And here is a message I posted on the same list more recently (3/16.07). "In reading Steve Krivit's summary, just published in the #21 issue of NET, I see a reference to a recent PACA-type experiments (Protected Against Chemical Attack) at SPAWAR. It is an indication that large dominant pits, possibly due to corrosion (term first used by Oriani, if I recall correctly), mask presence of smaller and much less abundant pits due to nuclear projectiles. Oriani's eight consecutive experiments confirmed presence nuclear tracks on PACA chips. SPAWAR team also reports presence of tracks "more than seven times the background." Unfortunately, our (beta 5) results, and preliminary results reproted by beta 2 and beta 6 teams of TGP, seem to be very different in that respect. I hope that the situation will become more clear when other beta teams, and other investigators, share the results of their Phase 2 observations on this list. It would be interesting to know if tracks observed on PACA detectors are also formed only when magnetic and electric fields are present. That would be a highly convincing argument that tracks are not from radioactive contamination.

9) Other things.
This section is a place for an insertion that has nothing to do with science of TGP. I plan to write that insertion after it becomes clear whether or not the SPAWAR effect is an example of a chemically induced nuclear activity. Keep in mind that only one half of the Phase 1 teams reported the results so far. According to our leader, Steve Krivit, the Phase 2 was supposed to be less rigid than Phase 1. It was not to be a project in which each beta team was expected to follow a protocol developed by alpha teams. Each beta team researcher was expected to participate in Phase 2. Let us hope for more reproducible and convincing data from the second phase of The Galileo Project.

Also keep in mind that the SPAWAR claim is not based only on recent discoveries made with CR-39 detectors; it is also based on other observations, as described in numerous papers. References can be found in the 2007 paper of S. Szpak et al.:

321) Scientific Issues in The Galileo Project

Ludwik Kowalski; 4/2/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Available results from The Galileo Project (TGP), as described in the March issue of this journal, confirmed the presence of copious SPAWAR pits. That is very important; it shows that the effect is reproducible. But is this discovery an example of nuclear activity (emission of nucleons from atomic nuclei) initiated by electrolysis? That question remains unanswered. About 30 researchers, from different laboratories, (two alpha teams, six beta teams and two advisers) continue to address it. I am one of these researchers. Let me outline six pending scientific issues that have emerged from the ongoing investigations..

1) Unconventional use of detectors
CR-39 detectors, used in TGP, are also used in other areas of science and technology. But we used them in the electrolyte, rather than in air. Is it possible that prominent pits, recorded in the electrolyte, are due to chemical corrosion and not to nuclear projectiles? That possibility was raised by the beta 2 team, after examination of their CR-39 detectors.

2) Relative sizes of prominent pits
Absolute sizes of CR-39 pits, due to nuclear particles, are known to depend on the time of etching and on the temperature of the etching solution. But relative sizes of pits, for example, in comparison with those due to alpha particles from an americium source, are likely to be much less dependent on etching parameter. According to two TGP teams (beta 5 and beta 2) diameters of prominent pits are about 2.5 times larger than diameters due to alpha particles (under identical etching conditions). Will this experimental fact be confirmed by other teams? That remains to be seen. My interpretation of this fact was offered at the recent APS meeting. It has also been described at

http://csam.montclair.edu/~kowalski/cf/319galileo.html

Will other scientists agree with me that large SPAWAR pits “cannot possibly be due to alpha particles or protons?” That also remains to be seen.

3) Emission of neutrons:
Two researchers, R. Oriani and L. Forsley, independently reported seeing pits on both sides of thick CR-39 chips. This led to a hypothesis, offered by Forsley, that at least some nuclear particles emitted in the SPAWAR effect are neutrons. Fortunately, two neutron detectors were used in one TGP experiment. Will the analysis of results confirm the hypothesis? That also remains to be seen.

4) PACA detectors:
Suspecting that dominant pits on post-electrolysis chips are due to some kind of corrosion, and expecting to detect less prominent pits due to nuclear projectiles, Richard Oriani started experimenting with PACA detectors. The acronym stands for Protected Against Chemical Attack. In his setup the CR-39 detector is separated from the electrolyte by a thin polypropylene film (5 microns). The wet side of the film is in contact with the cathode while the dry side is in contact with the CR-39 chip (located in air). He performed 8 consecutive experiments with that setup and reported positive results (at least ten times more pits on a PACA detector than on the control detector). Similar results were mentioned by Pamela Boss. Our beta 5 team was not able to replicate such results. This, however, does not necessary

conflict with positive results because experimental conditions were not identical. A confirmation of positive or negative results is likely to emerge when experimental conditions are normalized.

5) Electric and Magnetic fields:
According to the November issue of NET, tracks of nuclear particles are detected only when electrolytic cells are located in external fields, either electric or magnetic. The magnetic field effect was confirmed by our beta 5 team. But, according to the beta 2 team, magnetic field has no effect on the pit formation process. Results from other teams have not yet been announced. The issue remains unresolved.

6) Other nuclear signatures:
It is important to be aware that the SPAWAR claim, about a nuclear effect resulting from a chemical process, was not based only on CR-39 detectors in the electrolyte. It was also based on production of tritium (and other new elements), on generation of characteristic X rays, and on morphological changes on surfaces of cathodes. Hopefully these observations will also be subjected to scrutiny of independent investigations.

The above note was submitted to New Energy Times today. Unfortunately, the editor of this online journal, Steve Krivit, rejected the note without providing any explanation. SEE CORRECTION BELOW ! ! !

APPENDED ON 12/24/07
Let me clarify what I meant by the term "rejected." Steve Krivit actually suggested what the note should be improved. I decided not to do this because what is shown above seemed to be sufficiently clear. That is why I decided to post this summary note at my website. But the phrase "without any explanation" was wrong. This will be clear to anyone who reads his message (see below). I apologize for this misleading phrase. I also thank Steve Krivit for sending me copies of two messages shown below; they have been deleted from my mailbox long time ago.

Ludwik to Steve (4/6/07):
Hi Steve,
Many days ago you mentioned that the deadline to submit a piece for the next issue of TNT is April 20. With this in mind I am sending you this piece. I hope you will publish it. Your help in improving my style will be appreciated.

Steve to Ludwik (4/11/07):
Dear Dr. Kowalski,
Please attend to all of these required changes if you wish us to publish your letter.

1. You must explicitly refer to text or data that I wrote in my report regarding calibration curves, not what you think I believe.
2. If you wish to critique what I wrote in my March 16 article, you must do so only with what was known at the time, not what you have learned afterwards, because that would become an extension of the discussion, not a direct rebuttal.
3. If you wish to refer to data or results of experiments in your rebuttal you must include only that which has been presented in a legitimate science conference or journal publication.
4. If you want to discuss pit size, you must provide a scaled image, as well as an image of that area which shows the relative size of such pits that support your distinction of "dominant" pits.
5. In your presentation, you stated your conclusion, "analysis of our single experiment does not support the idea that dominant pits, on our CR-39 chips, are tracks of alpha particles, or less massive nuclear projectiles." In your letter of 6 April you stated it differently, "prominent large pits on post-electrolysis chips cannot possibly be due to alpha particle, to directly emitted protons, or to protons ìkickedî by neutrons." Please explain why, in your presentation, you did not state that the pits could be from more massive nuclear particles. Since your 6 April letter uses the absolute characterization, "cannot possibly be," please provide absolute proof that the tracks cannot be caused by protons kicked by neutrons.

Thank you,

Steve Krivit
Editor, New Energy Times

322) Rutherford-Bohr model questioned

Ludwik Kowalski; 4/11/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

This morning I received an e-mail message from a stranger, P.J.J. He wrote: ". . . This is a long and clumsy prelude to my quest for your help in determining the validity if any in the posit of the hydreno (not hydrino) theory..... "

Well I never heard about hydrenos. But Google helped me. A book entitled "Lattice Nested Hydreno Atomic Model" by Mark Porringa, is available over the Internet:

http://www.lnhatom.com/products.html

Jumping from link to link I finally found something scientific at

http://www.lnhatom.com/bohrrutherford.html

It is an extract from Porringa's book. What follows are my comments on his objections to the Bohr-Rutherford model of atoms. His words are in blue; my comments are in black.

"..... Aside from its undisputed accuracy in the prediction of the spectral lines of hydrogen, the Bohr-Rutherford atomic model appears to be in need of some serious rework.....Another objection is raised regarding Rutherford's [29] calculation of the size of the nucleus, which could be off by a very wide margin, due to several invalid assumptions including the erroneous exchange of terminology used in his analysis that permitted the "surface" of the nucleus, to be considered equivalent to the "center" of the nucleus. From the outset, Rutherford presumes a point like nature for the nucleus with a dimension conjectured to be less than 10^{-14} m. If the nuclear charge is in reality dispersed over a considerably larger volume than the presently conjectured 10^{-42} m^3, the coulomb interaction with a high velocity charged particle would be much different than Rutherford's presumption. A larger nucleus, with a much reduced electric field intensity, would permit the high energy alpha particles used in the Gold foil experiment to come much closer to the nucleus, possibly striking it."

Yes, this would happen if the nucleus were much larger than 10^{-14} m. and the dependence of the differential cross section on the angle would be very different from what was actually measured in 1911. (Scattering would not be due to Coulmbe force only). I measured differential scattering cross sections many times (not only on gold, and not only for alpha particles) and I know how well the results confirm the point-like approximation. This approximation, by the way, is no longer valid when the energy of the projectile is sufficiently large. The size of a nucleus can easily be estimated from the energy at which a cross section, for example at 150 degrees, starts to deviate from what is predicted by the point-like approximation. I have done this, several times, on the basis of data collected during my postdoctoral work at Columbia university.

" Rutherford also makes the mistake of presuming that the probability of large angle deflections is directly related to the thickness of the gold foil, ignoring the obvious tendency of the alpha particle to be channeled within the highly organized atomic lattice by the presence of the concentrated charge of the gold nuclei, and secondarily by the electron cloud surrounding it. "

I see no mistake in Rutherford's analysis of experimental data. He made an assumption (independent scattering of

alpha particles by individual point-like nuclei) and showed that experimental data, for very thin foils, were in good agreement with this model. What is wrong with this kind of validation?

"The beam trajectory being normal with respect to the foil, and therefore parallel to the internal lattice structure, would effectively prevent large angle deflections beyond the first two staggered layers of the cubic close-packed crystal structure.

A gold foil is not a monocrystal. Therefore the internal lattice structures are not always parallel to trajectories of alpha particles.

Barring a direct hit, or very close miss on a gold nucleus within these first two layers, the high energy alpha particle would simply continue on its merry way between the nuclei, effectively channeled through the entire foil, without any further prospects of high angle deflections. Only small deflections would be possible for the remainder of its travel, and these would be entirely insufficient to bump the alpha particle out of the defined channel provided by the lattice... "

But scattering at large angles does take place. The results, at low energies, are found to be consistent with the idea of independent scattering by individual point-like nuclei. That was the central point of Rutherford's discovery (1911). the only mistake he made, as far as I know, was in an argument (in the 1937 book) that practical applications of nuclear energy will not possible. He did not anticipate a possibility of chain reactions. But that is a different topic.

"The thickness of the foil used in the experiment is cited, near enough, as 10^{-8} m. Given the well-established atomic dimension of 10^{-10} m, the foil was less than 100 atoms thick, making it extremely unlikely that a single alpha particle could experience more than one large angle deflection. The proportion of large angle deflections greater than 90^{o} was found to be only one in 20,000. Following the reasoning above, about half of these deflections happen at the surface of the foil, the remainder occurring at the staggered layer of atoms immediately below the surface of the foil of the ccp structure. "

What evidence is available to support a statement that "about half of these deflections happen at the surface of the foil." ? In my opinion it is a speculation that has nothing to do with reality. All experimental data with which I am familiar, including my own, are consistent with the idea that the above assumption has nothing to do with reality.

