with the unaided eye."

That is a good general introduction. Structural damage is created along the paths of nuclear a particle in certain solids. Called latent track, it is like a tunnel that is too narrow to be seen through an ordinary microscope, even at the highest magnification. Keeping the chips in a hot sodium hydroxide solution is called etching. The etching solution penetrates the tunnel and enlarges it. After that a track can be seen under the common microscope. Quoting Frank Gordon, Steven writes: " 'CR-39 detectors are ideal for detecting particles in LENR experiments because we can put them right inside the cell where the placement of electronics would otherwise be highly impractical, ... You don't need complicated instrumentation like you do with calorimetry or tritium analysis, ...It's an easy detection tool that's very straightforward.' "

That is certainly true. How were CR-39 detectors used in SPAWAR experiments? This question is answered in two pictures; they were drawn by P. Boss and S. Krivit. The cathode is a gold wire, presumably coated with codeposited metals (Pd and Li) and loaded with deuterium. The wire is simply wrapped around the CR-39 chip. This method of recording, if I understand it correctly, has one serious limitation. If alpha particles are emitted from the cathode then

only a very small fraction of them would be seen; most of them would be stopped in the electrolyte before reaching the detector. If particles were observed on the entire surface of the CR-39 detector (Krivit's report does not say that this was the case) then the unavoidable conclusion would be that they are emitted from the electrolyte.

Let me assume that tracks are observed only where the wire and the detector are in contact. In a situation like this I would use a different approach. I would evaporate a thin layer of gold on the CR-29; it would still be transparent to track-forming particles. The layer of gold would be my cathode. After the experiment I would remove the layer, etched the CR-39 chip and looked for tracks. That would be a detector inside the cathode. About 25% of all particles would be detected as tracks. An ideal detector would record 50% of emitted particles, i.e. all particles emitted into its direction. A real CR-39 detector, on the other hand, does not display tracks of particle that are intercepted at grazing angles.

In future experiments, if the SPAWAR claim is confirmed by using CR-39 detectors, people will probably use the idea of the "detector inside the cathode" for electronic detectors. I am thinning about a box with a thin wall containing a silicon detector. The advantages of the silicon detector are obvious, they should allow us to measure the energy spectra of particle, and to determine their identity. Protons, for example, could be distinguished from alpha particles by using foils of appropriate thickness. Furthermore, a silicon detector could provide information on the rate of emission, and on its dependence on various parameters, such as time, electric field, magnetic field, etc. But all this will be possible if results are reproducible, as in other areas of science. The mechanism of the process (or processes) by which a nuclear activity results from a chemical activity will probably be identified in less than a year, once the importance of that topic is recognized agencies supporting research.

Below I will show messages (or extracts from messages) about CR-39 detection that I posted on the restricted Internet list for CMNS researchers since the SPAWAR discovery was first presented at the Navy Science and Technology conference in Washington, D.C. on August 2. I really believe that something very significant is going to happen in the controversial CMNS field very soon; may be as soon as two or three months.

Message 1 (posted on 11/14/06)

Last year i had a chance of examining the CR-39 that had a very low background, typically, 2 to 5 tracks per cm^2, The thickness was 2 mm, which is very convenient for microscopic examination. You focus on the side facing you and what id on the other side is not visible at all. People with more experience, especially Lipson, Roussetski and Orin, will probably have something to say about this. I do not recall the Japanese vender; ask Jiro Kasagi <kasagi@lns.tohoku.ac.jp>. Perhaps he will post this information, and the current price on the list.

To count tracks I recommend the magnification 40 (x4 objective and x10 eyepiece). To examine individual tracks magnification 100 will probably be sufficient.
(x10 objective with the same eyepiece). In principle, any traditional microscope should be OK. But I prefer a microscope equipped with a digital camera connected to a computer. That is how Orin works. This offers several obvious advantages. One of them is that counting tracks on a printed picture s more accurate, especially when track density is high (you circle tracks after they are counted, to avoid double-counting). For extremely low counting rates magnification 20 would probably be more convenient -- each picture covers four times larger area.

Message 2 (posted on 11/14/06)
Here is how I just replied to a private message. The reply might be useful to other beginners; that is why I am posting it here. Diameters 10 to 15 microns are good enough for easy counting of tracks. It is often frustrating to wait much longer. Typical track diameters depend on the etching time, as shown below

1) Etching at 65 C
==========
3 hrs 5 microns
5 hrs 10 microns
10 hrs 22 microns
15 hrs 35 microns The CR-39 chip become translucent (foggy), but that does not interfere with counting large tracks

2) Etching at 70 C
==========
3 hrs15 microns
5 hrs 25 microns
10 hrs 37 microns The CR-39 chip become translucent (foggy), but that does not interfere with counting large tracks
15 hrs 45 microns Even more foggy, but tracks are clearly identifiable. Did someone looked at them through a good magnifying glass? I didn't.

I suspect that some tracks might be etched away when etching is too long. Keep in mind that my measurements of diameters were not very accurate. But that was good enough for my purpose.

Message 3 (posted on 11/14/06)
In a private message someone pointed to a paper of Frenje et al. in the Review of Scientific Instruments -- July 2002 -- Volume 73, Issue 7, pp. 2597-2605. To get the article go to Google and type this into the search box:

CR-39 Frenje "Absolute measurements of neutron yields from DD"

A short description of the track formation process in CR-39 (in section IIA) is probably sufficient for the intelligent use of detectors. For a much more detailed description see the long paper of Nikezic and Yu, to which George Miley referred two days ago. The main purpose of the paper, by Frenje et al., is to describe how CR-39 are used to detect neutrons. As mentioned by Krivit, CR-39 are widely used to detect neutrons, when yields are large, in the range of 10^6 to 10^13. What is the difference between detection of alpha particles (or protons) and detection of neutrons? Any alpha particle intercepted by the CR-39, will create a track, provided the incidence angle is not too large. For neutrons, on the other hand, the probability of forming a track is usually much smaller than unity. To get the general 2002 review of track detectors by Nikozic and Yu, go to Google and type this into the search box:

Nikozic "Formation and growth of tracks"

Message 4 (posted on 11/15/06)
. . . Consider a 222Rn atom in air; it emits an alpha particle and the recoiling nucleus, 218Po, becomes a positive ion. Yes, outer electrons are often lost when an atom is pushed suddenly. The 218Po ion, or an ion of 214Pb, or an ion of 214Bi, etc. slowly drifts toward the electrically-charged screen. That is why dust collected from a TV screen (on a tissue) contains radioactive atoms. This can easily be checked with a simple Geiger counter. About ten years ago I convinced myself that the measured decrease in activity was consistent with the above explanation. The motivation for the experiment was a message posted on a discussion list for physics teachers. The author advised us to use TV screens as extremely inexpensive radioactive sources for classroom demonstrations.

But this is not a list for teachers. Why do I think that users of CR-39 should be aware of what I write here? Because it is very easy to charge a CR-39 chip electrostatically, most likely when the protective plastic is peeled off. An electrically charged CR-39 chip, if left in air for a long time, will have more tracks than a similar chip left in distilled water, for the same time. I checked this last year because I was aware of the TV screen effect. Fortunately static charges can easily be removed, for example by touching CR-39 surfaces with wet finger. Keep this in mind while looking for CMNS particles.

Message 5 (posted on 11/16/06)
In New Energy Times Steven also reported: "During the plating process, the cathode is in contact with a CR-39 detector in the cell to which the scientists had applied an external electric or magnetic field. After the experiments had completed their runs of eight to 11 days, Mosier-Boss and Szpak saw dense, cloudy areas on the portions of the detector near the cathode.

'The fact that the cloudy areas are observed where the detector was in close proximity to the cathode suggests that the cathode caused the cloudiness,' Mosier-Boss said. As a control, Mosier-Boss also exposed CR-39 detectors to electrolysis in a lithium solution without palladium in it. The result: only a sprinkling of tracks, randomly distributed

and so few in number that they could be accounted for by background radiation. She also immersed the detectors in the usual solution of palladium chloride and lithium chloride in deuterium but without applying the external electric current. The outcome was the same: no unusual shower of tracks from high-energy particles."

An easy way to produce a cloudy area on a CR-39 is to expose it to a source of alpha particles. A small 241Am source I used was form an old radiation-type smock detector (a new one costs about $10, for example, in Home Depot or Radio Shack). Exposing it to CR-39 -- with about 5 mm of air between the surfaces -- produced many well separated tracks. A ten times longer exposure produced proportionally more tracks, with frequent overlapping. Much longer exposures produced cloudy surfaces (after etching) visible to naked eye. I do not recall seeing cloudiness before etching. But it would not surprise me to see it after much longer exposures.

My suggestion is to expose a CR-39 chip to an alpha source for an hour or two. Would it become cloudy? Would it resemble the chip removed from the co-deposition cell after 11 days? Perhaps cloudiness, after 11 days of exposure, was an indication of many "giant showers" mentioned by John Fisher. But such test should be performed far away from the room in which the electrolysis experiments are performed. (One advantage of a smock detector source, over a piece of depleted uranium, [or over a welding electrode containing thorium], is that Americium is most likely coated by a very thin layer of something, to prevent contamination of air etc.) By the way, 241Am is also a source of 59 keV X-rays.

Message 6 (posted on 11/19/06)
. . . My experience was that only rarely (up to several % of cases -- when 241Am tracks were examined) did mechanical defects look like nuclear tracks. Most cases can be definitely resolved by refocusing in depth. When I worked with Orin, one year ago, he suggested uncertain tracks be ignored. In particular we ignored cases in which more than four (often more that ten) adjacent pits were on straight segments. We believed that these track-looking defects were due to mechanical scratches. I do not know how discrimination between tracks and non-tracks is handled by counting software. But visual examination is highly reliable, after some experience, when one sees more that ten randomly distributed tracks, (or clusters of tracks) per view.

By the way, Oriani's CR-39 chips were often precounted. Such time-consuming approach is justified only when background track are nearly as frequent as tracks attributed to CMNS reactions. That seems not be the case in the PamStan effect. (Precounting involves two etchings, First a chip is etched before being used in an experiment and background tracks are counted. Then it is etched again, after the experiment. Suppose the difference is 25-7=18. Then no statistical error is associated with 7. Measuring background with another chip is not as reliable as measuring it with the same chip. One can go one step further -- old tracks can be recognized by their relative locations, and by larger diameters. Fortunately, all this is not necessary when background corrections are small.)

Message 7 (posted on 11/27/06)
. . . I started to suspect that static charges on CR-39 surfaces (that could possibly be created by removing the protecting plastic) attracted positive alpha-radioactive ions. Such ions are always present in air. I already mentioned that, in most basements, dust removed from a TV screen is alpha radioactive. This can be checked by using a Geiger counter with a sufficiently thin window. Leave the TV on for a week or two and then remove as much dust as you can with a small piece of wet paper towel. I shared my suspicion with Orin and he said he will make sure charges are removed from CR-39 surfaces. Did this eliminate the effect? I do not know. Most recently Orin was studying cathodes after the electrolysis. CR-39 chips were applied to surfaces that were wet during the electrolysis, as described here in one of his recent messages. His results are shown in unit #314 at my CMNS website.

On Nov 30, 2006, at 12:58 PM, Scott Little wrote:
I"n the recent "Extraordinary Evidence" article in New Energy Times

http://www.newenergytimes.com/news/2006/NET19.htm#ee

There is a photo entitled, "Ag wire/Pd/D in Magnetic Field" with a caption below the photo that reads, "Dr. Gary Phillips: "They show a number of double tracks which you would see from a reaction that emits two particles of similar mass and energy."

The photo does show an abnormal incidence of double tracks...i.e. more than you'd expect from simple coincident landings of individual particles. But my limited understanding of nuclear physics suggests that two-particle reactions would normally send the two particles off in opposite directions. ..to conserve momentum.

Is there such a thing as a nuclear reaction that emits two particles in the
same direction?"

That could be a troublesome signature. I am thinking about tiny grains of uranium or radium codeposited on the electrode. The best way to check for this would be run the electrolysis for much longer than ten days. Suppose the percentage of doubles increases significantly, or triples start to appear. In that case one would have a proof of contamination. It did not occur for me that this could be the second independent test showing that contamination is not responsible for observed tracks. Steven already reported the first convincing test -- track formation stops when the external field is turned off. But, having a second test would be desirable, in the present situation.
P.S.
On the other hand, one can say doubles and triples do not necessarily prove that contamination is present; they prove that NAE is not uniformly distributed over the surface

Message 9 (posted on 11/30/06)
On Nov 30, 2006, at 6:22 PM, Scott Little wrote:

I'm wondering what to expect from CR-39 as an alpha detector. Will every alpha that hits normal* to the surface of the detector make a track?

Yes, and this track will be round. There is a critical incidence angle above which tracks would be so shallow that etching would destroy them. Roussetski and Lipson reported it. Perhaps one of them will reply to this message. My rule of thumb is that a CR-39 chip, located on top of cathode, detects about 25% of all particles as tracks. But that is only a quick estimate.

If not, what is the mechanism for an alpha striking normal to the surface and not making a track? Backscattering from near-surface nuclei seems possible in principle
but wouldn't the cross-section for that be very small?

I expect it to be extremely small. Rutherford scattering formula is highly reliable at at low energies. My guess that no more than one out billion alpha particles will be scattered into the backward hemisphere. Perhaps someone will theoretically confirm this intuitive guess

Is there any other mechanism besides backscattering that will cause an alpha particle NOT to make a track in CR-39?
*Low angle incidence alphas will certainly make nascent tracks but the track will be completely etched off during the etching process so you see nothing.