"In other words if the foil could have been reduced to only two layers thick the number of high angle deflections would have been essentially the same as that observed for the 100 atom thick foil. The remaining 98 atomic layers would have virtually no effect with regard to high angle scattering. Rutherford's inclusion of a thickness factor in his probability analysis would therefore appear quite unjustified, and would by itself give rise to a 100 fold error in the size of the nucleus..... "

When the target thickness is increased from 2 to 100 layers, the number of high angle deflections increases by the factor of 50. Once again, this is a well established experimental fact.

"Making no presumptions about the relative size of the nucleus, and the nature of the Coulomb interaction, a reasonable estimate could be asserted by considering only the high angle scattering at the surface of the foil, which clearly indicates that only about 1/10,000 of the surface area is occupied by something substantial (a heavy nucleus); the remainder being mostly empty space occupied by the orbital electron clouds. "

Which experimental data are being used to justify this 1/10,000 factor?

"This clearly and simply implies that the diameter of the nucleus could conceivably be roughly 1/100 of the atoms diameter. The result of this "ball park" analysis is that the nuclear radius may be about a thousand times larger than the presently conceded dimension of 10^{-15} m, which results in an atomic diameter in the range of 10^{-10} m, with a nucleus of 10^{-12} m; a much different view from that presently accepted. Even at 10^{-12} the absolute Casimir pressure is still a very substantial 10^{18} kPa and certainly adequate to hold the nucleus together against the substantially reduced

coulomb repulsion of the protons. ”

That reminds me a well known Polish saying: "Gdyby baba wasy miala toby dziadem sie nazwala." And the Russian sayng "Yielsi-by-da dakaby da wortu rosli boby to polutchilsia by nie rot a celyi ogorod". The English proverb, I was told, is "If wishes were horses beggars might ride."

“A thousand fold increase in the nuclear diameter, also results in a million fold reduction in the intensity of the mutual coulomb repulsion of the protons of the rarified nucleus, assuming for simplicity a radial field attenuation, according to the normal $1/r^2$ relation.

Strong nuclear forces have short range. What would keep protons inside atomic nuclei?

Such a dramatic reduction greatly improves the prospects of fusion at low energies and calls into question the present understanding of thermonuclear explosions, which are heavily reliant on the notion of an extremely intense coulomb repulsion within the nucleus....

Yes, thermonuclear reactions would be taking place at lower temperatures if atomic nuclei were much larger than they really are.

Thermal neutron absorption cross-sections cast further doubt on the notion of an extremely small nucleus. Gold 198 and Cadmium 113 for instance have cross-sections approaching 27,000 barns, which on a statistical basis, just so happens to equate to an apparent nuclear dimension of 10^{-12} m, again a thousand times larger than the presently accepted nuclear dimension. “

Very large cross sections (for 0.025 eV neutrons) do not conflict with small sizes of atomic nuclei. Cross sections become very small at 0.1 MeV and above.

“. . . Why is it that no stable isotopes exist for elements having an odd number of neutrons and protons? Why is it that only one stable form exists for over 25 elements while others have up to 10? What is behind the enigmatic chemistry of Nitrogen. Why does the hot fission of Uranium result in unequal fission fragments. How does cold fission frequently occur without radioactivity or the release of the vast amounts of energy characteristic of thermonuclear reactions. Why is it that no one seems to even bother anymore with such fundamental questions?”

Yes, there are many things we do not understand, including cold fusion. That is why being a scientist is so exciting. Rutherford and Bohr are giants on whose shoulders we are standing.

323) Defending the unit 319 conclusion

Ludwik Kowalski; 4/14/2007
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, 07043

The note shown below was sent, on April 6, 2007, to the Editor of New Energy Times, Steve Krivit. I wanted it to be published in the next issue of that online journal. The last sentence was: “Your help in improving style will be appreciated.” Unlike my previous short submission, described in unit #321, the second note was tentatively accepted by Krivit. But I decided to withdraw it, as explained below. Why do I elaborate on this episode? Because I believe that some readers might be interested.

Addressing our controversy

Ludwik Kowalski; 4/6/2007
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, 07043

In item 10 of the March 2007 issue, referring to my APS report, Steve Krivit wrote: “In Ludwik's case, we have a result that appears positive, yet he purports it to be negative. Neither case is beneficial to science, and neither case should be permitted to go unchecked.” The purpose of this note is to respond to this by describing the outcome of a new experiment. But first let me thank Steve for the last four photos in:

http://newenergytimes.com/Reports/Krivit-KowalskiCR-39Discussion.htm

The photos were made by SPAWAR researchers. The two right-hand pictures clearly confirm my statement about relative sizes of pits. My post-electrolysis chips are again about 2.5 times larger than pits due to our alpha particles, under identical etching conditions. The two left-hand pictures show that for the SPAWAR chips the ratio was close to 1.7. That lower ratio also supports my claim, as shown in:

http://csam.montclair.edu/~kowalski/cf/319galileo.html

The main issue is not the experimental facts (relative sizes of pits); it is their interpretation. That interpretation, as explained at the above webpage, is based on the CR-39 calibration curve of Russian scientists. That curve does not cover the region of very low energies. Steve apparently believes that the CR-39 calibration curve, for alpha particles, continues to go up when E goes down at very low energies. If this were true then I would agree with him and admit that the conclusion was tentative.

But I am a nuclear physicist and I know how density of ionization changes with energies of alpha particles. On that basis the dashed line was drawn in Figure 8 of the above webpage. On April 5, 2007, I performed an additional

experiment; it confirms, qualitatively, that Steve's expectation does not agree with reality. The diameters of pits do not rapidly increase when energies of alpha particles become very small. In that experiment very thin mylar foils were used to reduce energies of alpha particles, in small steps. Chips irradiated with alpha particles of several energies were etched together and their diameters were compared. No rapid increase in diameters was observed at very low energies.

This constitutes an additional validation of my main conclusion -- prominent large pits on post-electrolysis chips cannot possibly be due to alpha particles, to directly emitted protons, or to protons "kicked" by neutrons. Please note that I am referring to prominent pits only. I have good reasons to believe that tracks due to nuclear particles are also present on post-electrolysis chips. But these tracks are not as numerous as pits whose diameters we measured. Will this expectation be confirmed by those who are now addressing the issue? That remains to be seen.

= =

The reply from the editor came on April, 11, 2007. It was a suggestion that I make some changes, as shown below. Krivit wrote:

"Please attend to all of these required changes if you wish us to publish your letter.

1. You must explicitly refer to text or data that I wrote in my report regarding calibration curves, not what you think I believe.
3. If you wish to critique what I wrote in my March 16 article, you must do so only with what was known at the time, not what you have learned afterwards, because that would become an extension of the discussion, not a direct rebuttal.
4. If you wish to refer to data or results of experiments in your rebuttal you must include only that which has been presented in a legitimate science conference or journal publication.
5. If you want to discuss pit size, you must provide a scaled image, as well as an image of that area which shows the relative size of such pits that support your distinction of "dominant" pits.
6. In your presentation, you stated your conclusion, "analysis of our single experiment does not support the idea that dominant pits, on our CR-39 chips, are tracks of alpha particles, or less massive nuclear projectiles." In your letter of 6 April you stated it differently, "prominent large pits on post-electrolysis chips cannot possibly be due to alpha particles, to directly emitted protons, or to protons "kicked" by neutrons." Please explain why, in your presentation, you did not state that the pits could be from more massive nuclear particles. Since your 6 April letter uses the absolute characterization, "cannot possibly be," please provide absolute proof that the tracks cannot be caused by protons kicked by neutrons."

= =

Here is my reply to the editor, followed by comments on the above requirements.

1) You are asking too much for a little comment.
2) I do not think that it is worth our time to improve the draft. I will post it on my website.
3) To explain why I decided to withdraw the draft I would like to say something like this:

This piece was submitted as a note to be published in the New Energy Times. The letter was conditionally accepted but I decided to withdraw the submission. The alternative would be to spend more time on it in order to satisfy several preconditions, as explained to me by the editor. . . .

I asked for permission to quote the editor's reply and it was given to me today. The first precondition would be easy to to satisfy. I do not know what the second precondition was. But it does not matter because it was already deleted by the author. Now about the third precondition. No, I do not wish to critique what Steve wrote, I wish to inform readers that new information supports my claim. I think that "an extension of the discussion" is much more important than

pointing fingers at each other. What is wrong with leaning on factor 1.7 which was recently inserted into Steve's March publication? By the way, insertions should be dated. I was not aware that I was addressing an insertion and not the original text. I am glad that SPAWAR people also reported that dominant pits are much larger than pits due to alpha particles.

The fourth precondition points to the policy of the journal. According to <http://newenergytimes.com/news/news.htm>, NET "contains all the latest low energy nuclear reaction news and developments from around the world, as well as meaningful analysis and expert perspective." That makes it an appropriate place to submit a very short note directly related to The Galileo Project. The author of the recent article, the editor himself, wrote about my contribution. That prompted me to collect more experimental data and show that they also support the conclusion criticized by the author. I would also be happy to report that emission of nuclear particles resulting from a chemical process has been identified. Yes, my new results were not published elsewhere because I expected the NET to be the most appropriate place for this. First I posted the result on a list for CMNS researchers, expecting some criticism. No potential errors were identified. That encouraged me to publish the results at my own website. But, after some hesitation, I decided to share them with readers of New Energy Times. After all, I was addressing Steve's NET accusation that "Ludwik's conclusion at the APS conference does not appear to be supported by fact."

As far as precondition five is concerned, I was referring to photos and pit sizes that were already shown in Steve's publication. The last precondition can be split into two parts. What was initially called "less massive particles" is now qualified (by me) as protons that are emitted directly or are kicked by neutrons. Where is the conflict? The idea of "more massive nuclear particles," such as recoils from collisions with neutrons, was introduced by Larry Forsley. Why should I be addressing it while defending a statement about alpha particles and lighter projectiles? The second part of the last precondition has to do with the "absolute proof." I know what a proof in mathematics is. But what is an absolute proof in experimental science? Results of measurements can be more or less reliable but not absolute. The same is true about conclusions based on experimental data.

= =

Inserted on 4/20/07
The Galileo Project Team #2 posted their results at I know that other GPT reams, and the SPAWAR team, are still conducting their experiments. When will their results be known? Contrary to our results, the team #2 was not able to replicate the magnetic field effect. They did much more work than we did. But they used CR-39 that was purchased 4 years ago. That might be responsible for some differences. It would be better if all TGP teams were supplied with CR-39 from the same batch. Yes, it is easy to be smart in retrospect.

The space below is reserved for comments, if any, on my letter to the editor, and on what I wrote about his preconditions. Please send them to me at:

<kowalskil@mail.montclair.edu> .

P.S.
One does not need thin foils to verify that diameters of pits do not become very large at very small energies. The experiment can be conducted in air by changing the distance between the source and the CR-39 detector, up to about 60 mm. The well known range-energy relation for alpha particles can be used to calculate the average energy at each distance. The only disadvantage of this method, in comparison with the use of thin foils, is that exposure times for long distances must be much longer than for short distances, according to the $1/r^2$ law. This can be a very inexpensive student research project. Here are mean energies at different distances, at STP, for alpha particles of 5.5 MeV

Dist (mm) - - -Energy (MeV):
.0 - - - - - - - - - - -5.5
10 - - - - - - - - - - 4.5

20 - - - - - - - - - - 3.5
30 - - - - - - - - - - 2.3
40 - - - - - - - - - - 1.1
43 - - - - - - - - - - 0.0

324) Defending my APS conclusion

Ludwik Kowalski; 4/23/2007
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, 07043

1) Unit #323 was an attempt to defend the conclusion that prominent SPAWAR pits could not be due to alpha particles or lighter nuclear projectiles. The defence was based on an experiment whose purpose was to show that diameters of pits due to alpha particles decrease at very low energies. But that was an experiment belonging to the quick-and-dirty category. It was good enough to convince me (that the claim made in unit #319 was valid) but probably not good enough to convince others. A much better experiment was finished today. The results are more or less consistent with what has been reported in 2000 -- the diameters of pits due to alpha particles decrease when energies of alpha particles become samller than approximately 1 MeV. This is illustrated in Figure 1 below.

- - - - - - - - - - - - - - - - - -

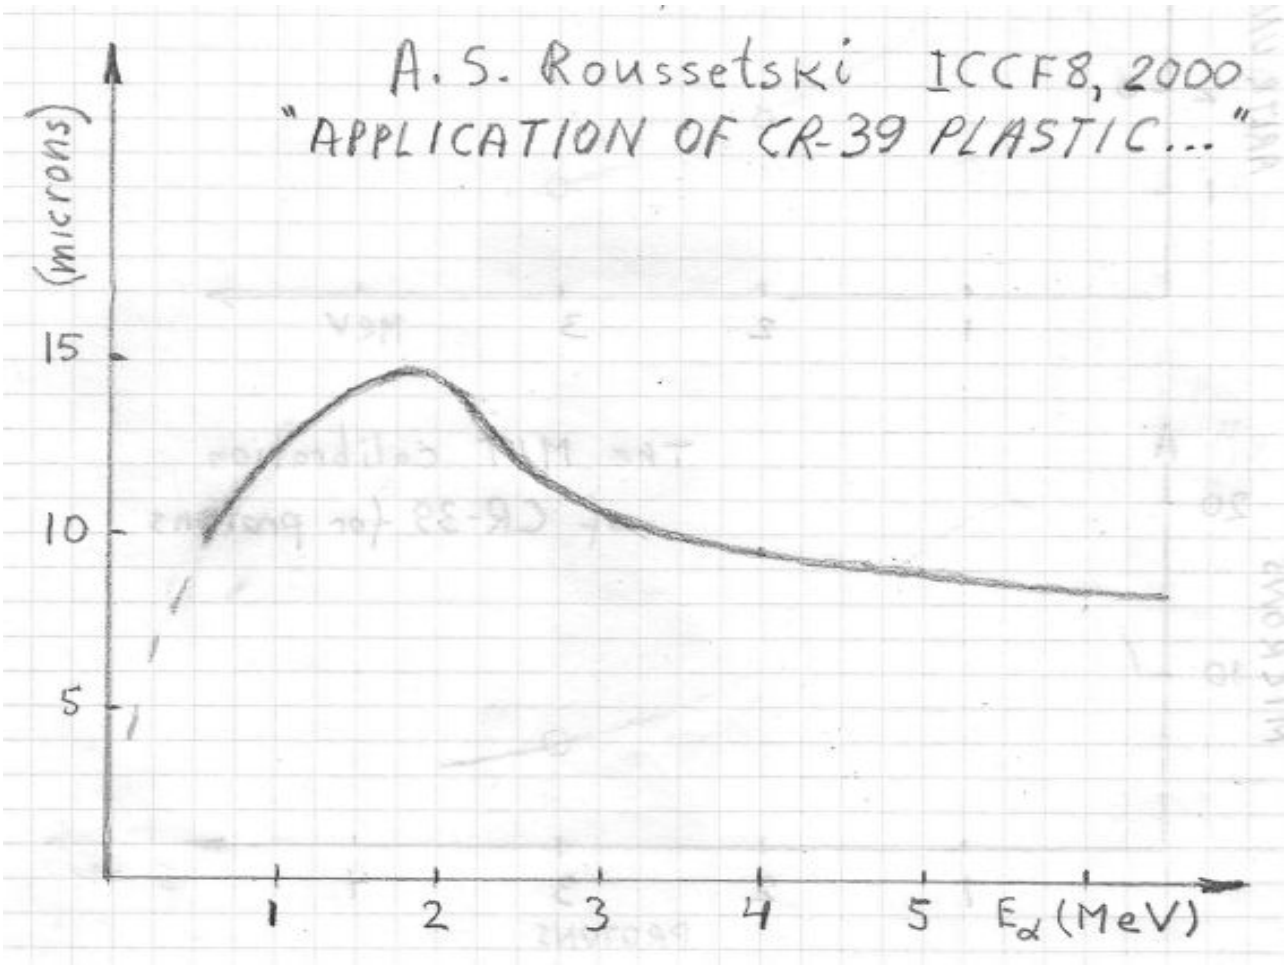

Figure 1
Dependence of pit diameters (in microns) on energies of alpha particles (in MeV), as reported in 2000 (at ICCF8) by

Roussetski. His important report can be downloaded from the library at <http://www.lenr-canr.org>.

- - - - - - - - - - - - - - - - - -

Using our Am-241 source, from a smoke detector, six chips were exposed to alpha particles, one after another. The distance between the source and the CR-39 detector (in air) was different for each chip as summarized in the table below. The exposure times were adjusted on the basis of the $1/r^2$ dependence.

dist (mm)	mean diameter (microns)	st. dev. (microns)	~ E (MeV)
5	8.0	0.53	3.56
10	8.8	0.62	2.98
15	10.3	0.90	2.19
20	11.0	0.74	1.18
25	6.3	1.85	0.20
30	only background tracks could be seen for that distance.		

- - - - - - - - - - - - - - - - - -

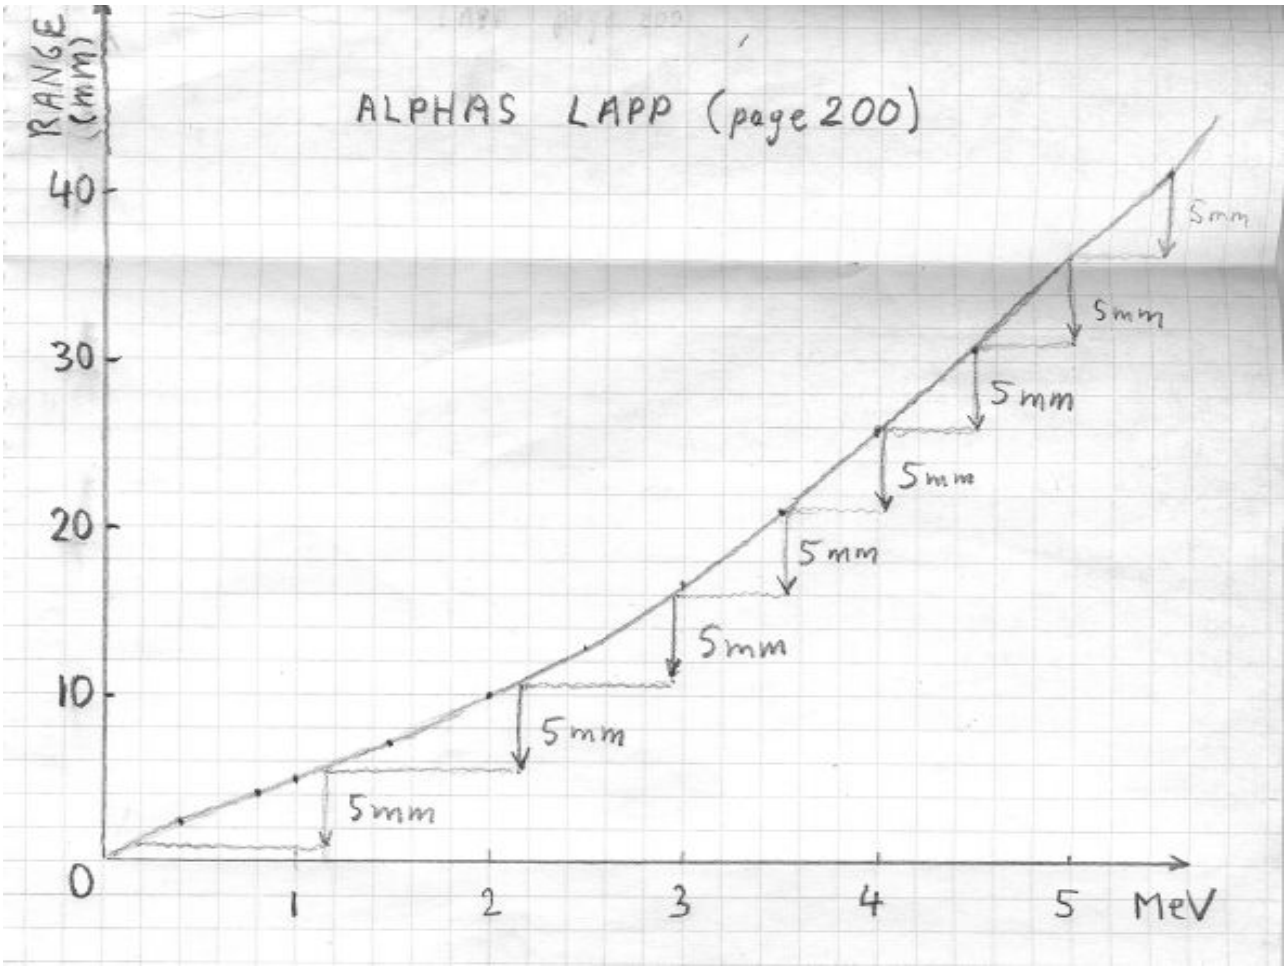

Figure 2
Dependence of the mean range of alpha particles in air (in mm) on their energies (in MeV).

- - - - - - - - - - - - - - - - - -

The next figure shows how the mean diameters of pits depend of the distance in air. The etching was in 6.25 NaOH, at 73 C, for 5.75 hours. For each distance 20 tracks were randomly selected and their diameters were measured. The points in Figure 3 are mean values while the error bars are standard deviations. Note that energies become smaller when distances become larger. Rapid decrease of diameters, at energies below 1 MeV is in very good agreement with the dashed line in Figure 8 of unit #319. That is why I think that this experiment validates the controversial conclusion made at the APS meeting (see unit #319).