P.S.
Assuming that NAE is distributed uniformly over the 1 cm^2 of the cathode (below a CR-39 chip, also 1 cm^2), and assuming that N tracks are recorded, what is the probability of finding two tracks very close to each other? The answer depends on two factors: the total number of tracks, N, and the definition of the "very close." I expect the issue raised by Scott to be noticed by referees. That is why it should be
addressed. Here is my rather trivial contribution. It is based on a Monte Carlo program I wrote today. I am assuming that a given number of

tracks, for example, N=10000, are recorded at randomly selected points on the 1 cm^2 of the CR-39. That fixes the track density. By changing N, I can simulate any density I want. The program compares location of each point with locations of all other points. If the distance between two points turns out to be smaller than d then my counter of coincidences is incremented by one. Any value of d can be imposed. As expected, for a chosen track density, the percentage of coincidences increases with d.

Diameters of tracks are probably 10 microns. With this in mind, my first choice was d=20 microns, for N=1000. Results collected during the debugging are shown below. I will run the program for N=1000, for d=20, several more times. This will give me the mean percentage and the standard deviation.

N=1000 tracks, d=20 microns; Ncoinc=5 (this is only 0.5%)
N=1000 tracks, d=50 microns; Ncoinc=35
N=1000 tracks, d=80 microns; Ncoinc=104
N=2000 tracks, d=80 microns; Ncoinc=446

For very large N every track will have a close neighbor.
P.S.
In running the first case 30 times, the mean turned out to be 6.5 coincidences; standard deviation 2.0 coincidences. Each run, for N=1000, takes only about 30 seconds on my old Mac. I would be happy to run the program with other N and d, if needed. the listing of the program is shown below; the code is in True Basic, but it should easily be translated into another computer language. Exclamation sign are beginnings of comments (up to the end of the line). I am dividing by 2, in the last print statement because each coincidence was counted twice in my primitive code.

Message 10 (posted on 12/1/06)
Scott Little wrote asked: “I'm wondering what to expect from CR-39 as an alpha detector. Will every alpha that hits normal* to the surface of the detector make a track?” I can now be more specific about the CR-39 efficiency.

According to a long review paper of Nikezic and Yu [Materials Science and Engineering R 46 (2004) 51–123] the critical angle depends on the energy of alpha particles. It decreases from about 60 degrees for the 6 MeV alpha particles to 45 degrees for the 10 MeV particles. This refers to etching for 6 hrs. Also note that the angles are between the particle's trajectory and the CR-39 surface.

How does the 60 degrees compare with my 25% rule of thumb? Their 60 degrees translates into the incidence angle of 30 degrees (with respect to the normal, as in optics). The solid angle corresponding to an incidence angle A is 2*Pi*(1-cosA). It is always a fraction of the total solid angle, 4*Pi. For A=45 the fraction is close to 0.15, or 15%. I expect this fraction to double when etching time is reduced to 3 hours. Note that all tracks would disappear for really very long etching. That would be 0% efficiency (a lot of nuclear particles but no tracks at all). The efficiency for protons should be much better than for alpha particles. Why? Because their latent tracks are longer than those of alpha particles of the same energy. My guess is that the efficiency, for 10 MeV protons, will be nearly ideal. i.e. 50%. Why am I guessing? Because I trust my intuition based on knowledge of ranges of charged particles in matter. The actual answer, after spending many hours, would nearly certainly be higher than 40%. To be more accurate I would have to perform calculations based on rates of etching, etc. Or I would have to look for references in published papers. This is also a lot of work, in such cases.

I recommend etching for 3 hrs. It has three advantages: (a) efficiency is higher, (b) tracks are smaller (but still clearly visible and recognizable), and (c) time is saved. Note that two nearby tracks might overlap after 6 hrs of etching but not after 3 hrs of etching. Orin drills tiny holes in CR-39 chips and suspends the chips into the etching solution, with nickel wires. My approach was different; I just dropped the chip into the etching solution which was constantly stirred with a rotating magnet. Stirring is important when the beaker is sitting on a thermostat-controlled hot plate. Small chips are never at the bottom. Without stirring chips would stay at the bottom and their temperature could be unacceptably high (overetching).

Low magnification, such as 4*10 (objective 4 and the rest 10) is desirable when tracks are rare. In fact, I would prefer 2*10 when densities are below ~100 tracks per square centimeter. But low magnifications make visual counting impossible when track densities are very high, which, I suspect, was the case in SPAWAR experiments. At the extreme, when tracks are too numerous, with frequent overlapping (for example, when track densities exceed ~100000/cm^2, instead of ~10/cm^2 background) one might use traditional optical densitometry. It would be simply a matter of comparing chips exposed to NAE with chips exposed to known numbers of aloha particles from a calibrated source. Let us hope that future experimental data will force us to abandon counting of tracks in favor of densitometry. ;-)
P.S.
The 2004 review of solid track detectors, by Nikezic and Yu, that was mentioned above can be downloaded from my website as:

Message 11 (posted on 12/2/06)
On Dec 1, 2006, at 7:04 PM, Michel Jullian wrote:

. . . Thinking back to my proposal of letting the alphas escape through the cell bottom so they can be detected outside, I recall you doubted that a sufficiently alpha-transparent material could stand the ~5 cm water column. And then I remembered your own proposal of coating the CR-39 detector with a few microns of Ni (~9 g/cm3), wouldn't a 10 microns "plastic wrap" for household use (LDPE, 0.9g/cm3 i.e. 10 times less dense than Ni), which definitely could stand the water column, be just as alpha-transparent as a 1 micron Ni layer? Or isn't density the only factor to take into account?

That seems to be a good solution. I am assuming you are suggesting a thin metallic coating on the plastic wrap (on the wet side) to be the cathode. That is better than wires you first suggested. The path seems to be open to use a Si detector after SPAWAR results are confirmed by people involved in the Galileo project initiated by Krivit. When will we know about the results? It is a matter of following a protocol already tested by SPAWAR people. I do not expect any problems with CR-39 detectors. But everything should be tested and this takes time.

Let me show range-energy relations in several materials. That information would probably be useful to those who are planing to implement the idea. R is the range in mg/cm^2. Illustrations on how to use range-energy information will be shown below.

10 MeV alphas in gold: R=45.5
8 MeV alphas in gold: R=33.4
6 MeV alphas in gold: R=22.8
5 MeV alphas in gold: R=18.0
4 MeV alphas in gold: R=13.6
3 MeV alphas in gold: R=9.6
2 MeV alphas in gold: R=6.1
1 MeV alphas in gold: R=3.2

10 MeV alpha in nickel: R=22.6
8 MeV alphas in nickel: R=16.3
6 MeV alphas in nickel: R=10.9
5 MeV alphas in nickel: R=8.5
4 MeV alphas in nickel: R=6.4
3 MeV alphas in nickel: R=4.5
2 MeV alphas in nickel: R=2.9
1 MeV alphas in nickel: R=1.6

10 MeV alphas in aluminum: R=16.5
8 MeV alphas in aluminum: R=11.6
6 MeV alphas in aluminum: R=7.5
5 MeV alphas in aluminum: R=5.8
4 MeV alphas in aluminum: R=4.2
3 MeV alphas in aluminum: R=2.9
2 MeV alphas in aluminum: R=1.8
1 MeV alphas in aluminum: R=1.0

10 MeV alphas in carbon: R=12.4
8 MeV alphas in carbon: R=5.6
6 MeV alphas in carbon: R=5.4
5 MeV alphas in carbon: R=4.1
4 MeV alphas in carbon: R=2.9
3 MeV alphas in carbon: R=1.9
2 MeV alphas in carbon: R=1.2
1 MeV alphas in carbon: R=0.6

10 MeV alphas in hydrogen: R=4.19
8 MeV alphas in hydrogen: R=2.81
6 MeV alphas in hydrogen: R=1.70
5 MeV alphas in hydrogen: R=1.24
4 MeV alphas in hydrogen: R=0.85
3 MeV alphas in hydrogen: R=0.53
2 MeV alphas in hydrogen: R=0.28
1 MeV alphas in hydrogen: R=0.11

In planning for an experiment it would be sufficient to use carbon as a representative for a plastic material (unless very accurate calculations are needed)..

Plot the R=f(E) curve and use the smooth curve to solve a problem. Here are two illustrations. How much energy will an alpha particle of 6 MeV have after traversing the Al foil of 2.5 mg/cm^2. The range of 6 MeV alpha is 6.5 mg/cm^2; thus it will pass through the foil. Its energy will be reduced. Subtract 2.5 from 6.5. The result is 4 mg/cm^2. What energy does it correspond to on your plotted curve for aluminum? My curve shows it is close to 3.9 MeV. That is the is the energy of the the alpha particle after traversing the foil perpendicularly.

Another typical problem is to chose the foil thickness for a desired output energy. For example, I want the 6 MeV alpha particle to emerge with 3.5 MeV. How much nickel would I need? Use the R=f(E) curve for In. It shows that 3.5 MeV corresponds to R=5.3 mg/cm^2. What is the range of the 6 MeV alphas in In? It is 10.9 mg/cm^2. Thus the foil you need is 10.9-5.3 = 5.6 mg/cm^2. How to convert this mass per unit area into the thickness in cm? The density of In is 7.9 g/cm^3. Therefore 5.6 mg/cm^2 translates into 0.00071 cm; this is 7.1 microns.

Message 12 (posted on 12/2/06)
Responding to my request for permission to be quoted (that is a rule on the private CMNS list) and to what I added, Michel I wrote: "Indeed coating the cathode on the transparent window (by CVD?) might be better than loose wires, but keeping it in the shape of wires would be better than a uniform coating as it allows correlating track density with wire proximity as Pam noted"

Message 13 (posted on 12/2/06)
Changing from uniform coating (uniform wet cathode) from nonuniform coating (strips simulating wires) would be only one of many parameters to explore. For the time being I am assuming that the purpose of gold wires (inside the electrolyte) was to become NAE. In that case concentration of tracks near wires is natural. If I recall correctly, they also had a picture with silver wire. Let us wait for results that Steve Krivit will report at the termination of Galileo project. In that project the task is to replicate the SPAWAR protocol and to describe the results. That might lead to many interesting experiments, deviating from the working protocol, one parameter at a time or in different directions, according to expectations. Our theoreticians will finally have reliable experimental data for validating theories. It would not take too long before the mystery of NAE is solved. Will this end the the dark age of discrimination? Will CMNS will become normal science? Let us hope so.

I would appreciate if someone could send me ranges for alphas in one or two plastic materials, and for water. An electrolyte is mostly water.

318) Theories, Meta-theories, etc.

Ludwik Kowalski; 12/4/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

An interesting paper was attached to a message posted this morning on the restricted Internet list for CMNS researchers. The author believes that deuterium ions inside metals create surface cracks, typically 10 microns wide. That is not difficult to accept; photographs of cathodes that were used in CMNS experiments often show surface irregularities. What is difficult to accept is a claim that electric fields between the walls of cracks can be as high as 100 million volts per centimeter. The rationale for this claim was not explained. Was it a postulate -- something like "that would be sufficient to explain nuclear particles and X-rays "-- or was it a conclusion based on something that is known to be true? Acceleration of ions in strong local electric fields could indeed be responsible for emission of nuclear particles. If real, that would be a true "electrochemically induced nuclear effect."

If one million volts per centimeter of air (or H_2 or O_2 or water vapor) in a crack, is an ad hoc assumption then the idea belongs to the category of ideas mentioned recently by Mike McKubre. He referred to polyneutrons, whose existence was postulated by John Fisher, and to stable neutrons inside solids, postulated by Hideo Kozima. Such theories are worth developing, in anticipation of an era of reasonable reproducibility. Such logical structures should not be confused with structures that begin with what is known to be true. A theory that begins with an ad hoc assumption can be wrong on two accounts (assumption and logic); a theory that begins with what is already known can be wrong on one account only (logic).

The concept of NAE, introduced by Ed Storms, is not a theory, it is only a name given to what makes nuclear activities induced by chemical activities possible. The same is true for the idea of "poison" that was introduced by Peter Gluck this morning. He wrote: "The problem of reproducibility, more precisely the painful and disturbing lack of it, deserves a thorough discussion. And, it has to be the central and most urgent task of our thinking and experimental studies. . . . True, we have tens of theories that cannot be translated in practical instructions, lines of trying for the experimenters. . . . [My] explanation is that all the cathodes are inactivated by some poison or some other unknown factor, and the task is to discover or to annihilate this something, protecting the working surfaces, sites. This has happened naturally, by chance, in very few cases during CMNS's complex history.I am ready to discuss an experimental strategy based on this meta-theory. .....Therefore I consider unknown poisoning more logical than overwhelming complexity."

Peter was replying to a message in which failures to replicate were attributed to the overwhelming complexity of natural phenomena at the atomic level. Rather than dealing with many factor contributing to complexity he prefers to deal with one factor, an unknown poison. Like NAE, that poison is a mystery. I have a name for it; let us call it NIE. This stands for the Nuclear Inactive Environment. That is funny. NIE NAE covers the entire universe, by definition. And what does it mean in Polish? It means "NOT NAE." The term meta-theory probably means something to philosophers. Is it a theory of theories or is it a theory outside all other theories (like metaphysics is outside physics)? Go to Google and type -- what is metatheory -- into the search box: I got 225,000 hits.