- - - - - - - - - - - - - - - - - -

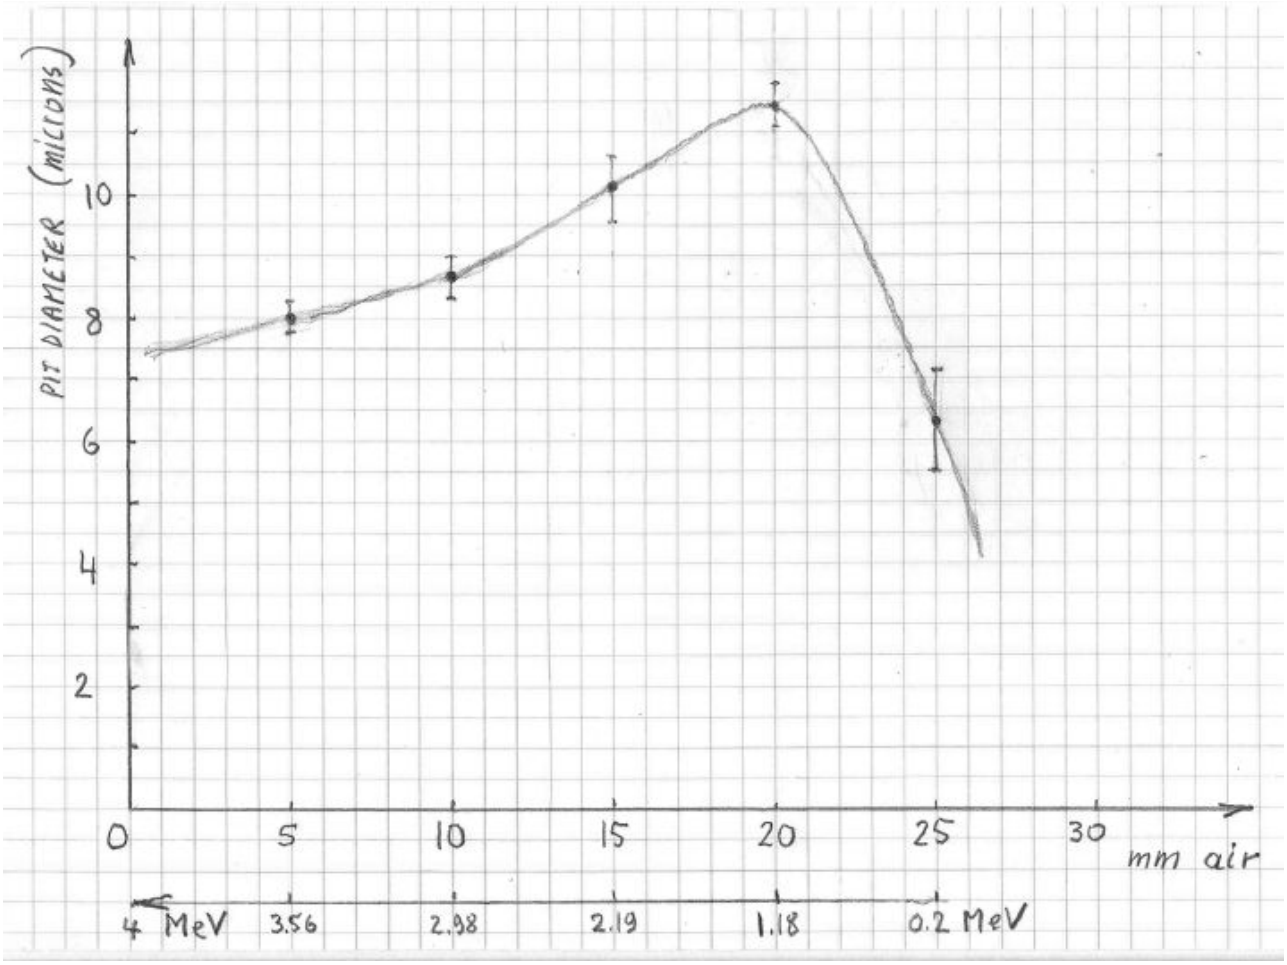

Figure 3
Dependence of the mean diameters (microns) on the distance from the source in air (cm). According to Figure 2, if alpha particles emerging from the source into air had the energy of 5.5 MeV then the maximum diameters would be near the distance of 35 mm. The shallow tracks, in that case, would be seen at 40 mm, and not at 25mm.

The following message was posted (three days ago) on the private list for CMNS researchers. I do not know how to interpret the fact not not a single Galileo Project researcher responded so far.

"It is important not to get lost in details. What do we want to accomplish? A claim was made, 18 years ago, that a nuclear activity of some kind can be induced by a chemical process. Many highly qualified scientists confirmed the validity of such claim. They measured amounts of thermal energy produced, they counted light nuclear projectiles, such as alpha particles, they showed that tritium, helium and heavier isotopes were produced [and destroyed] during some chemical reactions. What we need is a protocol for a simple, reproducible-on-demand test --we need an experiment to convince honest skeptics that a nuclear effect can indeed by induced by a chemical process.

The Galileo Project is an attempt to convince ourselves that the SPAWAR effect is an example of CANR (chemically assisted nuclear reaction). As demonstrated in the EarthTech report, based on a large number of experiments, the SPAWAR pits are quite easy to observe. Seven teams, studying the SPAWAR effect at the same time, should produce seven yes or no answers about reality of a particular kind of CANR. So far only two Galileo Projects (beta 2 and beta 5) have been completed. Their answers seem to be negative. When will we know about conclusions reached by remaining teams? The Galileo Project will become a missed opportunity unless all outcomes are reported. Please report the status of your project on this list, even if your work is still in progress."

The Galileo Project Team #2 conducted many experiments and their reseults are posted at <http://earthtech.org/CR39/>

Inserted on 4/24/07:
The corresponding curve for protons has the same general shape as the curve for alpha particles (see Figure 1 above), as illustrated by Steve Krivit in

http://newenergytimes.com/Reports/Krivit-KowalskiCR-39Discussion.htm

It was shown by the MIT team. Experimental details can be found in their report. According to the Internet, that report was published in Rev. Sci. Instrum. 73 (2002) 2597. But I did not check this. I simply went to Google, entered the "A modified accelerator for ICF diagnostic development" into the search box, and clicked on the first link to download the pdf file.

Inserted on 4/26/07:
a) The distances between the Am-241 source and the CR-39 chips were determined by numbers of iron nuts, each 5 mm thick, mounted on each other to support a detector. Alpha particles traveled along a tube formed by nuts. But energies in Figure 3 were estimated by using the range-energy relation. If I had a silicon detector I would measure energies as well. If the energy at d=5 mm were found to be 4.5 MeV, for example, rather than 4.0 MeV, then the energy scale in Figure 3 would changed accordingly. My subjectively estimated uncertainty (the location of 4.0 MeV with respect to d=0) is plus or minus 0.5 MeV.

b) Fortunately, such uncertainty does not weaken the initial conclusion -- pits whose diameters are 2.5 times larger than those due to alpha particles of Am-241 cannot possibly be due to alpha particles or lighter projectiles. Unfortunately, no comments concerning that conclusion have been posted on the CMNS list so far. I do not know how this should be interpreted. Does it mean that most subscribers consider my conclusion to be obvious or does it mean they did not read this unit? The posting of the unit was announced on the list and the URL was given. Steve Krivit was also informed about this unit.

c) Using a silicon detector to measure energies directly would increase the accuracy, in comparison with the method I used. And it would have another advantage; in addition to mean energies the distribution of energies would also be known. The ideal way to calibrate the CR-39 would be to use nearly mono-energetic particles form an accelerator. That approach was described in the 2002 paper of Roussetskii et al., downloadable from the library at http://lenr-canr.org .

d) My simple study was undertaken because I wanted to know what happens to pit diameters at very low energies. I was not aware of the existence of the curve shown in Figure 1 above. The location of the maximum on that Figure does not coincide with the location of the maximum in Figure 3. At least part of the difference is due to limited accuracy of two experiments. Fortunately, my conclusion about copious SPAWAR pits does not depend on the location of the maximum, it depends only on the relative sizes of pits at the maximum, in comparison with sizes of pits due to alpha particles from the Am-241 source.

Appended on 4/27/07:
Hmm, patent protection? If I were motivated by a patent I would unsubscribe from the CMNS list and would not talked at ICCF conferences. The list, as far as I know, consists mostly of people whose motivation is scientific. We are interested in the main CF claim -- a nuclear process, such as emission of neutrons or alpha particles, can be induced by a chemical process, such as electrolysis or diffusion. This is not patentable. The sounding board function is as important to us as the peer review is important to readers of a traditional journal.

325) Larry's Findings

Ludwik Kowalski; 5/12/2007
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, 07043

The May 10 issue of The New Energy Times, at

http://newenergytimes.com/news/2007/NET22.htm

contains an interview that Steve Krivit had with Larry Forsley. Larry was the first author of a SPAWAR team paper entitled "Time Resolved, High Resolution, Gamma-Ray and Integrated Charged and Knock-on Particle Measurements of Pd:D Co-deposition Cells." That paper was presented at the March 5 APS meeting in Denver, Colorado. Other authors were: P.A. Mosier-Boss, G.W. Phillips, S. Szpak, J.W. Khim, and F.E. Gordon. Larry's talk was based on twelve Power Point slides. Steve's interview was entitled "Charged Particles for Dummies: A Conversation with Lawrence P.G. Forsley." My purpose here is to make some comments on the content of slides, and on what was said in the interview. Please download Larry's slides from the above URL before reading the rest of this piece.

1) SPAWAR results were obtained by using a method of codeposition. That method, invented by Stanislaw Szpak and Pamela Mossier-Boss, has been used in numerous experiments during about ten years. The goal was to gather evidence that a nuclear process takes place during the electrochemical process of codeposition. But methods of detection were different in different experiments. Use of the CR-39 detectors was relatively recent and Larry became one of the partners. The content of Larry's slides is interesting but not everything is clear to me. I do not like the telegraphic style -- inevitable in a slide show -- I prefer traditional papers with illustrations.

2) On the slide #12 Larry states: "Tracks are not of chemical origin, although chemical damage may occur." I am glad that a possibility that some pits might not be due to nuclear projectiles is now recognized. That was the main point of my own APS presentation, as described in the unit #319. And what about the remaining pits? They do look like tracks of nuclear projectiles. Taking this for granted, Larry advances several interesting hypotheses. One of them is massive presence (about 75% of all tracks on the front surface) of low energy projectiles -- protons with energies below 0.5 MeV and alpha particles with energies below 1.5 MeV. These particles are stopped in the mylar foil of six microns. Another hypothesis is about presence of neutrons; they are said to be responsible for the tracks on the back surface.

3) Slide 1 is the title of the talk at the APS meeting. Slide 2 tells us that each field under the microscope is 0.6 by 0.5 mm. Thus, a chip whose size 20 by 10 mm, will have to be photographed 200/0.3=666 times. In practice this becomes 1000 times because some overlapping of fields is desirable. That is why the task of analysis is performed by a computer (TASL scanner) and not by a human being. But the scanner was not designed for very high densities, such as those discovered by the SPAWAR team. The dilemma of "what to count and what not to count" has been addressed and the software was set up to be very selective. Even a shadow of doubt was sufficient to assume that a pit is not a track. Larry found that the numbers of tracks per field, determined by visual inspection, were often ten times larger than what was determined by the TASL scanner.

4) Slide 3 shows range-energy relations for various nuclear projectiles in CR-39. According to these curves, expected nuclear projectiles would be stopped in CR-39 chips. This becomes important in the context of explaining presence of tracks on both sides of detectors. Slide 4 informs us that PACA detectors with mylar were used in a "dry experiment" by SPAWAR team. But, as far as I can tell, most data on other slides refer to "wet experiments," that is to experiments in which CR-39 were in the electrolyte. In the interview Larry tells us that track density is reduced considerably when

mylar film of 6 microns is placed between a wire and the CR-39 detector. It means, according to Larry, that protons with energies below 0.5 MeV and/or alpha particles with energies below 1.4 MeV are emitted from the cathodes. About 3/4 of all identified tracks are, according to Larry, due to these low energy projectiles. What is the difference between green and red rectangles on the right chip of slide 4? I do not know.

5) Slide 5 is not important. Slides 6 and 7, to which the first half of the interview was devoted, are indeed very interesting. They show that three different wires, Pt, Ag and Au were used as cathodes at the same time. For some reason track densities, on the back side of the chip, are different for different wires. Is this because each metal is chemically different or because contacts areas between the wires and the CR-39 chips were slightly different? Later in the interview Larry states that silver is "special." I am not convinced. The most interesting thing on slides 6 and 7 is presence of pits on the back side of the chip. They are more numerous than in the estimated background. That, according to Larry, is a clear indicator that neutrons are also emitted during the electrolysis. But why is the number of neutron-induced tracks, on the back of Ag, much smaller than on the back of Pt and Au? That is not clear.