After reading the above, Peter posted this message: "(a) I have been speaking and writing re poison as reproducibility killer in CMNS- for years. And I have told that the "usual suspects" are the well known impurities due to air pollution i.e. nitrogen oxides, H2S, SO2, CO, COS and VOC (volatile organic compounds)- plenty of them everywhere. Poisoning can be acute i.e fast as for the Pd cathodes or chronic - the most spectacular storyy being that of the Patterson system - the beads have lost their ability to generate excess heat- rather slowly. But once they were dead,

they remained so. Poisoning is, at least in part, reversible- laser irradiation can reactivate some sites on the cathode. Bacteria are are also plentiful; should they also be included in the list of poisons? Then Peter added: "(b) The best definition for a meta-theory is at < http://www.answers.com/topic/metatheory > " I clicked this link and the following definition popped up: metatheory is "a theory devised to analyze theoretical systems." That definition puts metatheories into the domain of philosophy. They are theories of theories, making sense of theories. They are not tools for making sense of experimental data.

Replying to Peter, Michel Jullian wrote: "Which makes me think, sorry if this has been discussed before, that the SPAWAR codeposition method could be used to bypass the cathode poisoning problem by regenerating the top cathode layer when needed: just pour some palladium salt into the electrolyte every time the effect seems to die, this will build a fresh palladium hydride layer on top of the dead one." That is an interesting observation. Peter's ad hok assumption about poisons will become testable, like other theories, after reproducible protocols are published. I do not think that he is offering a meta-theory. In replying to Michel he elaborated:

"The idea is good in principle, however unfortunately the liquid phase contains solved air, including the poisonous impurities. So the newly formed surfaces are poisoned at their birth, more or less (actually less, this is one of secrets of the superior results via codeposition. The same impurities are doing harm to chemical catalysts and it seems that our CMNS active sites are smaller and even more sensitive than the catalytic ones. In my 1992 paper -see lenr-canr.org I concluded that CF/CMNS is an extreme form of catalysis. Some polymerization processes are also very sensitive to impurities, e.g. 20 ppb (parts per billion sulfur) destroys a kind of acrylic polymer- you don't obtain a latex (milk like emulsion) but rather great beads. The solution of this problem is NOT to try to measure with great care and effort the impurity- a very difficult task; you add 0.5 grams copper salt to a 40 cubic meter vessel and this inactivates completely, kills the impurity. Probably in the case of CMNS a similar strategy could work:

1) the surface of the cathode has to be covered with a very thin, monomolecular layer of a substance permeable to hydrogen/deuterium but not to the impurities;

2) the liquid phase has to be cleaned, desaerated, some filters/chemical filters retaining them added to the cell .

You remember that Fleischmann and Pons have discovered that the boiling cells are working better than those at ambient temperature? Giving more excess heat? The complexity meta-theoiry does not explain this, but for the poisoning theory the effect is obvious- boiling cells contain less air, and less impurities, the cathodes are more active. Unfortunately, the poisoning metatheory is usually rejected ab ovo by our colleagues. I don't understand exactly why."

Experiments designed to test Peter's idea should be conducted after CMNS is transformed from protoscience to science. We are probably very close to this historic transformation now. Yes, I am assuming that the SPAWAR discovery is going to be confirmed in the TGP (the Galileo Project initiated by Steve Krivit)

The <http://yunus.hun.edu.tr/~saritan/cargo.htm> link was posted today on Phys-L, a list for physics teachers. It points to a piece written by Richard Faynman. In that piece, referring to a good theory, Faynman wrote:

"Details that could throw doubt on your interpretation must be given, if you know them. You must do the best you can - if you know anything at all wrong, or possibly wrong - to explain it. If you make a theory, for example, and advertise it, or put it out, then you must also put down all the facts that disagree with it, as well as those that agree with it. There is also a more subtle problem. When you have put a lot of ideas together to make an elaborate theory, you want to make sure, when explaining what it fits, that those things it fits are not just the things that gave you the idea for the theory; but that the finished theory makes something else come out right, in addition.

In summary, the idea is to give all of the information to help others to judge the value of your contribution; not just the information that leads to judgment in one particular direction or another." I think it is good advice. A theory must predict at least one unknown fact in order to be testable. Addressing another issue Feynman wrote: "

"I would like to add something that's not essential to the science, but something I kind of believe, which is that you

should not fool the layman when you're talking as a scientist. I am not trying to tell you what to do about cheating on your wife, or fooling your girlfriend, or something like that, when you're not trying to be a scientist, but just trying to be an ordinary human being. We'll leave those problems up to you and your rabbi. I'm talking about a specific, extra type of integrity that is not lying, but bending over backwards to show how you're maybe wrong, that you ought to have when acting as a scientist. And this is our responsibility as scientists, certainly to other scientists, and I think to laymen.

For example, I was a little surprised when I was talking to a friend who was going to go on the radio. He does work on cosmology and astronomy, and he wondered how he would explain what the applications of his work were. "Well," I said, "there aren't any." He said, "Yes, but then we won't get support for more research of this kind." I think that's kind of dishonest. If you're representing yourself as a scientist, then you should explain to the layman what you're doing - and if they don't support you under those circumstances, then that's their decision. "

And here is another wise observation, from the same source: "I was shocked to hear of an experiment being done at the big accelerator at the National Accelerator Laboratory, where a person used deuterium. In order to compare his heavy hydrogen results to what might happen with light hydrogen, he had to use data from someone else's experiment on light hydrogen, which was done on different apparatus. When asked why, he said it was because he couldn't get time on the program (because there's so little time and it's such expensive apparatus) to do the experiment with light hydrogen on this apparatus because there wouldn't be any new result. And so the men in charge of programs at NAL are so anxious for new results, in order to get more money to keep the thing going for public relations purposes, they are destroying - possibly - the value of the experiments themselves, which is the whole purpose of the thing. "

Appended on 2/3/07:

An interesting, but not recent, review of the cold fusion situation has been "advertised " by one of the subscribers to an Internet list for CMNS researchers. The title of the 1999 article was: "Whatever happened to cold fusion,. It was published in PhysicsWeb.

http://physicsweb.org/articles/world/12/3/8

The occasion was the 10th anniversary of Cold Fusion. The author, David Voss wrote that the main motivation was to generate unlimited amounts of energy. Some people, like Patterson and Case, did expect material rewards but I do not think that this applies to most CF researchers. The field is still very far away from practical applications; the main task is to convince ourselves that a chemical process can trigger a new nuclear process. Those who stubbornly continue to conduct CMNS experiments are most likely motivated by desire to discover, or to confirm, new phenomena. Applications and theories will develop naturally after scientific claims, such as transmutation of isotopes and excess heat, are finally recognized as valid. The person who dug the old article asked: "a number of criticisms are made of CF expts. How valid are they?" Here is how this was answered by an active CMNS researcher, Scott Little. First he quoted this paragraph:

"Sporadic reports have continued to trickle in from various small research efforts, but in each case the results have proved erratic or impossible for other groups to replicate. It appeared to be a classic case of what the Nobel chemist Irving Langmuir called "pathological science", in which the results are always near the limit of detectability and the proponents always have an ad hoc answer as to why."

Then he added: "In my experience and area of study, particularly for excess heat results, this is largely true. One would reasonably expect to see some increases in the amount of excess heat obtained from cold fusion experiments as the years go by. I believe the opposite is the case. People keep building better and better calorimeters and, in general, the magnitude of their excess heat results keep shrinking.

As to the ad hoc explanations, isn't that just what you would expect in a field where nobody really understands how the "reaction" works in the first place? Another criticism, not mentioned in the article, which I would level at CF expts is

their tendency to believe that any anomalous "positive" result in their experiments is a sign of nuclear reactions. For example, if a complex calorimetry experiment is underway and the instrument shows a small excess heat of, say, 50 milliwatts (out of 15 watts total input), I know that some CF expts would say something like, "Ahhh. now we're getting some excess heat". In my opinion, the reaction should be more like, "Hmmmm. ...50 milliwatts is only 0.33% relative of my input power. Is my calorimeter that precise? This could easily be the result of a systematic error... how can I check for that?"

The 20th anniversary of the 1989 announcement of Cold Fusion is not very far away. Will the field be recognized as truly scientific by the majority of mainstream scientists, and by scientific establishment? I think I will be in a much better position to answer this question by the end of this year. The ongoing investigations of the SPEWER discovery (emission of nuclear particles when an electrolytic cell is placed into a magnetic field) has been described in The New Energy Times. The answer will depend on the outcome of The Galileo Project, directed by Steven Krivit. Look for the upcoming issues of The New Energy Times, published every two months. That online magazine is already an important source of information about CMNS research.

The person who dug out the Voss' article wrote that transmutation experiments seem to be less vulnerable to criticism than the excess heat data. What follows is the reply from Scott Little.

"At Earthtech we have expended some effort on the transmutation claims. We were one of the few participants in the RIFEX experiment promoted several years ago by CETI (Patterson et al). You should read the report(s) I wrote about this work to get some idea of the difficulties in confirming transmutation claims.

http://www.earthtech.org/experiments/rifex/rifex.pdf

Executive summary: trace contaminants in the electrolyte could easily explain most of the elements claimed to be created in the cell.

And this report on the purported excess heat made by Patterson beads:

http://www.earthtech.org/experiments/rifex/rifexcal.pdf

Executive summary: No excess heat was observed. Our detection limit was about 0.1 watts in this experiment.

[You wrote that methods of generating excess heat at much higher rates might have been developed but the inventors prefer to be quiet about this.] Indeed. Do you think a substantial cash prize, say $1,000,000 US dollars, would get such people to reveal their discoveries? Of course, I wouldn't expect them to give up their discoveries for a relatively small amount of money like that but what if we just asked for a simple demonstration of the excess heat effect and awarded the prize to the first group to succeed?"

Referring to the suggestion that effective excess heat devices might exist but information about them is hidden, Michel Julian asked: "But for how long? This argument couldn't hold indefinitely, not for 18 years anyway." Then he added: "CF researchers could be (well, are) accused in earnest by honest skeptics (like we ourselves may be in other topics such as free energy, UFOs, your own mind-matter stuff, etc.), of being either frauds, or incompetent experimenters, or self deceived indefectible optimists, or face savers. In support of the last point: How could Mizuno's sudden disinterest for his 100W-in 130W-out GDPE experiments be explained logically, apart from 'I was wrong but I won't admit it' ?

It can't be denied that apart from a few rare exceptions we do not criticize/analyze/verify each other's work and claims as diligently as we should. This is IMHO what keeps the field in this state of suspended life. We need more people to take up Earthtech's generous offer of free expertise, and if they pass Scott's hawk's eye they can go and claim the Randi prize right away ;-)" Another researcher reminded the list that in some experiments (Swartz et al. and Dardik et al.) excess heat was large and exceeded the input energy by the factor of ten and more.

I promised not to post this report before the item shown below was published in The New Energy Times by Steven Krivit.

http://newenergytimes.com/news/2007/NET21.htm

I hope that experiments now in progress will bring more clarity into the SPAWAR effect discovered by Stanislaw Szpak et al. They have been studying several codeposition effects for more than ten years. But their use of CR-39 detectors is relatively recent.

319) A contribution to Galileo Project

Ludwik Kowalski; 2/25/2006
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction

As described in the unit #314, I volunteered to be part of the The Galileo Project (TGP) organized by Steven Krivit. Before reading beyond this introduction, please go to

http://newenergytimes.com/news/2006/NET19.htm

and click the link to item #7, entitled "Extraordinary Evidence." You also should read item #8; I do not want to repeat what has already been described on the above webpage. Read these two items carefully and then read what is below. This unit is about our attempt to replicate one of the recent SPAWAR experiments. The study was conducted together with Michael Stolarz, a physics major at Montclair State University, and with two colleagues -- Brian Scanlan and Simon Young. Michael will present a separate paper at the Sigma Xi student research conference. Richard Oriani, who lives in Minneapolis, was our adviser. It is important to emphasize that several papers about nuclear processes triggered by chemical processes in electrolytic cells have already been published by the SPAWAR team in professional journals (see references in 1). The experiment we attempted to replicate has also been published (6).

The heavy-water electrolyte we used was identical to that described in (1). The time table for the electrolysis (see below) was also very similar. We were able to replicate SPAWAR results that were presented, by Frank Gordon (2). But our interpretation of results is different from that offered by SPAWAR team. The diameters of dominant dark pits, on our CR-39 detector, were found to be too large to be attributed to to alpha particles, or to smaller nuclear projectiles.

Inserted on 3/3/07--> After finishing writing this unit, three days ago, I decided to make a presentation at the upcoming APS meeting. I wrote to the session chairman, Scott Chubb, that I have something important to share and would be happy to take place of someone who does not show up. He offered me a time slot and suggested that I write an abstract and distribute it at the conference. Here is my abstract"

Title: Nuclear or not nuclear? That is the question.
Authors: Ludwik Kowalski, Brian Scanlan and Simon Young.

Text: An experiment described by Frank Gordon, last summer (1), has been successfully replicated at Montclair State University. Copious pits were observed on the CR-39 chip that was in contact with the silver cathode wire in the magnetic field. No such pits were observed on the identical chip from the cell that was not in magnetic field. The two cells were in series with each other during the electrolysis. Diameters of large post-electrolysis pits have been compared with diameters of pits due to alpha particles from a radioactive source. On the basis of this analysis, and on the basis calibration curves reported by Roussetski et al. (2), we conclude that large pits on our CR-39 chip, from one experiment, cannot possibly be attributed to alpha particles, or to less massive nuclear projectiles.

2) Experimental Method

Two identical electrolytic cells were connected to power supply, as shown in Figure 1. The little boxes, at the upper left corner represent integrated circuits designed to maintain constant currents. To change the current we simply had to replace one box by another. The voltage of the power supply was sufficiently high (up to 50 V) to support this mode of operation. This inexpensive method of keeping the current constant was introduced to us by Dr. Winthrop Williams. The experiment would not be possible without his help in dealing with numerous practical problems.

- -

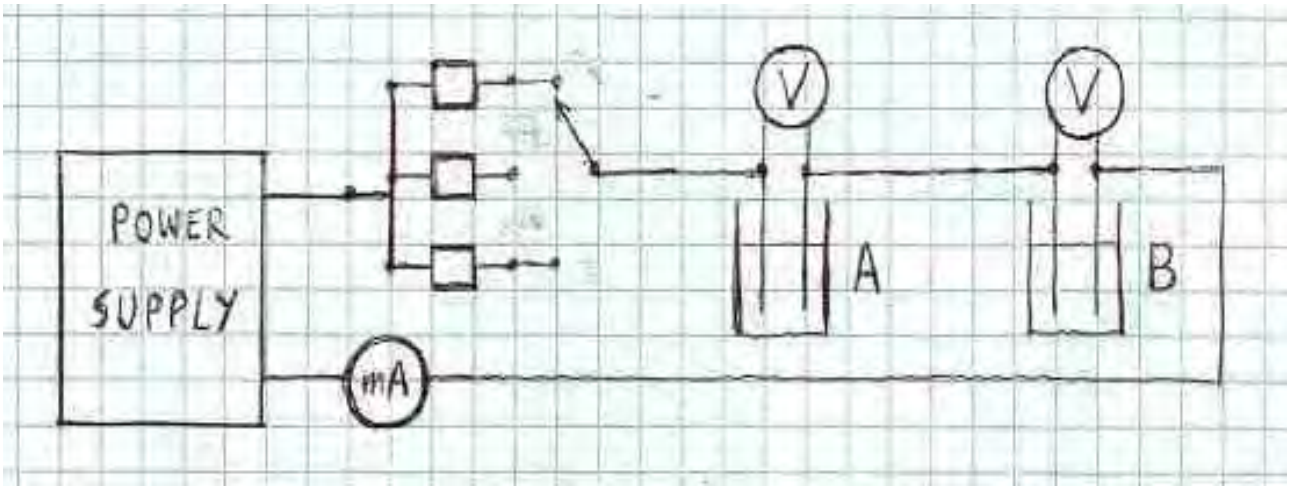

FIGURE 1
Our electric circuit contained nine integrated circuits (LM334 for lower currents and LM317T for higher currents). Only three of them are show in this diagram. A third cell was connected in series with A and B. It is not shown in this figure because it was part of another experiment (to be described in another unit).

- -

The two electrolytic cells, like those described in (1), were made from acrylic. Each has a wire-made platinum anode and a wire-made silver cathode, as shown in Figure 2. A CR-39 detector of nuclear particles was mechanically applied to the silver wire of each cell.

The only difference between the two cells was that one (A) was placed in a magnetic field crated by two very strong

neodymium magnets while the other (B) was far away from any source of magnetic field higher than terrestrial.

- -

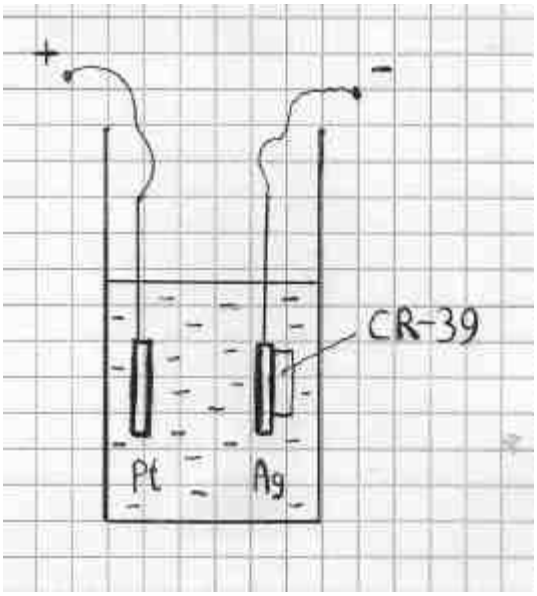

FIGURE 2
The distance between the anode and the cathode was approximately 15 mm. The height of the acrylic cell was 80 mm. The direction of the magnetic field lines (in cell A only) was from the anode toward the cathode. The magnetic field near the cathode was close to 0.2 T.

- -

The following time table was used during the electrolysis:

Current 0.11 mA, 24 hours
Current 0.21 mA, 24 hours
Current 0.56 mA, 12 days, till the electrolyte changed from brown to transparent
Current 1.0 mA, 24 hours
Current 5.0 mA, 24 hours
Current 10.1 mA, 24 hours
Current 26.9 mA, 24 hours
Current 55 mA, 24 hours
Current 127 mA, 24 hours

Heavy water had to be added to cells in order to compensate for what was lost due to evaporation and electrolysis. Increases in electric current were accompanied by increases of potentials across the cells. The potentials at the beginning of the electrolysis were 0.96 volts on each cell; the potentials at the end of the electrolysis were close to 8 volts. (At 1 mA they were close to 1.6 V and at 50 mA they were close to 5.5 V).

After the electrolysis the CR-39 chips were removed and visually examine. The opalescencent lines were seen on the chip from the cell A, more or less where the cathode wires were. No such lines were seen on the chip from the cell B. Another detail is worth mentioning. Before the electrolysis the cathodes in both cells were in contact with detectors along the entire length. After the electrolysis the cathode wire in cell B was still in contact with the detector along the entire length. But the cathode wire in the cell A bulged away from the detector, except near the edges. The chips ere etched together for 3 hours in the standard NaOH electrolyte (6.25 N and 68 C), rinsed and examined under the

microscope. The CR-39 chip removed form the cell A had several areas in which numerous pits were observed, as illustrated in Figure 3. In that respect our results are in very good agreement with results reported by the SPAWAR team. The CR-39 chip removed from the cell B had no areas covered with such pits. That observation is also consistent with what was reported by the SPAWAR team. We agree with them that the magnetic field plays a role in the formation of pits. The mechanism of this effect is not clear at this time.

- -

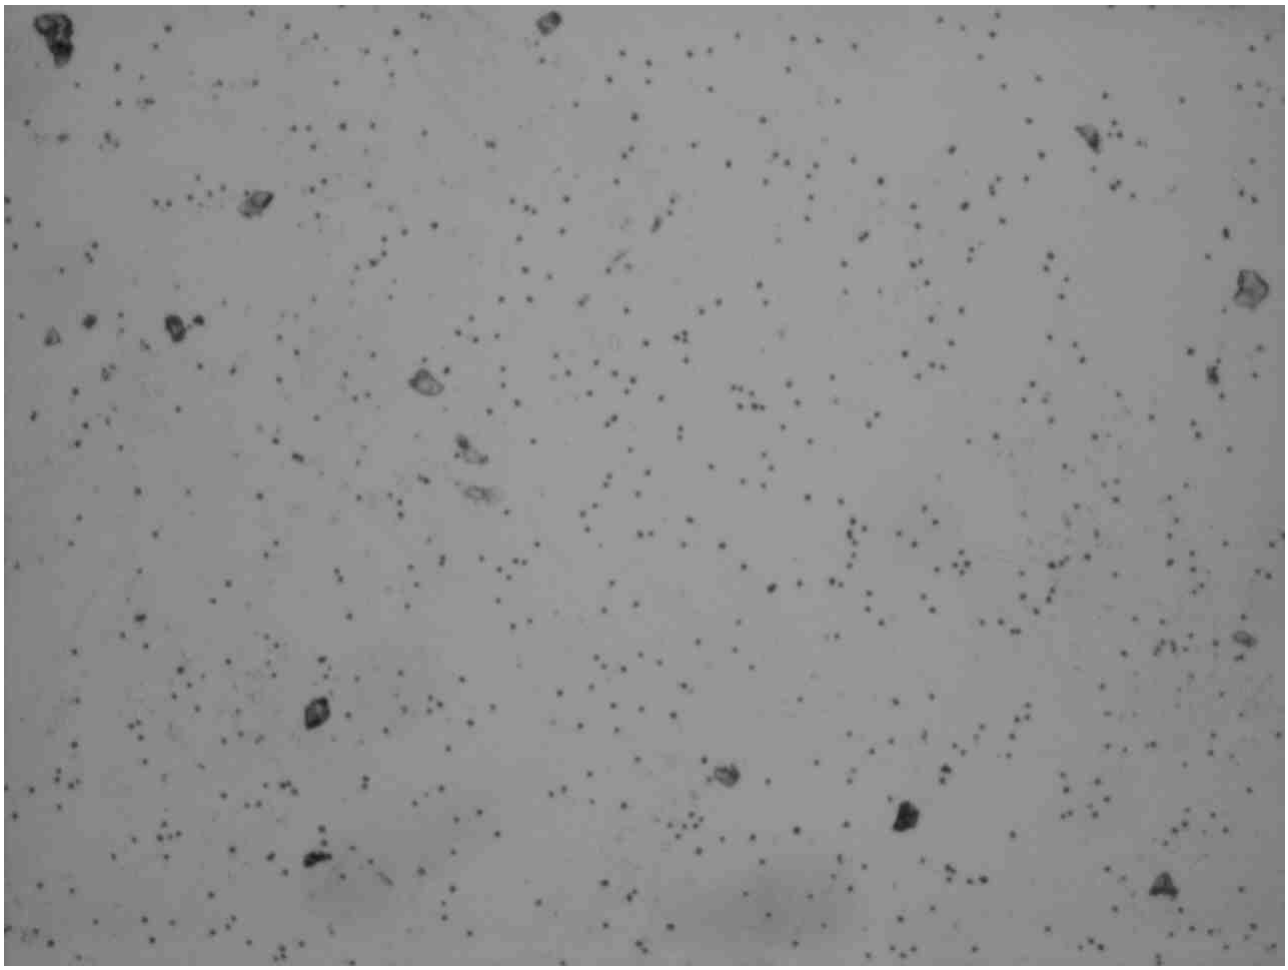

FIGURE 3A
Dot-like pits due to alpha particles from our Am-241 source at magnificatin 40. Surface defects or dust can also be seen. The area on this low magnification photo is 1.3 by 0.9 mm.

- -

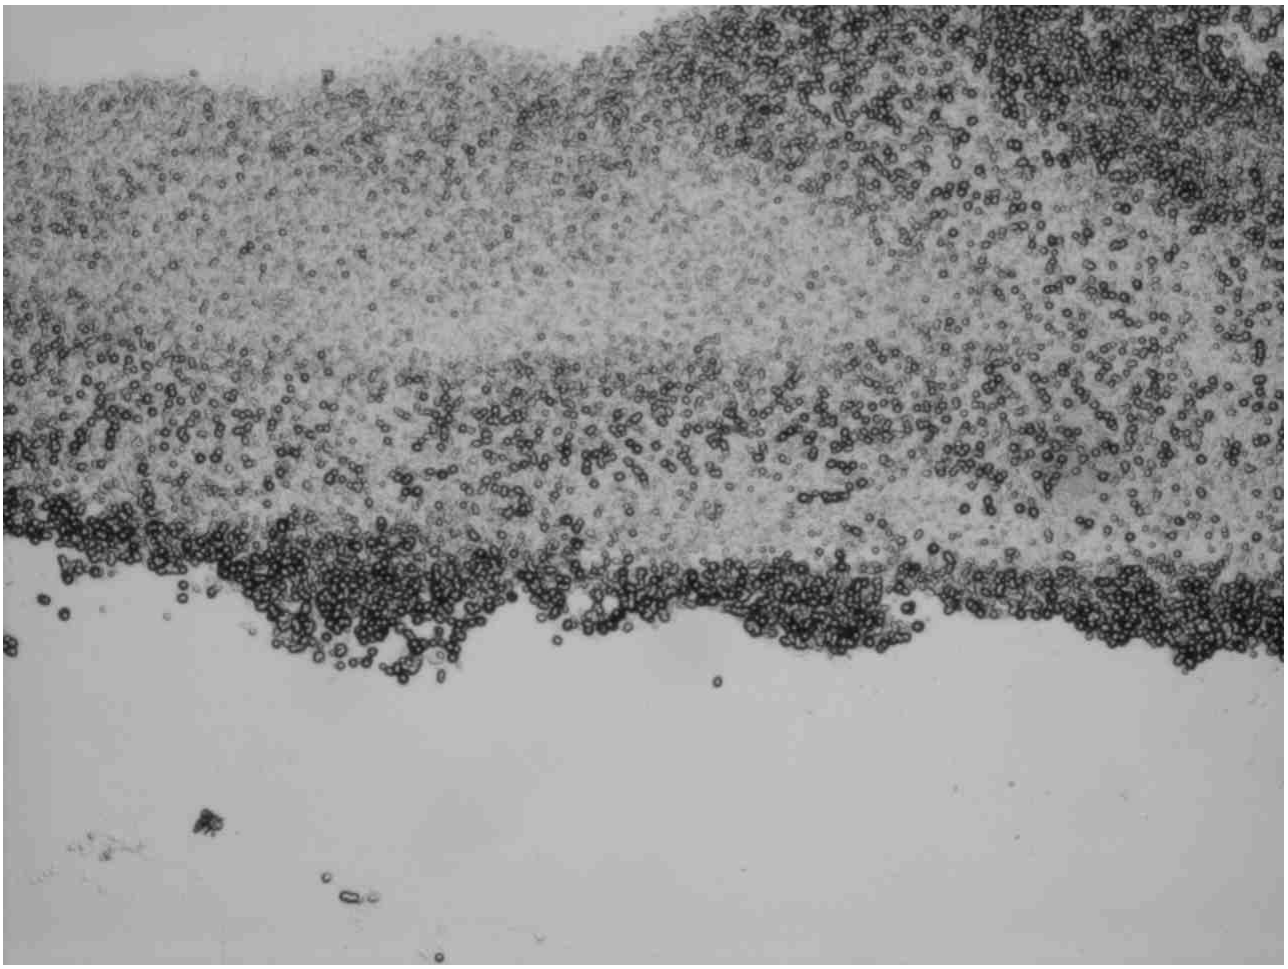

FIGURE 3B
Piits on the post-electrolysis chip from the cell A. Etching conditions and magnification were the same as for the photo on Figure 3A. The area on this low magnification photo is 1.3 by 0.9 mm. Next four figures should be used to compare diameters of post-electrolysis pits with diameters of pits due to alpha particles.