6) Slide 9 tells us that only one neutron out of many (for example, out of 100,000) is actually detected. Multiplying numbers of pits displayed on the back of the chip (see Slide 6), by 100,000 I am inclined to think that the number of neutrons exceeds the number of charged particles. Is this consistent with the results obtained with two detectors of neutrons during one of the SPAWAR experiments? I do not know. For some reason nothing has been reported about what was learned from neutron detectors. Why is it so? I think that all experimental results should be reported. Another interesting thing, on slide 9, is a suggestion that neutrons of energies larger than 12 MeV can be detected not only via elastic scattering on protons but also via decomposition of C-12 into three alpha particles.

7) Slide 8 show distributions of pit sizes. The U-238 source was probably "thick;" otherwise the distribution of track diameters (actually major axes) would be narrower. Larry shows that dominant frontside pits have diameters between 6 and 16 microns. The dominant backside pits, on the other hand, have diameters ranging from 10 to 22 microns. That is indeed puzzling. Distributions of pit sizes, due to neutrons of various energies (between 1.2 MeV and 19 MeV), are shown on slide 9. They are taken from a 2004 reference. Were the etching condition in the reference the same as in the SPAWAR work? i suppose they were; otherwise comparing what is on the slide 8 with what is on the slide 9 would be meaningless. Larry thinks that large tracks, on the back side of the CR-39 chip, are due to high energy neutrons. That what I would expect if higher energy neutrons were main contributors to the neutron-alpha reactions.

8) Slide 10 compares tracks on the back of the SPAWAR chip with tracks due to neutrons from a Pu-238 source. Larry states that etching conditions were not identical; tracks from the Pu-238 experiment were etched about 25% longer that tracks from the SPAWAR experiment. Taking this under account, he concludes that sizes the largest tracks are roughly the same. Then he addresses the issue of smaller tracks. I agree with him that tracks due to neutrons would begin at different depths inside the chip. That would indeed produce a mixture of tracks of different diameters. In fact that is what I saw, several years ago, when chips irradiated with neutrons from a Pu-Be source were examined.

9) Slide 11 shows preliminary results deduced from gamma rays detected during the electrolysis. Larry identified them as coming from the Sr-92 and Zr-97. These are, presumably, transmutation products resulting from nuclear reactions induced by neutrons. The intensity of gamma ray radiation from the Sr-92 was found to be about ten times higher than from the Zr-97. This, according to Larry, is consistent with what one would expect if the numbers of atoms were identical. But he also mentions missing lines in the recorded gamma ray spectra. This weakens his argument about the presence of the above two radioactive isotopes. An identification is certain when all known gamma rays are present and when the rates of decay matchhttp://csam.montclair.edu/~kowalski/cf/325forsley.html the known values (2.7 and 16.9 hours). Why were the rates of decay not measured? I would make several measurements of counting rates, each lasting about 30 minutes, not 13 seconds. Perhaps they were looking for isotopes with much shorter half-lives.

10) How do SPAWAR results differ from the results of Richard Oriani? The most obvious difference is the number of tracks, and the fact that these tracks are concentrated near wires. Oriani-type clusters would be difficult to identify among the much more numerous pits produced in the SPAWAR codeposition experiment.

326) Online logbook of a PACA experiment

Ludwik Kowalski; 4/9/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction
This unit is the continuation of unit #320; please read unit #320 first. As you know, Oriani and Fisher wrote that the secret of reproducibility, in working with PACA detectors, is in a bit of hardware taken from a successful experiment. Oriani had eight consecutive successes because his cell was preconditioned to reproduce the effect. A success leads another success, he believes. He suggested that I incorporate the O-rings, and the mylar, that were used in his most successful experiment into my setup. These pieces of hardware were sent to me today (1/9/07). This unit will be the electronic logbook for the experiment that I will start very soon. I want it to be open to all who are interested. Hopefully, people will look into my reporting each day and make useful suggestions or critical comments. The experiment will probably last several days; this will be followed by the analysis of CR-39 chips, and possibly by additional control experiments. Entries of this unit will be numbered sequentially.

1) Anticipated protocol:
The goal is to replicate Oriani's experiment I will follow his procedure. The electrolyte will be Li_2SO_4 in light water (concentattion 20 grams per 100 cc). The cathode will Ni (wire whose diameter is 0.25 mm) and the anode will be Pt, more or less as in Figure 2 of unit #320. The exposed length of the cathode will be 2 cm and the constant current will be 25 mA, as recommended by Oriani today. I will have two cells in series; one made of glass (a replica of Oriani's cell) and another made from a polyethylene bottle (as described in the appendix -- see below).

Important insertion (5/1/07):
A serious mistake was made in the experiment described in this unit. The concentration of the Li2SO4 electrolyte in water was 9 times larger than that used by Oriani (it should have been 2.2 grams per 100 cc of H2O). Is this the reason why I was not able to replicate his results? Yes, that is a possibility. The mistake was discovered today, as I was examining my notes critically. The experiment with correct concentration, to be performed this week, will be described in unit #327. The CR-39 chip used in the new experiment will by about 3 by 3 cm.

2) Anticipated control experiments:
The most obvious control experiment, testing the radioactivity of the electrolyte (both as powder and after dissolving it in discilled water) are not necessary because I have already done this one and a half years ago. Alpha radioactivity from glass, from nickel and from platinum were also shown to be negligible. But I will perform these tests again if a significant excess of tracks is found (in comparison with background). I will also check for alpha radioactivity of mylar. Oriani urges me to begin the experiment as soon as possible because the O-ring and mylar might be loosing what is responsible for favorable conditions.

3) About statistical levels of confidence.
Suppose a Geiger counter is used to measure radioactivity from a weak source. One measurement, lasting two hours, gives N1=100 counts when the source is near the detector. Another measurement, also lasting two hours, gives N2=49 counts, when the source is removed. Is the difference 100-49=51 significant? And if so then what level of confidence should be assigned to this significance? That is well known problem. Knowing that distributions of results (if measurements were repeated many many times) are essentially Gaussian we estimate standard deviations as square roots of the numbers of counts. Thus S1=10 and S2=7. To simplify the problem slightly we use the mean standard

deviation, 8.5. The difference of counts, 51, is six time larger than standard deviation. That corresponds to a very high level of confidence. The well known rule is that, for example, the level of confidence is about 99.7% when (N1-N2)/S is equal to 3. According to statistical tables, the level of confidence becomes higher than 99.999% when the ratio is 6.

But that kind of analysis would be questionable, for example, if the electronic threshold of detection were not very stable, or if the high voltage fluctuated during each experiment. Under such conditions the S=sqr(N) would be strongly underestimated. It is conceivable that by repeating each measurement many times one could find that S1=60 and S2=50. Now the mean S is nearly the same as the difference between the mean values of N1 and N2. The level of confidence, in such case, becomes 68%.

A well designed Geiger counter is usually more stables than in the above illustration. But the illustration has a pedagogical value. Suppose that a measurement lasting four days yielded N1=100 tracks in the post-electrolysis chip and only N2=49 tracks in the control chip. I am assuming that chips were etched identically and that their areas are identical. How to estimate standard deviations. This if far from being obvious because of the “count or not to count dilemma. I know from experience that in addition to tracks of nuclear particles the surface of an etched CR-39 chip displays other defects, some of them do not resemble tracks while others resemble them. It is very difficult to be consistent about what to count and what not to count. This is equivalent to a Geiger counter fluctuating threshold of detection.

Ideally, the values of N1 and N2 should be determined by several, for example ten, equally trained people. This would allow one to calculate mean values of N and corresponding standard deviation. The alternative, which I will use, is to count how many times, N’, the “to count or not to count” hesitations were encountered. A typical example might be N1=100 with N’=60 and N2=49 with N2’=20. In that example I would assume, arbitrarily, that S1=60 and S2=20. Note that the mean S’=40 is not very different from the N1-N2=51. Also note that N1’ and N2’ would probably not be very different if the N1 were much larger, for example, 300. In that case the ratio of (N1-N2)/S’ would be 251/40=6.3 and the level of confidence (believing that the effect is real) would be very high. All this simply illustrates the obvious, the value of S must be estimated and the (N1-N2)/S must be large to be certain that the effect is real.

I know from experience that S is often not very different from N2/2. Taking this for granted, one has the following table for the levels of confidence:

99.7% confidence when N1/N2 =2.5
95% confidence when N1/N2 =2.0
68% confidence when N1/N2 =1.5
0% confidence when N1/N2 =1.0

In other words, under specified assumption (to be verified each time) the number of tracks in the post-electrolysis chip must at least twice as large as on the control chip. Otherwise the level of confidence (in claiming that the effect is real) becomes questionable. In a much more favorable case, when the “count or not to count” dilema is faced in only 10% of counting for N2 (instead of 50%, as above) one has:

99.7% confidence when N1/N2 =1.3
95% confidence when N1/N2 =1.2
68% confidence when N1/N2 =1.1
0% confidence when N1/N2 =1.0

The above is true when only the “count or not to count” uncertainty is responsible for random fluctuations of experimental results. And only when results are qualitatively reproducible. Random fluctuations contribute to limited precision while systematic errors, for example personal bias in dealing with the “count or not to count” dilemma, contribute to limited accuracy. It is very difficult not to be biased when one knows what is at stake. The way to avoid personal bias is to have an assistant who does not know what is better, too many tracks or not enough tracks. Fortunately, I am trying to replicate experiments in which N1 was always at least ten times larger than N2. Therefore I do not have to worry about gray areas in which statistics becomes intolerably sadistic.

4) Experimental setup

- - - - -

The geometry of cell #1 is essentially the same as shown in Figure 2 of unit #320. But geometry of the cell #2 is slightly different. The bottom of the cell is the bottle cap. Inside that cup is one CR-39 chip (area 2 cm2); it is protected from the electrolyte by a mylar film. As in the cell #1, the anode-cathode system, shown below, is rigid. It stands on the nickel cathode (a foot), supported by CR-39, below the mylar film. A large copper ring fits loosely inside the bottle. The nominal thickness of my mylar, 6 microns, corresponds to the surface density of 0.84 g/cm2 (based on the mylar's density of 1.4 g/cm3). This is small in comparison with ranges of alpha particles of 2 and 6 MeV (1.10 mg/cm2 and 5.14 mg/cm2, respectively, according to "Charged Particles tracks in Polymers" by R.P. Henke and E.V. Benton, 1966.)