The claim of nuclear origin of pits, made by SPAWAR team, was based on comparisons of observed pits with pits that were known to be due to alpha particles. We followed the same approach. A fresh CR-39 chip was irradiated with alpha particles from an 241 Am source. It was etched together with the post-electrolysis chips. Figure 4 shows pits due to alpha particles, under the microscopic magnification of 200. Figure 5 shows pits on the chip removed from the cell A, under the same magnification. It is clear that the post-electrolysis pits are larger than pits due to alpha particles. The same conclusion can be reached by comparing pits in Figures 6 and 7. They were taken under the magnification of 400.

- -

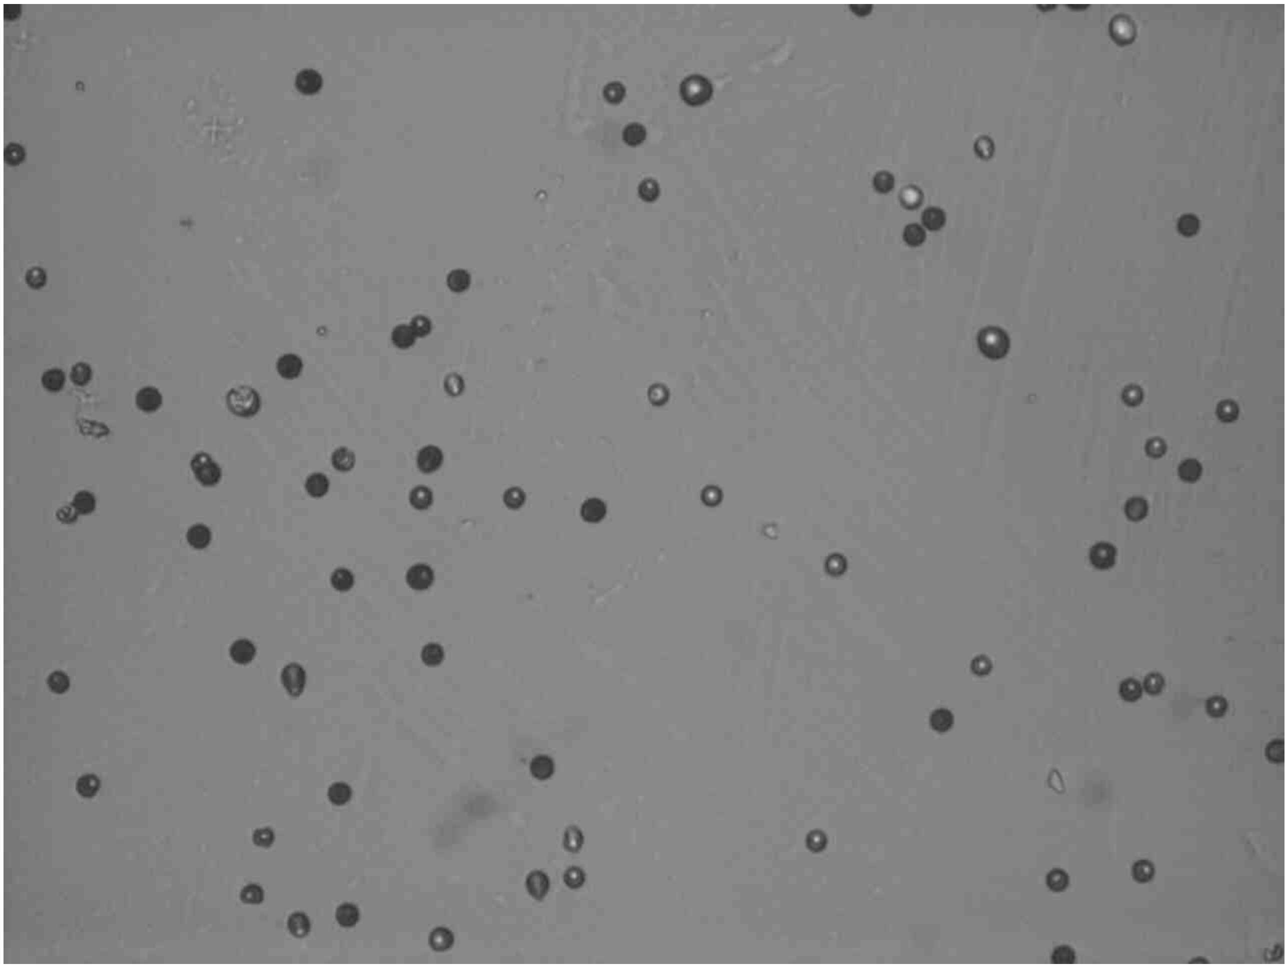

FIGURE 4
Pits which are known to be tracks of alpha particles, under magnification of 200

- -

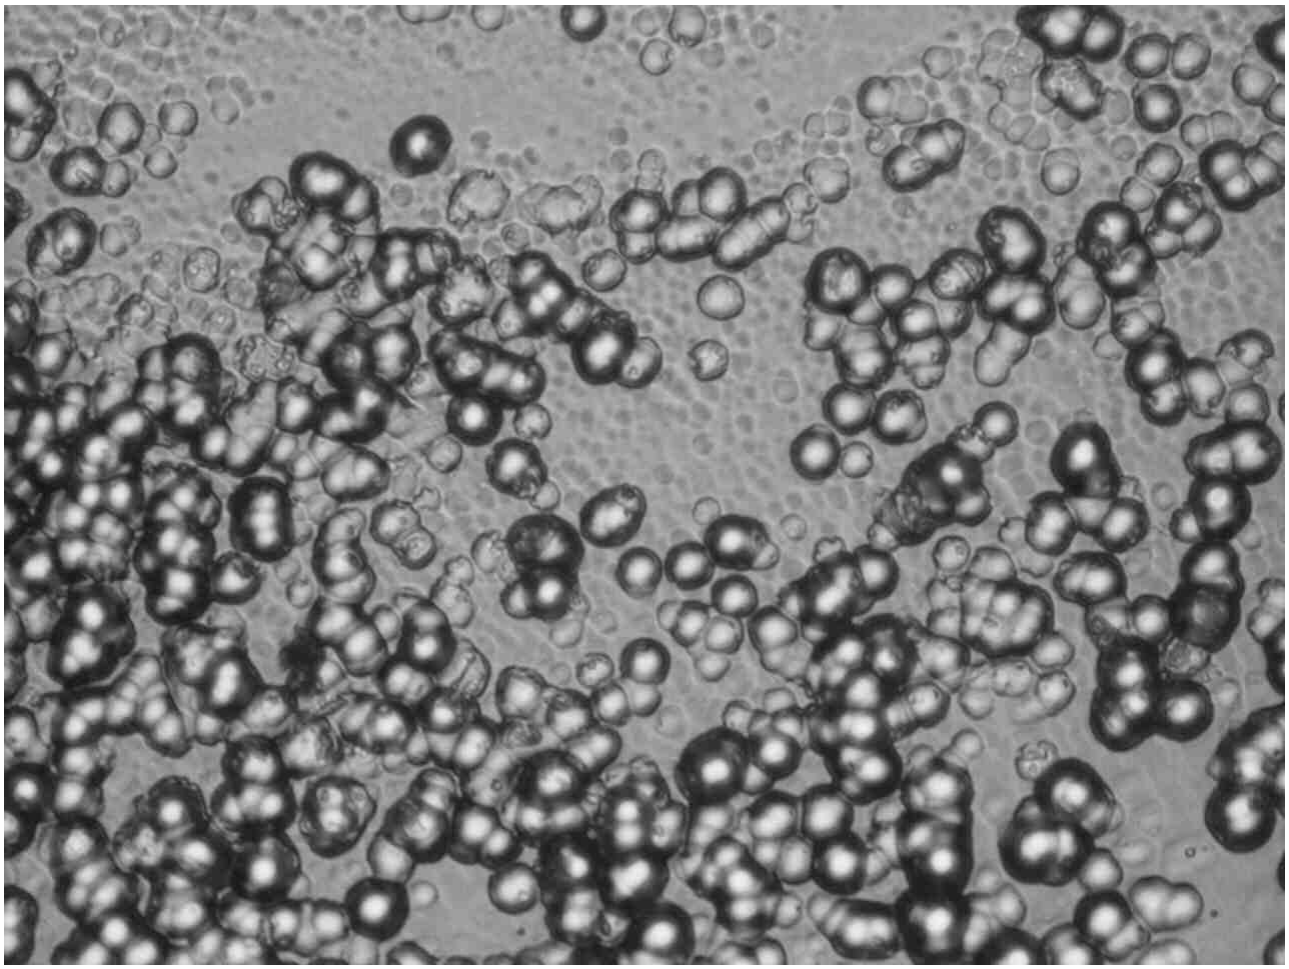

FIGURE 5
Pits on the post-electrolysis chip from the cell A. Etching conditions and magnification were the same as for the photo on Figure 4. Note that diameters of faint pits are about the same, and smaller, than diameters of dark pits in Figure 4. Large dark pits can't be due to alpha particles, or lighter projectiles.

- -

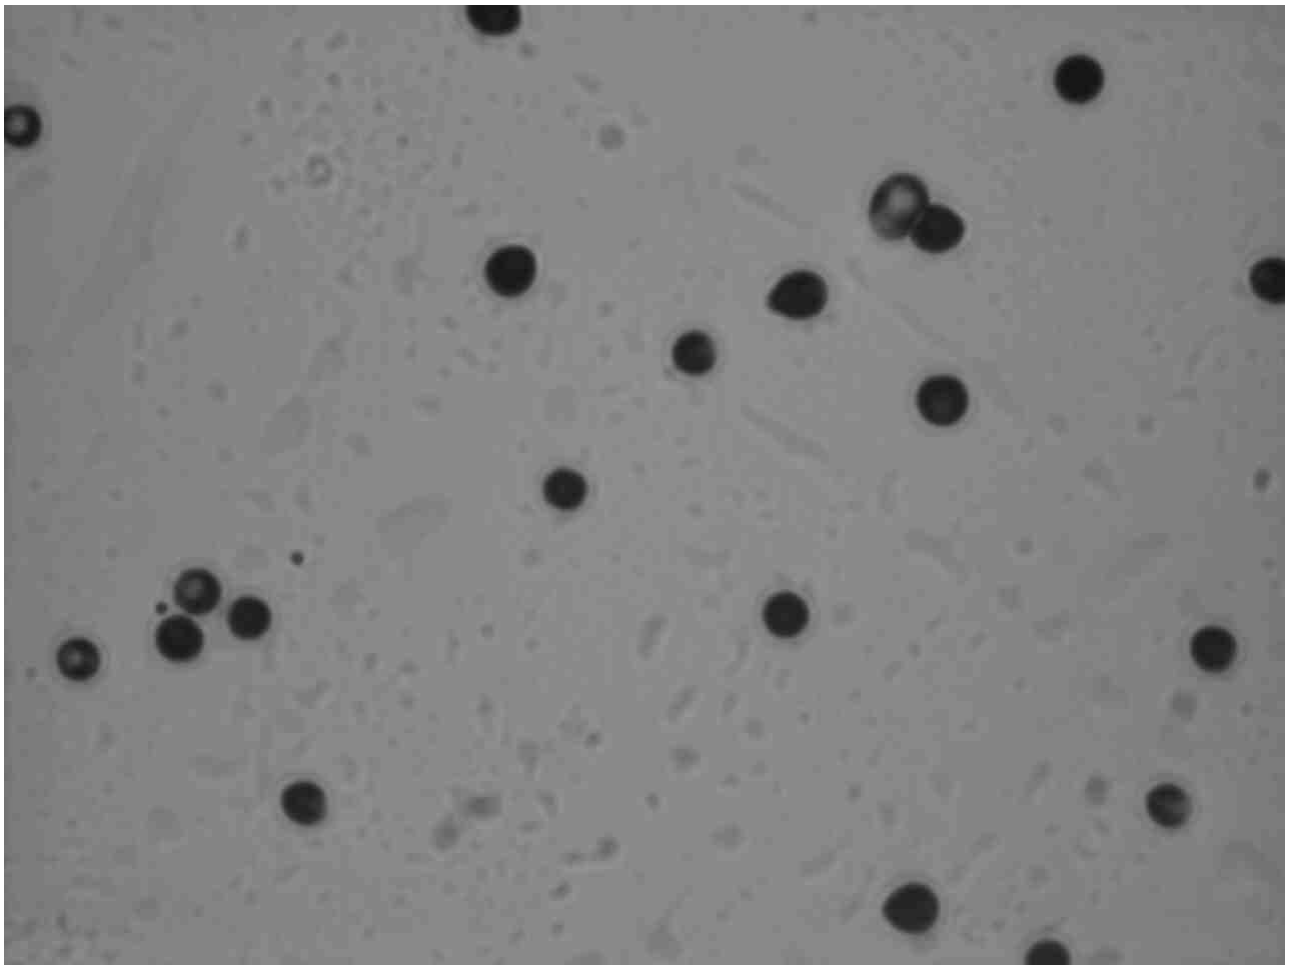

FIGURE 6
Pits which are known to be tracks of alpha particles, under magnification of 400

- -

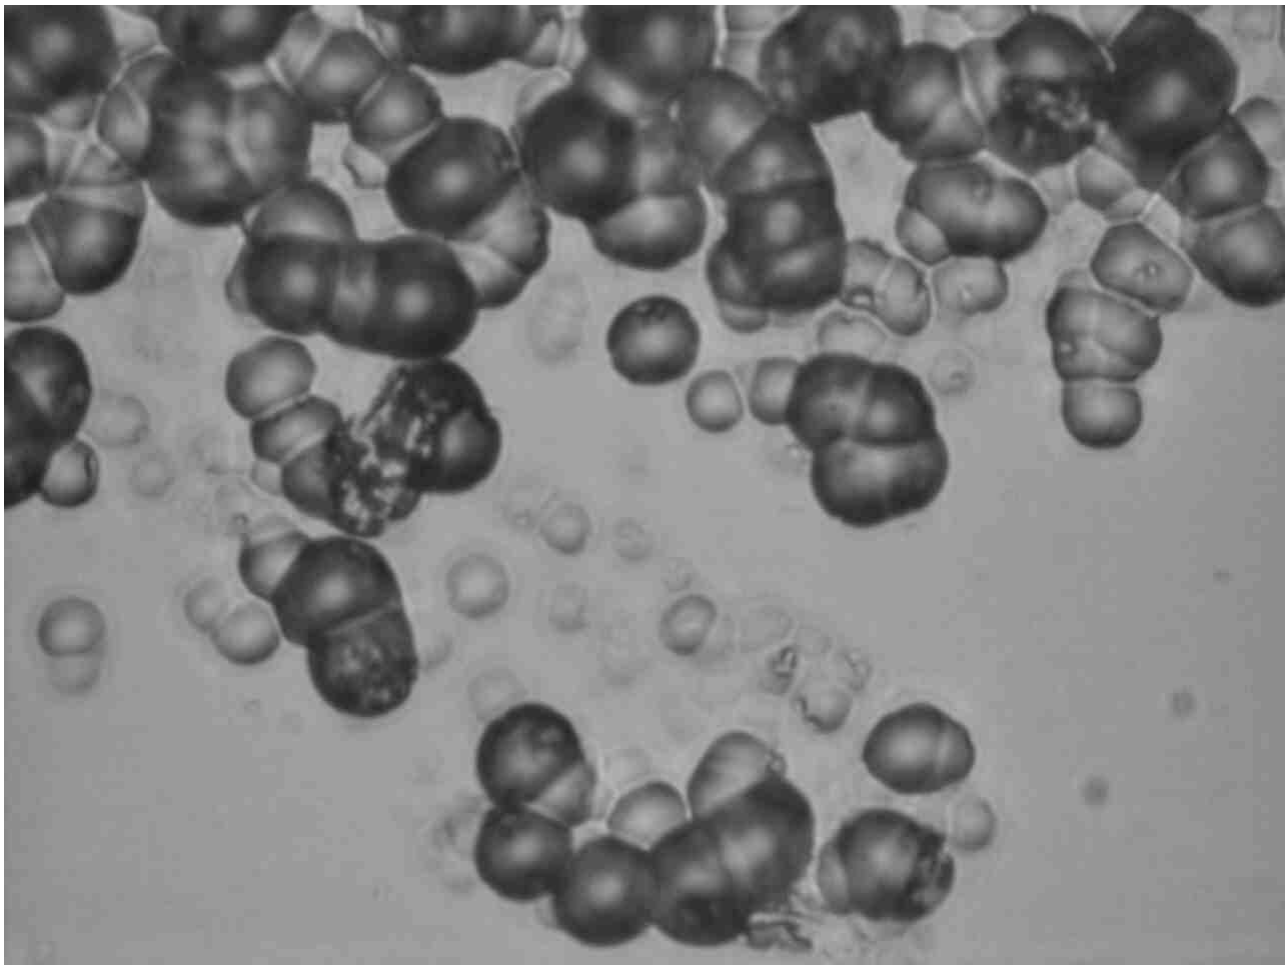

FIGURE 7
Pits on the post-electrolysis chip from the cell A. Etching conditions and magnification were the same as for the photo on Figure 6. Note that diameters of faint pits are about the same, and smaller, than diameters of dark pits in Figure 6. Large dark pits can't be due to alpha particles, or lighter projectiles.

- -

Use of CR-39 detectors in air is common (3). But their prolonged use in the electrolyte, initiated by SPAWAR team, is new. A separate test was necessary to verify that prolonged exposure of CR-39 to the electrolyte does not interfere with its ability to detect alpha particles. A small piece of CR-39 was cut from the chip A, after the electrolysis, and exposed to alpha particles. It was then etched and examined under the microscope. Presence of familiar tracks reassured us that ability to detect particles was not lost during the electrolysis. Furthermore, the thickness of the post-electrolysis chip A, after etching, was compared with the thickens of the blank chip that was etched with it. The difference, if any was, smaller than 5 microns. This additional test was necessary to rule out a possibility that exposure to the electrolyte changed the bulk etching speed.

Absence of pits on the post-electrolysis chip B was a strong indication that the pit-formation process was strongly influenced by the magnetic field. That fact reminded us Marie Curie's attempts to influence radioactivity by magnetic fields. These attempts, like those undertaken by other investigators, were not successful. Magnetic fields do influence some atomic processes but their ability to either slow down or to speed up emission of alpha particles (or protons) from atomic nuclei has never been demonstrated.

3) Discussion

Differences between ^{241}Am pits and pits found on the post-electrolysis chips are not limited to sizes (typical alpha

particles tracks are about 2.5 times smaller than typical post-electrolysis pits). Another difference becomes obvious when one tries to refocus the microscope under a larger magnification, such as 200 or 400. Isolated post-electrolysis pits seem to be more shallow than pits produced by alpha particles. Most post-electrolysis chips appear so close to each other that the individual boundaries are no longer identifiable. The areas covered by overlapping pits are whitish, as if they were affected by some kind of chemical corrosion.

Let us assume that individually identifiable post-electrolysis pits are due to nuclear particles, as claimed by the SPAWAR team (6), and not to a chemical, thermal or mechancal effect. What kind of particles can produce pits shown in Figure 3? To answer this question we will use results of measurements made by Roussetski et al. (4). These Russian scientists exposed CR-39 chips to protons and alpha particles of various energies. Then they etched the chips, measured the diameters and summarized the results in the form of a very useful graph. The smallest diameter (5 microns) was for protons of 3 MeV, the largest diameter (12 microns) was for alpha particles of 2 MeV. The etching in the NaOH (6N, 70 C) took 7 hours.

Our etching conditions were quite different, as specified in section 2. For that reason we decided to modify the original graph slightly, as shown in Figure 8. Our diameters are expressed in arbitrary units named prots. One prot, by definition, is the diameter due to 3 MeV protons, no matter how many microns it is under different etching conditions. The advantage of that representation is obvious; it decouples essential information (relative sizes of pits) from the laboratory-specific details about etching. The modified graph is likely to be valid, at least approximately, when etching conditions are not exactly the same as those used in (4).

- -

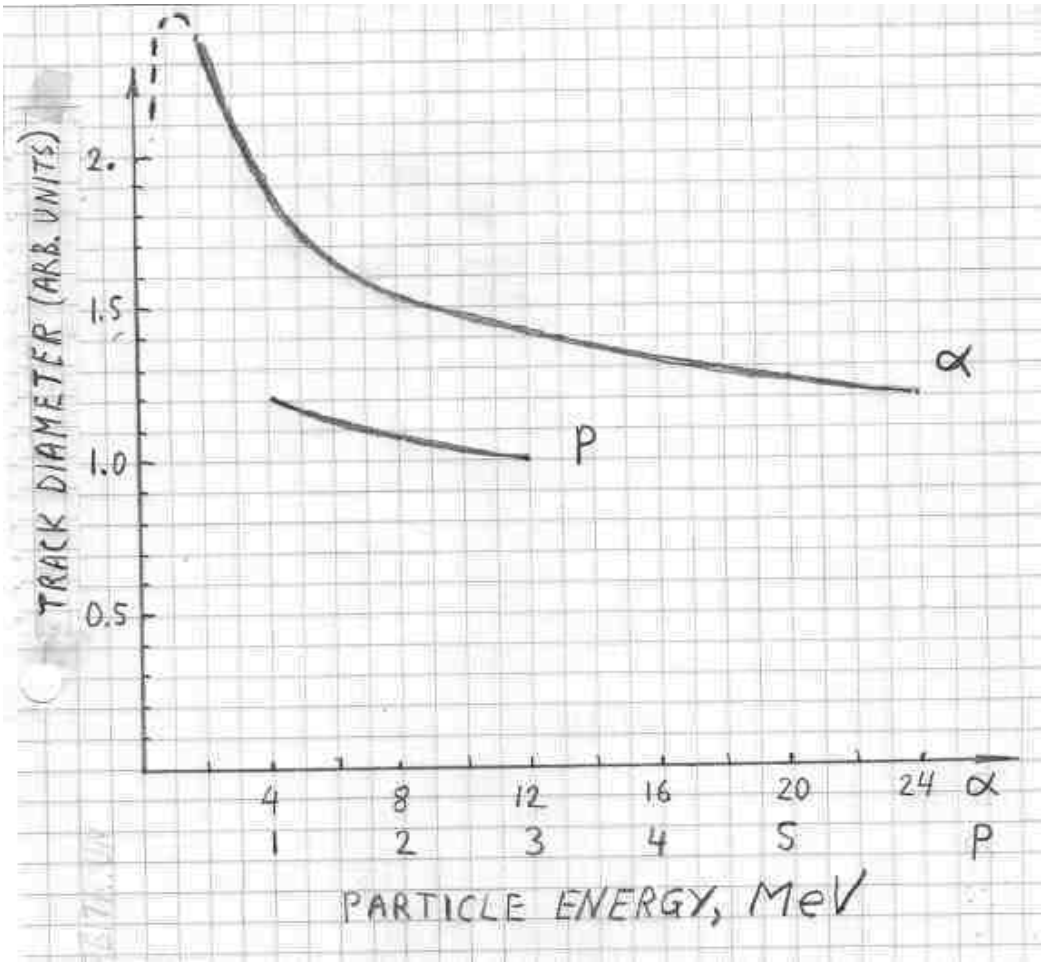

FIGURE 8
Relative diameters of tracks due to alpha particles and protons of various energies. The dashed line, at the upper left

corner, was added to indicate that alpha particles cannot possibly produce tracks larger than about 2.5 prots. This expectation is based on the well known fact that alpha particles at energies below 2 MeV tend to capture electrons when they slow down. The dE/dx values do not increase when E becomes sammler than about 2 MeV.

- -

According to Figure 8, the mean diameter of alpha particles from ^{241}Am (~ 5 MeV) is 1.7 prot. According to Figures 6 and 7, individually identifiable post-electrolysis diameters are about 2.5 times larger than those due to ^{241}Am. In other words, their average pit diameters are 1.7*2.5=4.5 prots This at once rules out a possibility that the post-electrolysis pits are due to protons or to neutrons; diameters of tracks due to these particles would be smaller than 1.5 ports. It also rules out a possibility that poste-electrolysis chips are due to alpha particles; diameters of these would be smaller than 2.5 prot. The only available avenue, for defending nuclear origin of post-electrolysis chips, it to assume that they are caused by nuclear projectiles that are much heavier than alpha particles. Fission fragments from a californium source, for example, were shown (5) to produce pits that were about 2.5 times larger than those due to alpha particles. But that does not mean that any large pit on the CR-39 surface is a track of a massive nuclear projectile. An additional evidence would be needed to defend such claim.

According to (6), "the density of tracks registered by a CR-39 detector was found to be of a magnitude that provides indisputable evidence of their nuclear origin." Our analysis of diameters of pits does not support this interpretation, unless only massive particles are responsible for the large pits shown in Figures 5 and 7. A more likely explanation is that post-electolysis pits are due to a non-nuclear process taking place near the cathode. This kind of interpretation is supported by presence of glossy regions on the chip from the cell A, visible before the chip was etched (see section 2). Prolonged exposures of CR-39 to alpha particles, undertaken to produce overlapping pits, did produce foggy (but not glossy) areas on chips, but such areas could be seen only after etching. One might speculate, for example, that hydroxyl ions, produced by reduction of water, somehow concentrated near the CR-39 surface, attacked the plastic.