- - - - - - - - - - - -

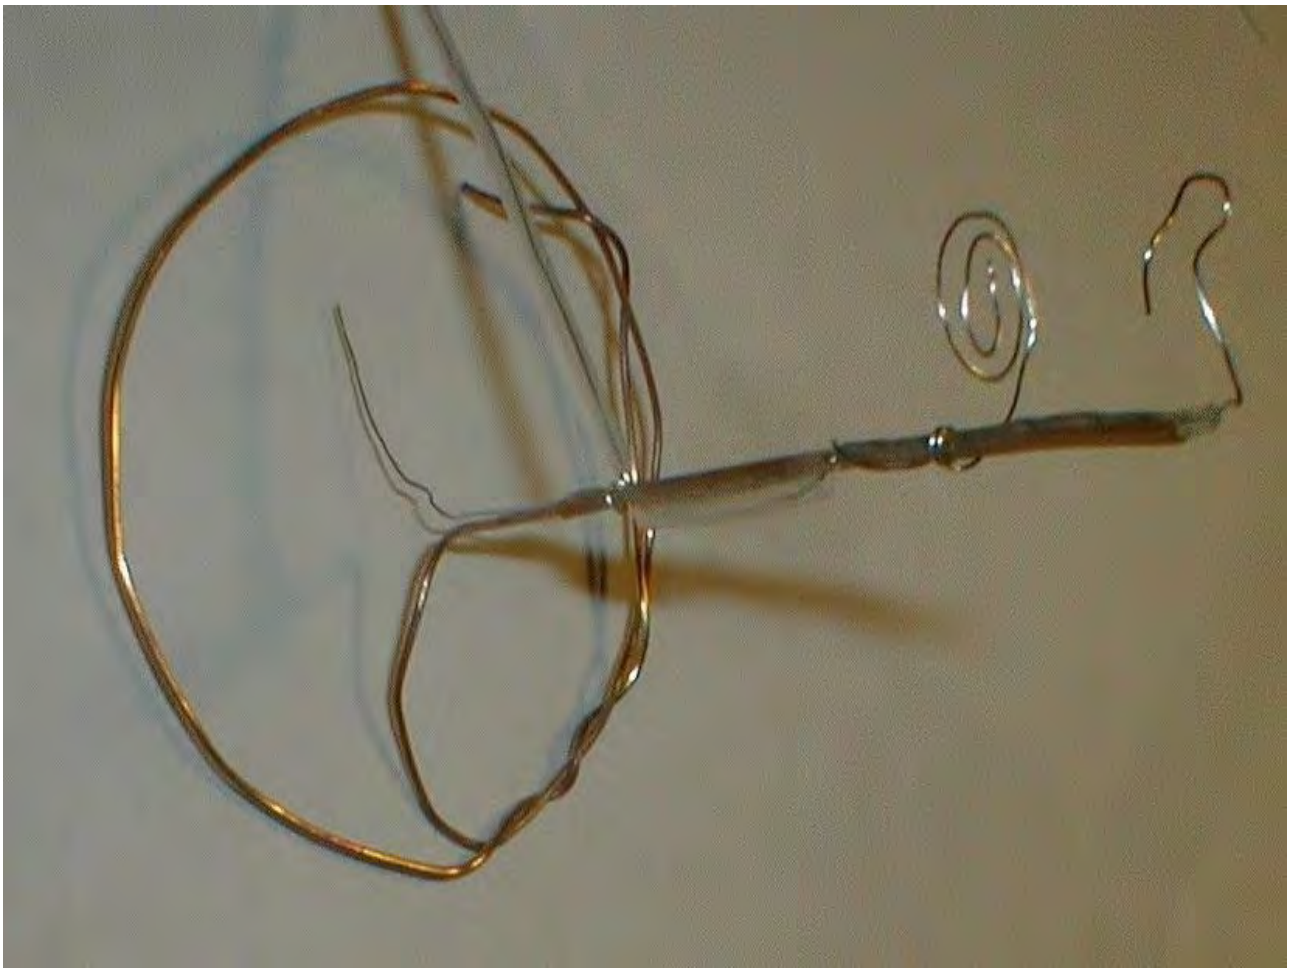

Figure 1

The rigid cathode-anode setup for the cell #2. The end of the nickel wire, near the upper right corner, is going to be the foot, standing on mylar above the CR-39 chip. Only 2 cm of that wire is outside the heat shrink. The other end of the cathode wire will comes out of the heat shrink above the electrolyte. A thick copper wires also inside the heat shrink. But it is not in contact with the electrolyte. The purpose of this wire is to provide rigidity, in the form of the large circle, inside the bottle, The spiral platinum anode is mounted on the heat shrink column; its distance from the cathode (foot) is 22 mm. Diameters of the Ni and Pt electrodes are 0.25 mm.

.....

5) It is 4/12/07; I was ready but . . .

The two O-rings that Oriani sent me arrived today. So I started preparing cell #2 (made from the bottle). I am using a new mylar film. Here are labels of my CR-39 chips:

1) Chip below the mylar film (the cathode wire is on top of it) -- 8810900
2) Control chip (blank) in the next room -- 8810888
3) Chip outside the cap -- 8810896
4) Chip outside the cap (below it) -- 8810901

5) Chip outside (on the conical part of the bottle -- 8810891
6) Chip outside (about 60 mm above the cathode)

The cell has been positioned and connected to the cirquit. But it is still empty. Then I started preparing the cell #1 (replica of Oriani's cell). The mylar film has dark spots on it, probably some kind of dirt from the experiment in which it was used. At that moment I decided not to start the experiment today. I took another CR-39, chip 8810899, and wrapped the mylar around it. It would be a big mistake not to check for alpha radioactivity on mylar foil. I know that Oriani already did this; but it is a good idea to make another check. I will start the experiment tomorrow, without etching this last chip. It will etched with all other chips, probably in one week or so. It will exposed to Oriani's mylar for only 12 hours. The mylar in cell #2 is not going to be tested for alpha radioactivity before the experiment. I can do it later if a lot of tracks are found.

6) Observations during the electrolysis:
a) The CR-39 that was exposed to Oriani's mylar was put into another room (where the balnk chip is kept). Am-241 was used to irradiate a chip (half of it through one layer of mylar). The cell #1 has only two chips, one about 2 mm below mylar and another on the outside glasss wall. The center of that chip is at the level of the anode.

b) The electrolysis stareted, with two cells in series, at 13:45 of 4/13/07. With the current of 25 mA the potential differences were 4.49 V and 4.17 V, on cells #1 and #2 respectively. Bubbling of hydrogen and oxygen is not very intensed.

c) One hour later. All is about the same. Below is volt-amp lines for my two cells. They were taken at about 2:00 p.m. I suppose that the common intercept, at about 3 volts has something to do with work functions; two cells are chemically identical. Small differences in slopes are are probably due to differences in geometry inside the Li_2SO_4 electrolyte.

- - - - - - - - - - - - - - - - - -

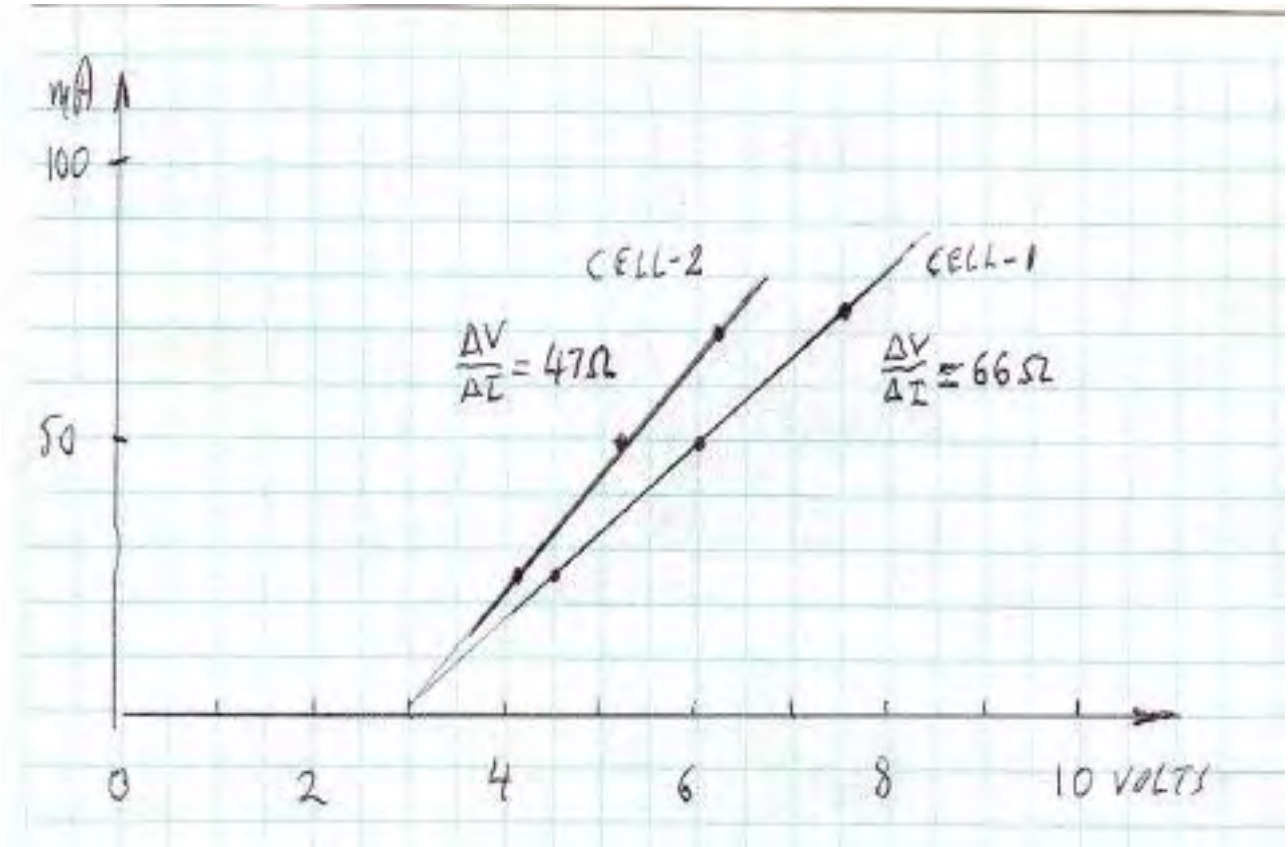

Figure 2
The volt-amp lines for my two cells.

- - - - - - - - - - - - - - - - - -

d) 4/14/07: I forgot to mention that no electronic current stabilization is used in this experiment. But everything is very stable. Loss of water has been small so far. Here are the values from my notebook:

4/13/07 --18:00 -- 25 mA, -- 4.44 V and 4.08 V
4/13/07 --21:00 -- 25 mA, -- 4.42 V and 3.98 V
4/14/07 - - 5:30 -- 25 mA, -- 4.49 V and 4.05 V
4/14/07 --10:30 -- 25 mA, -- 4.43 V and 4.02 V
4/14/07 --12:00 -- 25 mA, - 4.38 V and 4.05 V ..... adding 1 cc of water to each cell
4/14/07 --12:30 -- 25 mA, - 4.43 V and 4.02 V

My milliammeter is analog and fluctuations of up to one or two mA might remain unnoticed. The current 25 mA is used because it was Oriani's last recommendation.

e) An observation: Tiny bubbles continuously rise up, like a cigarette smoke, toward the surface. Occasionally large bubbles appear. I have seen this many times before. But my cell #2 is very wide and I discovered something peculiar. Big bubbles, above the spiral Pt anode suddenly, yes very suddenly, stop rising and turn toward the wall of the bottle, or toward the heat shrink tube. It seems that they are attracted toward the plastic maescape from the electrolyte at once, like tiny bubbles?
terial. After traversing at least 1 cm of the electrolyte (sometimes 2 or 3 cm), the bubbles stick to the surface and remain there for long time, for example an hour or more. Their sizes are between 1 mm and 3 mm. At any given time I can see at least 20 or 30 bubbles. Why large bubbles are formed during the electrolysis? Why do they not
g) It is 8:00, Monday, 4/16/07. No significant changes in the current and voltages. The cell #2 needs more water to compensate for more evaporation from its much larger surface, in comparison with the cell #1. Losses due to electrolysis are probably identical because the same current flows through two cells.

h) It is 23:00, all as before. My notebook has many nearly identical lines, like those on the first day.

i) It is 10:20, Tuesday, 4/17/07. Oriani suggested to run the experiment for four days. That means I have about 3 more hours. But I am tempted to add another day, at much larger current. This will not destroy tracks that are already on The chips. The only disadvantage will be loss of information about when the tracks were formed. But that does not matter. At this stage I just want to see a lot of tracks with my own eyes. I would not mind performing several additional experiments, one for each current, if this two-in-one experiment produces the same result as Oriani's experiments.

j) Tuesday, 4/17/07; last line before going to the higher current.

4/17/07 --9:30 -- 25 mA, - 4.42 V and 3.98 V (total duration nearly 4 days, 92 hrs)

k) Increasing the total voltage to get higher current
4/17/07 -- 9:44 -- 150 mA -- 10.03 V and 8.17 V
4/17/07 -- 10:12 -- 150 mA -- 9.34 V and 7.86 V
4/17/07 -- 10:30 -- 150 mA -- 9.50 V and 7.79 V
4/17/07 -- 16:40 -- 168 mA -- 9.60 V and 7.93 V
4/17/07 -- 17:00 -- 150 mA -- 9.36 V and 7.35 V
4/17/07 -- 17:45 -- 150 mA -- 9.86 V and 7.42 V (Stop electrolysis. 92+8 = 100 hrs)

Note that 8 hrs at 150 mA --> 48 hrs at 25 mA (same number of coulombs).

7) Dismounting the cells.
a) The CR-39 below mylar were found to be dry below each cell. That is VERY GOOD.
b) In cell #1 (glass) only a small part of cathode (perhaps 3 mm) was in contact with mylar because the foot was nos not horizontal.
c) The cathode in cell #2 was nearly horizontal. That means the contact between the cathode and the mylar was probably on about 10 mm of the wire.

d) Visual examination of chips (before etching) did not reveal anything abnormal.

- -

Figure 3
Cell #1. Two O-rings and the 6 micron mylar film (received from Oriani) are located between two parts made from glass. Cell #2 is not shown because it is just a polyethylene storage bottle with a removed lower part, as described above. The coin leaning on the cell has the diameter of 25mm. Let me add that glass components of Oriani cell can be ordered from: http://www.kimble-kontes.com/html/pg-671750.html The inner diameter of tubes are close to 16 mm.
- -

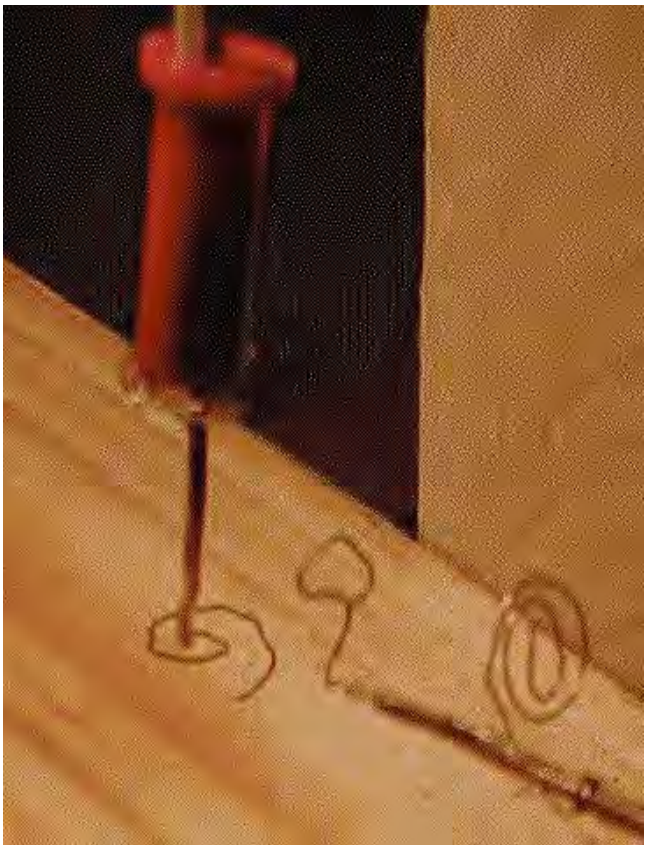

Figure 4
The rigid cathode-anode setups for two cells. The setup from the cell #1 is on the left (vertical) while the setup from the cell #2 is on the right (horizontal). Spiral anodes can also be seen.

8) Etching:
(NaOH at 6.25 N, temp ~73 C) 6 hours.

9) Results:
a) Executive summary: Nothing above background.

b) Detailed results of counting:
Chip exposed to Am-241 -- numerous tracks, as usual
Chip 8810-0888 (blank, 1.8 cm^2) 9 tracks on the labeled side and 4 on the other side.
Chip 8810-0899 (15 hrs exposure to Oriani's mylar, 1.8 cm^2) 5 tracks on the labeled side and 4 on the other side.

Chip 8810-0888 (PACA chip, 0.9 cm^2, below mylar cell #1) 4 tracks on the labeled side and 7 on the other side.
Chip 8810-0900 (PACA chip, 1.8 cm^2) below mylar cell #2) 11 tracks on the labeled side and 8 on the other side.

Chip 8810-0898 (1.8 cm^2, chip outside cell #1) 5 tracks on the labeled side and 4 on the other side.
Chip 8810-0891 (1.8 cm^2, chip outside cell #2, lower) 4 tracks on the labeled side and 14 on the other side.
Chip 8810-0885 (1.8 cm^2, chip outside cell #2, higher) 8 tracks on the labeled side and 8 on the other side.

10) Discussion:
I do not know why my three consecutive attempts to replicate Oriani's results were not successful. Something essential must be present in his cell but in my cells. How else can this be interpreted? Will other TGP researchers, still conducting experiments, be more successful? That remains to be seen. For some reason the CMNS list for cold fusion researchers is silent about TGP experiments performed in March and April.

11) Inserted on 4/19/07:
From a private telephone conversation with Oriani I heard about another spectacular result. He is now investigating the effect of another parameter. Meanwhile he asked me to put the CR-39 between the O-ring for several days. I started this experiment today.

12) Appendix :
The easiest way to describe my polyethylene cell is to reproduce a message that I posted several days ago, on a private list for CMNS researchers. Here it is:

POSITIVE RESULTS WITH A DIFFERENT BOTTLE ! THANKS KEVIN.

On Apr 5, 2007, at 11:06 AM, Ludwik Kowalski wrote:

2) In a private message to me a TGP researcher wrote: "Ludwik, Thanks for suggesting this very low-tech way to make a cell with Mylar protecting the CR-39 in the screw cap of a vitamin bottle. Upon having a repeatable result, this could be a simple setup for others to duplicate without machine tools or laboratory glassware. Have you leak-checked it yet?" Well, the test performed yesterday turned out to be negative. Water did manage to leak (during the night) into the space that was expected to remain dry. Perhaps the cap was not screwed strong enough. I will try again, also with water (and with dry tissue instead of CR-39). Please join me in the effort to offer a simple setup for students and teachers. Weeks ago Scott reported on using the epoxy glue. That is worth trying.

Here is my original description:
a) Take a small plastic bottle with a screw-top lid. I am experimenting with a bottle in which vitamins are sold in the USA.
b) Using a knife, remove the bottom from the bottle (the created opening will become the top of your cell).
c) Place the CR-39 detector into the lid.
d) Cover the detector with the six-micron-thin mylar foil (~ 5 by 5 cm) and screw the bottle into the covered lid.
e) Gently pour the electrolyte into the bottle. The electrolyte will not be in contact with CR-39.
f) Mount the electrodes (more or less as in Figure 2 mentioned above) and start the experiment.

I mentioned the 2-HDPE label on the bottle. Francis Tanzila commented: "2-HDPE is a grade of high density polyethylene and the white pigment is probably TiO_2. These should be fine with Li_2SO_4 but I would look for an un-pigmented plastic bottle just to be safe."

The second test (a better bottle) turned out to be positive. Here are details, for those who might be interested:

a) The vitamin bottle cap used in the first test was wider than the cup on the new bottle -- inner diameter 45 mm versus 29 mm.
b) The first cap takes only about 150 degrees to either screw or unscrew it. The second cap takes slightly more than 360 degrees.
c) The second cap has an O-ring-looking plastic rim at the bottom, to seal the bottle very well. That built-in plastic O-ring was probably the most important contributor to my success.

The material is "high density polyethylene" but without pigment. It is a standard 500 cc bottle used by chemists; the inner diameter 70 mm. Such storage bottles can be purchased from any supplier of chemical hardware. I used the same mylar sheet that failed in the vitamin bottle test. First I had a column of water of 5 cm. I emptied the cell after 6 hours and found that the mylar-protected tissue was dried. Then, using the same mylar sheet, I increased the height of the water column to 9 cm. This test was also positive, after another 6 hours. The 500 cc bottle is probably too large for our purpose. But that what they use in our chemistry lab.

327) Oriani's effect in Phase 2

Ludwik Kowalski; 5/2/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction:
This unit is continuation of what was in unit #326. In what follows I will assume that the reader is familiar with the content of units #320 and #326. About a week ago I asked myself about what to do next. The idea to abandon TGP work did come to my mind. But that would not be consistent with my goal -- to reach a clear positive or negative conclusion about the SPAWAR claim. The only conclusion I reached so far is that prominent SPAWAR pits cannot possibly be attributed to alpha particles, or lighter projectiles. That is only a small fraction of pits produced during the electrolysis. Oriani claims that some smaller pits are tracks of nuclear particles. He told me that nineteen consecutive experiments convinced him that a nuclear effect is induced during the electrolysis. Several days ago he had only seventeen results, as shown in the table below.

That table was posted on the private list for CMNS researchers. Column A shows the experiment number and column B shows which cell was used. Column C shows the current or currents (in mA) used in the experiment. Column D is the duration of the electrolysis, in hours. Columns E and F show track densities. The first track density (column E) refers to the CR-39 surface that was facing the mylar and the electrolyte The second track density (column F) refers to tracks on the opposite side of the CR-39 chip. The area, on each side of the chip, over which tracks were counted was close to 10 cm^2. Thus numbers in columns E and F must be multiplied by 10 in order to estimate the actual number of counts on each side of the CR-39 chip. According to Oriani, tracks are often clustered; the numbers in columns E and F refer to mean track densities.

The first eleven experiments were made by using the CR-39 in which the mean background density was 26 tr/cm^2 (st.dev. 12). The last six experiments were performed by using the CR-39 in which the mean background density was 12 tr/cm^2 (st.dev. 6). The last column, G, shows the signal to noise ratio -- ratios of numbers from columns E and F divided by mean background densities. A symbols cb indicates that the surface was coated by a layer of blue plastic that stops alpha particles of up to 10 MeV. The symbol D (experiment 15 and 17) indicated that a small container with heavy water was located below the cell and the detector. In experiment #3 the chip was lost before the actual counting. The >100 and >100 are estimates based on preliminary quick examinations.

A	B	C	D	E	F	G
		mA	hrs	tr/cm^2	tr/cm^2	sign/noise
1	S	.2 to 25	168	209	163	8.0, 6.3
2	S	.1 to 45	120	144	120	5.5, 4.6
3	S	12,41,100	101.5	>100	>100	>3.8, >3.8
4	S	70,117,143	67	162	96	6.2, 6.7
5	S	30,75	96	267	289	10.2, 11.2
6	S	50	97	75	39	2.9, 1.5
7	S	5,10,25,50	96.5	151	75	5.8, 2.8
8	S	10,25,75,100	94	120	81	4.6, 3.1

9	S	300	65(?)	48	42(cb)	1.8,	1.6
10	B	10,25	98	74	22(cb)	2.8,	0.8
11	S	12,28	97	234	40(cb)	9.0,	1.5
12	S	20	95	35(cb)	78	2.9,	6.5
13	B	27	95	--(cb)	778	*,	64.8
14	S	20	94	43	104	3.6,	8.7
15	B	19	94	97	323(D)	8.1,	26.8
16	S	40	94	26(cb)	87	2.2,	7.2
17	B	39	94	264	200(D)	22.0,	16.7

These results are really impressive. After talking with Richard on the phone I decided to follow his new protocol in order to obtain similar results. Following Oriani's footsteps I will again use a PACA (protected against chemical corrosion) CR-39 detector. Note that three previous attempts to use these detectors yielded negative results. Our first PACA detector was used in the SPAWAR electrolyte, our second PACA detector was used in Oriani's electrolyte, as described in the unit #320. The third experiment was described in unit #326. Unfortunately, due to an error, the Li2SO4 electrolyte, used in the third experiment, was about ten times more concentrated than Oriani's electrolyte. That might be a reason for failure to replicate Richard's results. Another reason for the failure might have to with the small size (only 0.9 cm^2) of our CR-39 detectors located below the mylar inside the cell tube.