Inserted on 4/6/07:
Let me comment on the four pictures at the bottom of:

http://newenergytimes.com/Reports/Krivit-KowalskiCR-39Discussion.htm

The photos were made by SPAWAR researchers. The right two clearly confirm what I was saying about relative sizes of pits. Pits on the post-electrolysis chips are about 2.5 times larger than pits due to our alpha particles, under identical etching conditions. The left two pictures show that for SPAWAR chips the ratio was close to 1.7. This lower ratio also supports my hypothesis. It implies that a typical diameter of promenent pits is 1.7*1.7=2.9 prots. This is larger than the maximum for alpha partcles, as indicated in Fifure 8.

External fields:
The most puzzling fact, discovered by the SPAWAR team (6), and confirmed by our experiment, is that the unexplained pits are produced only when magnetic field is present. Suppose the post-electrolysis pits are due to a non-nuclear process of some kind. In that case the role played by magnetic field is also far from being clear. As far as we know, magnetic fields do not drastically change rates of chemical reactions. If this is true then something new, and totally unexpected, has been discovered by the SPAWAR team. The magnetic field effect is interesting and worth investigating, even if pits are not of nuclear origin. The magnetic field effect, by the way, is a very good indication that observed pits are not due to a familiar process, such as radioactive contamination in the cell or an ordinary chemical attack.

The effect of the electric field, reported in (2), is even more puzzling. The difference of potential of 6000 volts, applied to parallel copper plates situated outside the cell with acrylic walls, should make a negligible contribution to the electric field inside a cell with the electrolyte. This is due to the very high resistivity of acrylic in comparison with the low resistivity of the electrolyte. And yet, the removal of an extremely small electric field stops a process by which track-looking pits are formed on the CR-39 detector. This effect is also interesting and worth investigating.

Additional reflections. (Inserted on 3/16/07):
Why do many scientists reject the idea that a nuclear process can be triggered by a chemical process? Because this idea conflicts with the atomic model they have already accepted. That model, progressively evolved during the 20th century, makes sense out of a large number of experimental facts. It states that chemical reactions are changes at the level of the outermost electrons orbiting around atomic nuclei. Nuclear reactions, on the other hand, are changes occurring in tiny central regions of atoms. Nuclear force bounding protons and neutrons in these tiny regions have very short ranges; they have no effect on orbiting electrons. Coulomb forces between electrons and protons are negligibly small in comparison with nuclear forces. That is why electronic rearrangements (chemical changes) are generally expected to have negligible effects on what is going on inside atomic nuclei.

In research, and in teaching, we progress from what is already known toward what remains hidden. New models of reality are refinements of models that are known to be consistent with experimental facts. That is why many scientists say that cold fusion claims are extraordinary. They feel that one has to be extraordinary reserved toward such claims. To "be reserved," however, does not mean to "reject." It means to ask many more questions than in the case of claims that are consistent with accepted models.

It is important to emphasize that that SPAWAR scientists, like many other cold fusion researchers, are experimentalists. They observe what happens and try to interpret it in terms of familiar concepts. Our photos (shown in Figures 3, 5 and 7) are very similar to their photos (shown in reference 2). But we do not know if large pits on their post-electrolysis chips are also considerably larger than pits on their chips exposed to alpha particles (under identical etching conditions). The disagreement is about the idea that large post-electrolysis chips can be attributed to alpha particles, and lighter nuclear projectiles. Fortunately, experiments seem to be reproducible. In that situation the disagreement can easily be turned into an agreement, one way or another. It becomes a simple matter of remeasuring, or repeating the experiment. Will the clear picture emerge before the next week anniversary of cold fusion? I hope so.

Inserted 3/23/07
Our paper was discussed extensively on the private list for CMNS researchers. Replying to one message I wrote:

From past experience (placing CR-39 on a Pu-Be neutron source) I know that most tracks due to neutrons (via collisions with hydrogen nuclei in that material C_{12}-H_{18}-O_7) have diameters that are clearly smaller than diameters due to alpha particles from the Am-241 source. Less than one percent of tracks due to neutrons had diameters comparable to those seen on the chip exposed to Am-241. I attributed these large pits to the (n,alpha) reactions. That is why I said that pits larger than those due to Am-241 (identical magnification and etching) cannot be attributed "to neutrons." Perhaps I should have said "to protons produced by neutrons." I am not denying a possibility that large dark pits on our photos might be due "to carbon or oxygen ions produced by neutrons," as suggested at the APS meeting by Larry.

Let me estimate the number of neutrons that would be responsible for large pits Larry observed on the "back side" of his CR-39 chip. The rule of thumb used by Frank Gordon (private communication during the APS conference) is that only one out of hundred thousand fast neutrons, passing through a CR-39 detector, interacts with with atomic nuclei insid the detector. Taking this for granted, let me estimate the number of neutrons from the number of large pits. To accomplish this I will make the following assumptions (which can easily be modifies). To accomplish this I will make four simplifying assumptions. These arbitrary assumptions can be modified, if necessary.

a) One half out of 100,000 intercepted neutrons is colliding with heavy nuclei in CR-39 producing ions of C and O. The other half is scattered on hydrogen.
b) The mean range of heavy ions in CR-39 is 1 mg/cm^2, which is 8 microns.
c) Larry's large dark pits are due to only 25% of heavy ions produced in the last 8 microns of CR-39.
d) The thickness of the CR-39 chip is 1 mm, which is 1000 microns.

Thus the fraction of ions responsible for Larry's pits is 0.25*8/1000=1/500. In other words, the number of large pits will be 500 times smaller than the number of neutrons interacting with heavy nuclei inside the CR-39 chip. If 100,000 neutrons produce one interaction then 500*100000=5*10^7 neutrons will produce one Larry's pit. For 1000 pits the

number of neutrons would be 5*10 . This is 50 billion. Another conclusion is that large pits should also be observed on the front surface of the CR-39 chip.

This speculation was posted on the private list for CMNS researchers. Here is a comment from one researcher: " If 50 million neutrons were emitted by the cell during the last 48 hours of the run when the current is at its highest value (and presumably making the nuclear reactions happen), the flux onto the CR-39 chip would be 290,000 neutrons/sec. That'd make any neutron detector sing, so to speak. Also, assuming the neutrons are 2.5 Mev, it only takes 20 neutrons/cm^2/sec to make a dose rate of 2.5 mrem/hr (1)... so the CR-39 chip would see a dose rate of ~36 rem/hour (assuming the chip was 1 cm^2). The dose falls off rapidly with distance but, still, such an experiment would be of considerable hazard to the health of bystanders. (1). Radiation Detection and Measurement, Glenn Knoll, 1979, p. 802."

After reading the 2002 paper of J.A. Frenje et al. (Review of Scientific Instruments, vol. 77, July 2002, p 2595) I realized that the assumption (a) above was highly unrealistic. Experimental data show that the number of large pits due to heavy ions represents only a very small fraction of one percent of all pits, even for 14 MeV neutrons. For that reason the 50 million neutrons was underestimated by orders of magnitude. To produce 1000 pits on CR-39, the number of neutrons had to be much larger than 5 billion. Fortunately, a Landauer neutron detector was used in one of The Galileo Project experiments. How many neutrons were actually detected during that experiment? I will answer this question as soon as the outcome is announced.

320) Phase 2 of Galileo Project

Ludwik Kowalski; 3/29/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction (written in September of 2007):
CMNS researchers are fully aware that a simple reproducible-on-demand demo of a nuclear effect, such as emission of alpha particles, caused by a chemical process would have profound effect on mainstream scientific community. The accepted point of view is that chemical processes (interactions involving valence electrons in atoms and molecules) are too weak to produce emission of nucleons, or groups of nucleons, from atomic nuclei. Yet, several researchers, such as Lipson, Jones, and Oriani, have been reporting unexpected emission of alpha particles, for many years.

About two years ago I decided to replicate Oriani's effects. This was described in unit #192 at this website. I did observe results reported by Oriani but they were not sufficiently reproducible. Last summer I found out that Richard Oriani has a draft of an unpublished paper in which new results, confirming emission of nuclear particles, are described. The methodology used by him was essentially the same as that described in unit #192. But instead of investigating several effects he decided to focus on one effect -- emission of alpha particles from a cathode, after the end of electrolysis. Thirty seven similar experiments were performed; a typical electrolysis time was 3 days and a typical counting time was 2 days. The mean track density, attributed to nuclear particles, turned out to be 90 tracks per cm^2. The standard deviation was 35; and the lowest result was 40. This was significantly higher than results from 24 control experiments, where the mean track density turned out to be 20. The standard deviation for the control samples was 11 and the lowest value was zero.

2) Inserted on 3/28/07:
Impressed by the above results, I decided to perform similar experiments. But plans changed after The Galileo Project (TGP) was organized by Steve Krivit. The Phase 1 of that project, and our contribution to it, are described in unit #319. When we were busy with the Phase 1 Oriani was performing a new sequence of experiments. The major modification, in comparison with his earlier setup, was a very thin window (5 microns of polypropylene) placed between the O rings. The cathode wire was above that window (in the electrolyte) while the CR-39 detector was below that window (in air). With this setup Oriani was able to record tracks of nuclear particles, presumably alpha particles or protons. They were emitted during the electrolysis, not after the electrolysis. The numbers of tracks on chips below the cathode were about two orders of magnitude higher than on blank chips of the same size. The photo of tracks after one of his experiments is shown in Figure 1 below.

The idea of using thin foils separating CR-39 detectors from the electrolyte has been discussed extensively on a special Internet list for TGP researchers. But Oriani was the first to implement this idea. He was also the first to use the term "PACA detector," for a CR-39 chip "protected against chemical attack." In fact, he invented this term after being convinced that at least some of copious SPAWAR pits resulted from chemical, rather than nuclear, activity.

- -

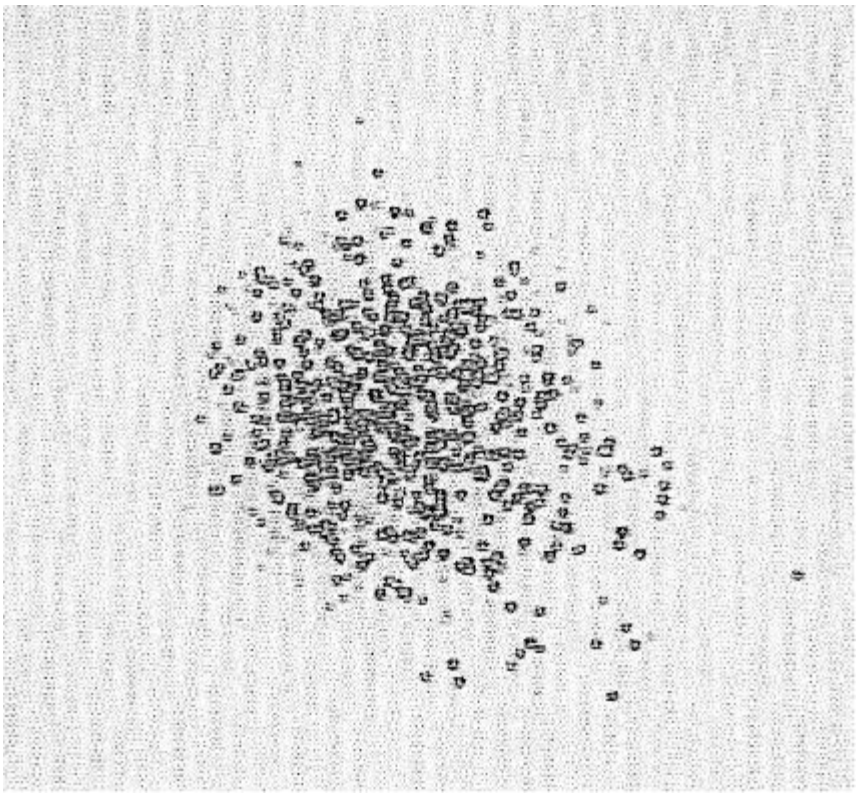

Figure 1
A spectacular shower of Particles reported by Richard Oriani. Magnification was 100; the area on the photo is about 1.5 mm^2." The clustering of tracks is remarkable. In a private message (4/2/07) Richard wrote: "In past work I have compared mean diameters of tracks produced by Am241 and by my experiments when both detector chips are etched at the same time, and have found that the tracks produced in the experiments are a bit smaller than those produced by Am 241. "

- -

Our Phase 1 contribution to TGP project has been described in a paper presented at the recent APS meeting (see unit #319). Proceeding toward the Phase 2 we wanted to replicate new Oriani experiments. What follows was composed from my own notes, and from pieces of information supplied by other people. Numbering of individual sections of this unit corresponds to chronological order, more or less, in which separate pieces were added and modified. I apologize for some repetitions.

3) Experimental method
Our version of Oriani's thin-window cell is shown in Figure 2 below. Note that only one O-ring was used in our first Phase 2 experiment. Oriani, on the other hand, used two O-rings, one on the wet side of the window and one on the dry side. In at least one case he used the same heavy water electrolyte as the SPAWAR team (see unit #319) in other cases he used Li_2SO_4 in light water. Results, he reported, were not very different. He did not use magnets. In our first Phase 2 experiment the electrolyte was also the same as that used by the SPAWAR team. In our second Phase 2 experiment, still being analyzed, we used the same electrolyte as Oriani (2.367 grams of Li_2SO_4 in 100 cc of light water)

- -

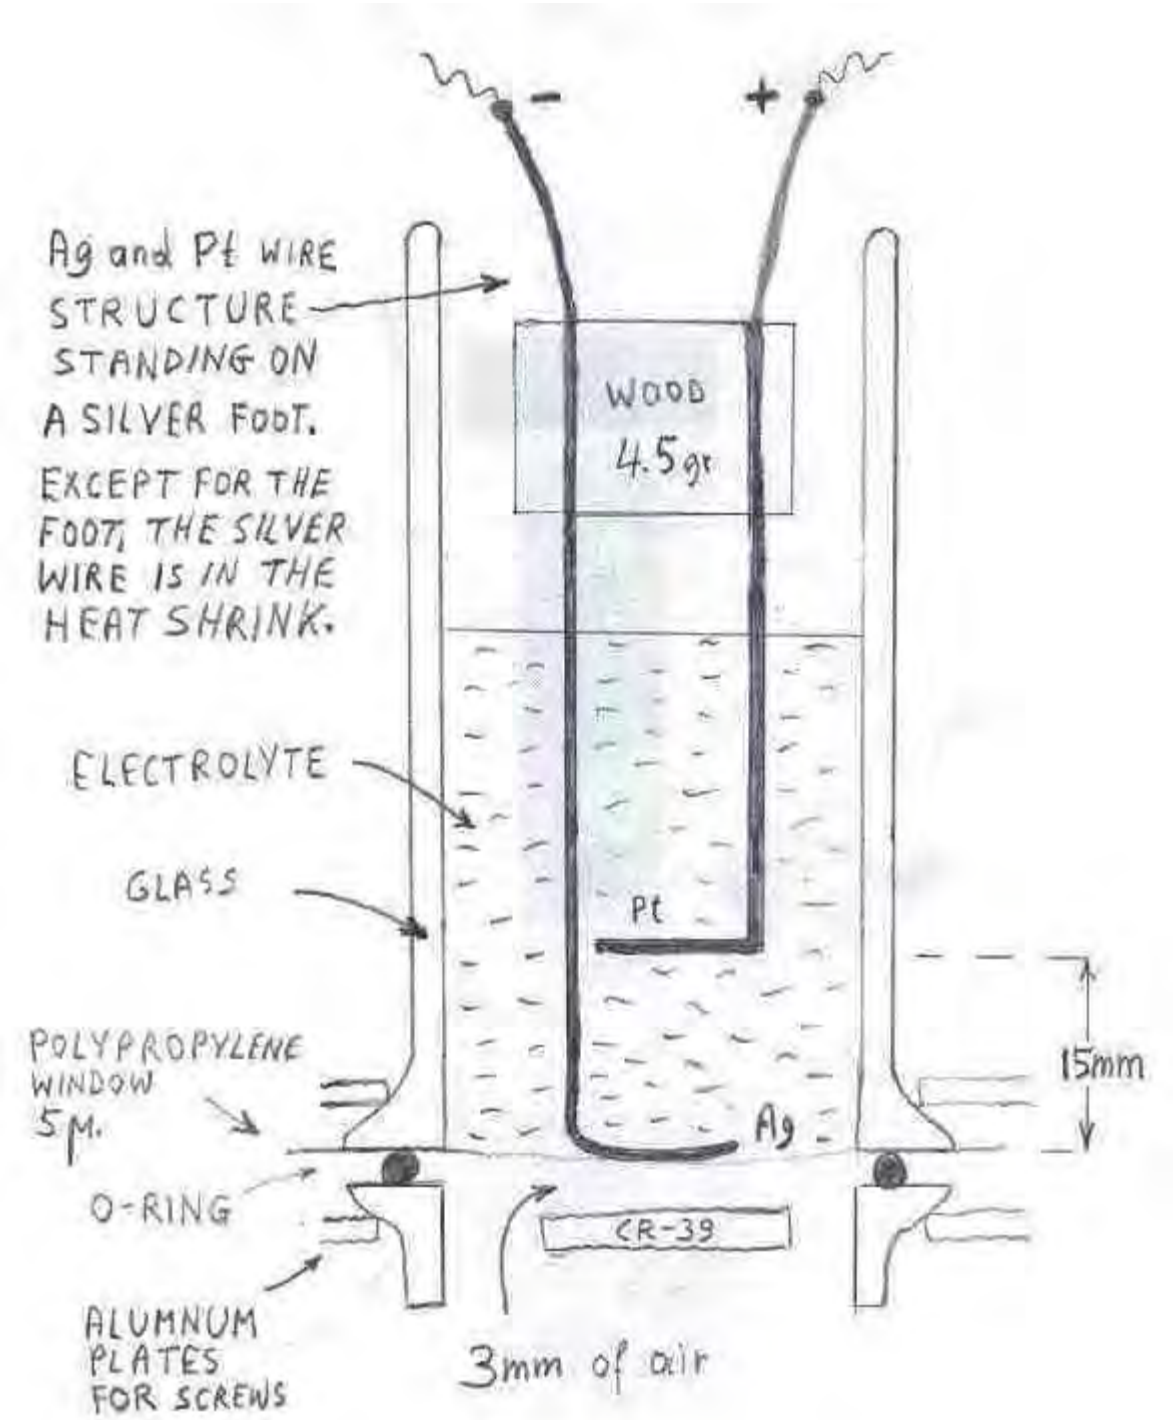

Figure 2
An Oriani-type cell with a thin polypropylene window. The rigid cathode-anode structure is supported by the thin layer of polypropylene.

- -

Contact between the polyethylene window and the silver-wire cathode (see Figure 2) was due to the weight of the cathode-anode structure. The total mass of that structure, in the first experiment, was close to 7 grams. In the second experiment the weight was close to 17 grams -- wood was replaced by a plastic cylinder and an iron nut.

4) Additional experimental details.
The electrolysis time schedule was as described in unit #319, except that the first day (I=0.5 mA) was skipped; the

third cell was inserted into the circuit one day after the first two cells. The CR-39 chip was located below the window. Another CR-39 chip was located next to the glass tube (see Figure 2). The two chips were etched and analyzed, as usual. Here is how the result was described in a message posted on our CR-39 list, on 3/1/07:

"We etched all chips in a fresh NaOH solution for 6 hrs at ~70 C and americium pits confirmed that etching was sufficiently long. But post-electrolysis chips did not show anything significantly larger than the background. Here are details:
a) The area of the chip below the thin window was about 0.95 cm^2. The surface facing up (looking at the cathode wire 3 mm away) recorded 17 track-looking pits.
b) The blank chip, exposed to air, far away from the cell, had the area of 1.6 cm^2. The number of pits one one side was found to be 17 while on the other side it was 10.
c) The area of the chip in contact with the glass tube (in air, looking toward the electrolyte above the anode, the bubbly region) was 1 cm^2. The number of pits on the side facing the tube was 27, the number on the opposite side was 14.

In my opinion the signal should be at least ten times stronger that the noise (number of pits on the blank chip) before it can be taken for granted. I know that three standard deviation is considered to be sufficient, under well defined conditions. But such conditions are not satisfied in our experiments. Oriani's signal/noise ratio was much larger than 10; our results are significantly different from his results. But Richard's experiment was not exactly like our's. Today we started another Oriani-type experiment; it will last about 10 days. The experiment will be supervised by Mike because I will be away. The geometry is similar to our first Phase 2 experiment but the cathode is made from nickel wire and the electrolyte is Li_2SO_4 in light water. "

The cell for our second Phase 2 experiment was essentially the same as in Figure 2 above. But the distance between the anode and a cathode was 24 mm. Here is how our preliminary result was described on 3/15/07 (in a message sent to Oriani, Brian and Simon).

"Oriani 2 experiment ended today. Working with Mike we examined three CR-39 chips that were positioned to detect particles during the electrolysis. Quick examination showed that there might be slightly more tracks on these chips than on the blank chip. But it will certainly not going to be the factor of ten difference (as reported by Oriani) or the factor of 7 (as in a recent SPAWAR experiment, according to Pam). Mike will analyze the chips and will report the actual number of pits. This will be the main part of his paper, to be presented at the Sigma-Xi student research conference. The other part will be comparison of background on CR-39 from three sources. And he will have an appendix explaining CR-39 detectors.

Before specifying details I want to mention an interesting observation. The chip that was below the cathode (originally about 2 mm from it, in air) had a naked-eye-visible circle when we removed it. Contrary to my expectation, the circle was not washed away after 4.5 hours of etching at ~78 C. Microscopic examination (after etching) showed that the circle is not made from track-looking pits; it was a grayish area matching the cathode wire "foot.". What can this circle be? Here is my guess. The polypropylene foil, supporting the weight of the electrolyte, and the weight of the cathode-anode structure, sagged and was actually in contact with the CR-detector. In other words, the cathode "foot" was separated from the CR-39 by only five microns of the plastic window. The circle (imprint of the cathode) was probably due to a thermal (or mechanical) effect. What else can it be?

a) Electrolyte: Li_2SO_4 in distilled H_2O (2.367 grams in 100 cc of water)
b) Distance from the circulat cathode (Ni) and pancake anode (Pt) was 24 mm.
c) Timing: 30 hrs with 10 mA, 72 hrs with 50 mA, 192 hrs with 127 mA and 30 hrs with ~270 mA (at the end, without a current stabilizer).
d) Three CR-39 chips were used. One bolow the polypropylene window (where the circular imprint was discovered), one in the air above the tube (exposed to escaping H_2 and O_2) and one applied to the external side of the cell (at the level below the anode). We also had two blank CR-39 chips and two chips exposed to Am-241. Pits due to americium were well developed."

5) A message from Oriani:

Here is a very interesting message that Oriani posted on the CR-39 list for TGP researchers: "I thought that it may be useful for me to submit for your consideration my results so far from experiments with film-protected CR39 during electrolysis in which the cathode is in close contact with the protecting film. The work so far has been designed only to see if one can get repeatedly more tracks than background level with this procedure. A systematic investigation to try to optimize the production of tracks is still to be done. . . .

I believe that one can conclude that the SPAWAR electrolyte composition in D_2O is not particularly advantageous. One sees also that the formerly used O-ring adds considerably to the tracks/cm^2 seen in an experiment. Additional experiments have shown that the O-ring retains a residual radioactivity after an electrolysis, and presumably so do other portions of the apparatus employed in an electrolysis experiment, as described by Fisher's polyneutron theory. All of the results so far share the characteristics that the track distributions are bi-modal, ie. groups and widely separated tracks, and that there is no discernible correspondence with the position of the cathode wires. There is also no correspondence between the tracks on one side of the detector and the tracks on the other side. These are independent events."

6) Future plans and ideas

After reading the above message, I decided to perform at least one more Oriani-type experiment. But not immediately; I want to learn more from the ongoing Phase 2 experiments of Pamela Mossier Boss et al. And I am not the only one who made such decision. In a private message received this morning Oriani promised to send me some "kindling" for another attempt to observe showers.

Will our result -- prominent pits on post-electrolysis chips are about 2.5 result larger than pits due to alpha particles, under identical etching conditions -- be confirmed by other researchers? So far I have seen only one confirmation (from TGP beta team #2) and not a single negation. This is not enough; hopefully other TGP researchers will soon ether confirm or negate our results. I also want to know if my interpretation of the above result is valid. This section will probably be expanded when new results, and new interpretations, become available. Please do not miss unit #321 which I am posting at the same time. It shows my view of scientific issues raised in The Galileo Project.

7) Polyneutrons

Oriani referred to a theory developed by John Fisher. My understanding of that theory has been described in units #191 and #227. But that was about two years ago. I know that John has been improving his theory constantly. Unfortunately I am not familiar with the curren version. Here is a recent message from John; it was posted on the CMNS list (3/13/07):

"Some researchers have regular success with starting nuclear reactions in their laboratories whereas others, notably those trying for the first time, can wait for weeks or months without success. This may not be the fault of the beginners. Polyneutron theory suggests that a free polyneutron is required to initiate a reaction (just as a free neutron is required to initiate a fission reaction), and that such polyneutrons are emitted by precursor particles in the air and water. The precursor particles are exceedingly rare and it can take considerable time for ignition of the first reaction in a laboratory. After that things get easier. A successful reaction produces large numbers of the required precursors, many of which stick to the experimental equipment or escape and condense on surfaces throughout the laboratory. On subsequent attempts they are available in the equipment, or are desorbed from the laboratory surroundings, enabling much prompter ignition. Hence it may be helpful to seed a start-up experiment with a bit of hardware or electrolyte taken from a successful one. This is equivalent to transporting an ember from a fire to a stack of kindling, rather than waiting for lightning to strike."

That is an interesting observation. Replying to the above I wrote: "Irreproducibility is taken by John as an experimental fact. Guided by that fact he found a theoretical explanation. That seems to be consistent with scientific methodology. But is the explanation valid? Oriani had eight consecutive successes in observing CINA (chemically induced nuclear activity). Our one recent attempt to reproduce it failed. That attempt was made at the same time (February and March 2007) at which we were able to successfully reproduce the SPAWAR experiment. Another attempt to reproduce Oriani's experiment is in progress. If it fails then I will ask Oriani to send us kindling pieces. I suggest that other researchers, using CR-39 and thin foils, do the same. Were we just lucky to replicate the SPAWAR

effect [without any kindling] or Fisher's theory does not apply to SPAWAR effect? . . . "