Time zero; starting the experiment (13:00, May 1, 2007):
The initial concentration of the electrolyte is the same as in Oriani's cells (2.0 grams of Li2SO4 in 100 cc of distilled H2O). I am using a 3 by 3 cm CR-39 chip that Richard sent me. The current is 41 mA; it is kept constant with the TL317T operational amplifier, as described in the unit #319. The potential difference on the cell is 6 volts. I know from experience that fluctuations of the cell current are small when a constant difference of potential is applied to it. That is why I think that using the TL317T is not essential in this experiment. I am using the operational amplifier because I have it. The cell has been operating for three hours.

Time=22 hrs (11:00, May 2, 2007):
Oriani suggested that I stop adding water to compensate for losses. He allowed the concentration of the electrolyte to increase during each experiment. The rate at which the level of the electrolyte is going down is not high enough to reach the anode in four days. The inner diameter of the cell is close to 16 mm.

Time=32 hrs (21:00, May 2, 2007)
All is stable. Let me describe the control experiment, also in progress since yesterday. The second large CR-39 chip, sent to me by Richard, has been squeezed between two O-rings far away from any electrolytic cell. The blue protective cover has not been removed from that CR-39 chip. I just want to have experimental evidence that pressure alone cannot be responsible for clusters of pits on both CR-39 surfaces. The control experiment O-rings are pressed toward each other by two flat wooden plates (using four small bolts with nuts). Both large chips will be etched at the same time in the same solution. I forgot to mention that one little corner (about 2 mm^2) of my experimental chip has been exposed to alpha particles from the Am-241 source. That will allow me to compare sizes of pits, after identical etching conditions.

Time=45 hrs (10:00, May 3, 2007)
I noticed that the the cell potential is no longer 5.96 V; it is 5.86. V. At least part of this is likely to be due to changes in the room temperature (probably by no more than 5 C). But this is also consistent with the fact that the concentration of the electrolyte (ion density) increases. The potential would not change if water was added to keep the concentration constant. The current is constant because I am using the TL317T stabilizer. Otherwise the current would go up and I would have to lower the potential, to bring the current back to 41 mA. That is the advantage of the stabilizer. But such

advantage would be only important if keeping the current at exactly the same value were important. Oriani's data (see the table above) seem to indicate that the effect does not depend on the current. The cell potential is nothing else but I*R, where R is its electrical resistance, for a given ion density.

Time=53 hrs (18:00, May 3, 2007)
The level of the electrolyte keeps going down and the cell potential decreases; it is 5.75 V now.

This morning, while cleaning my digital desktop I discovered a piece of text that was composed before Oriani's table (see above) was posted. I simply forgot about this draft; it should have been appanded to unit #326. It describes control experiments performed after my unsuccessful attempt to replicate Richard's results with a small CR-39 chip. Note that in the experiment described in unit #326 only mylar was squeezed between the two O-rings sent to me by Oriani. That CR-39 chip was not squeezed, it was resting on a solid support, about 2 mm below the mylar film. I wrote:

"After learning about my negative results, Oriani asked me to apply the CR-39 to his O-rings for 4 days. He also asked me to take the CR-39 that was below his mylar (in the experiment described in unit #326) and etch it again. After four days the three chips that were in contact with O-rings and the previously etched chip were etched for 5.75 hours.

(a) Chip that had 7 and 4 tracks after 6 hours of etching, had 14 and 7 tracks after additional etching. I think that this is not significant because of the frequent "count-or-not-to-count" dilemma.

(b) Chip #1 (2 cm by 0.5 cm) applied to O-rings; 8 pits on one side, 5 on the other.
(c) Chip #2 (2 cm by 0.5 cm) applied to O-rings; 3 pits on one side, 6 on the other.
(d) Chip #3 (2 cm by 0.5 cm) applied to O-rings; 8 pits on one side, 6 on the other.
(e) Chip #4 (2 cm by 0.5 cm) blank; 2 pits on one side, 4 on the other side.

In other words, additional etching did not reveal more tracks than the first etching. In all cases there were nothing but usual background. These results convinced me that Oriani's was correct in claiming that O-rings were not contaminated by something alpha-radioactive."

Time=58 hrs (23:00, May 3, 2007)
About 25% of water has been lost (electrolysis + evaporation), The cell potential is 5.65 V.

Time=68 hrs (9:00, May 4, 2007)
The cell potential is back to 5.86 V. That is not what I expected. The current remains the same as it was at time zero.

Time=76 hrs (17:00, May 4, 2007)
The cell potential is 5.54 V. The current remains the same as it was at time zero. I suspect that presence or absence of a large bubble, just below the anode, is responsible for fluctuations of the resistance of the cell. Bubbles are sometimes grow slowly below the anode, before escaping. I did not pay attention to this before.

Time=90 hrs (7:00, May 5, 2007)
The cell potential is 5.56 V.

Time=95 hrs (12:00, May 5, 2007)
The cell potential is 5.38 V. In one hour it will be four days. Instead of finishing at that time I plan to do the following.

(a) Disconnect the current stabilizer and collect data on the mA versus volts.
(b) Add water, to find our exactly how much was lost in four days.
(c) Collect data on current versus volts for the original concentration.
(d) Restart the electrolysis at higher current, for example 100 mA, till tomorrow.
(e) Etch both CR-39, post-electrolysis and control.

What else is worth doing? I will examine the chips next week.

Time=97 hrs (14:00, May 5, 2007)
The cell potential is 5.57 V. I am going to perform a, b, and c, as described above.
It is now 14:10 and I am at point d (see above). The current is 160 mA and the cell potential was 16.2 V at the first moment. But now it is 13.2 V while the current is 150 mA. It fluctuates, probably due to bubbles.

The amount of water lost in 4 days was about 2.75 cc. Taking the Volts-Amps data showed that things are not simple. For some reason the curve seem to be nearly the same at both concentrations. I am not sure because of the hysteresis effect -- coming to 10 V from below does not give the same current as coming to it from above. I do not want to deal with this; it is not my area. Roughly the R is about 90 ohms. But this seems to depend on many factors. Fortunately, it does not matter. I will keep the current more or less constant by manually adjusting the power source voltage.

Time=~0.5 hrs (14:30, May 5, 2007)
All seems to be going on smoothly. I=160 mA at 12.5 V

Time=2 hrs, 16:00; 5/5/07
All is fine, only small corrections of voltage (up to about 10%) have to be made from time to time. If I do not make them then the current fluctuates slightly. But this is OK; Oriani does not claim that the effect occurs at specific currents. But he said that the experiment with I=300 mA did not produce good results. Recalling this, I decided to lower the current. At t=2 hrs the potential difference was reduced to 8.10 volts and the current became 80 mA. This is only two times larger than the current I used in the first 4 days.

Time=6 hrs, 20:00; 5/5/07
Current 80 mA, potential 8.02 Volts.

Time=18 hrs, 8:00; 5/6/27
Current 85 mA, potential 8.3 Volts. I will bring the current back to 80 mA now. The increase of current was qualitatively consistent with a significant loss of water, about 20% or so.

The increase of current was qualitatively consistent with a significant loss of water, about 20% or so. This morning I informed the CMNS list that my experiment will end this afternoon. In that message I asked for advice on what else should be done before this to maximize the amount of information. Here is a reply from Scott Little. My only suggestion is that you take care to handle the CR-39 from this experiment very gently. It is surprisingly easy to make tiny scratches in the surface of CR-39 and scratches will often produce pits upon etching. We will be starting our version of this same experiment early next week.

That is great; nothing is better than a situation in which several laboratories are performing the same experiment. That is the only way to find hidden truth, and to validate a scientific claim. Hidden truth about “cold fusion” does not depend on our wishes. It exists and scientists try to discover it. Then they try to validate what has been discovered, according to well established rules. I think we are following these rules correctly. We are not pseudo scientists, as many believe. We know how to distinguish wishful thinking from objective reality. The rules of the game have been established long time ago and most of us are simply following them. Pseudo scientists are those who refuse to learn about current investigations conducted by qualified researchers, not those who are trying to either confirm or refute various claims.

Why did I put quotation marks around cold fusion? Because we have no evidence what kind of nuclear process we are trying to validate. Fusion of two independent atomic nuclei is only one mechanism. That is why the term cold fusion is now often replaced by CMNS (condense matter nuclear science), LENR (low energy nuclear reactions) and CANR (chemically assisted nuclear reactions). My preference is CANR because the central issue is, as it has been since 1989, reality of a strong nuclear process triggered by a much less strong chemical process. If reality of such process is established then scientists will try to understand it. I would not be surprised to learn that there are different “cold fusion” phenomena. Replicability is essential at this stage of the game. That is why I am so happy that Scott and Marissa are also going to perform the same Oriani’s experiment.

Time=20.5 hrs, 10:30; 5/6/07

The current is still 80 mA, potential 7.96 Volts.

Time=24 hrs, 14:00; 5/6/07
The current is 80 mA, the potential is 7.95 Volts. The electrolysis will be ended in two hours.

Time=26 hours, End of electrolysis.

The current was 80 mA, the potential was 7.97 V. The total electrolysis time was four days at 41 mA, one day at 80 mA and two hours at 160 mA.

I will continue reporting in this unit.
= =

1) Etching of two large CR-39 chip (post-electrolysis and control) started at 16:15. Before etching the corner of the control chip was irradiated with alpha particles from my Am-241 source. Two scratches were made near that corner, on the same side that was exposed to alphas. Following Scott's advice, I skipped the cleaning with the toothbrush step. I know it does not create scratches but . . .

2) Etching (in NaOH 6.25 N) took 6 hours. The temperature fluctuated between 73 and 75 C; most of the time it was at 74 C. Tomorrow I will go to school and examin the chips.

3) The first thing I did was to count tracks on the control chip. My fear was that I might discover them. That would indicate that an artifact (mechanical pressure) is responsible for Oriani's successes. There were twenty of them, he told me today. I was afraid because CR-39 chips are usually not used under pressure, just as they are normally not used in electrolytes. The result was reassuring. I counted 8 pits on one side of the chip and 16 on the other. These numbers were highly inflated because I was very very generous in deciding what to count as pits. By my usual criterion the count would be 3 and 6. The chip area was 9 cm^2 and this amounts to 2 tr/cm^2 or 0.5 tr/cm^2. No matter how I count the result is much lower than the expected background (mean=12 and st.dev.=6).

On that basis I decided to start another experiment; what was the control chip became the experimental chip. The new experiment started at 18:15 today (5/7/07). Marissa Little also received large CR-39 chips from Oriani, plus the O-rings and mylar. These were used by him up to last Saturday morning. They also started the experiment today. I am using the same cell, the same O-rings, the same mylar, and the same electrolyte as in the previous experiment. The current is again 41 mA; the cell potential is 6 V (the power supply potential is 15 V. Will the results will be equally spectacular? I will probably know next Monday.

4) After examining the control chip I started to examine the post-electrolysis chip.

= = = = = = = = = = = = = = =

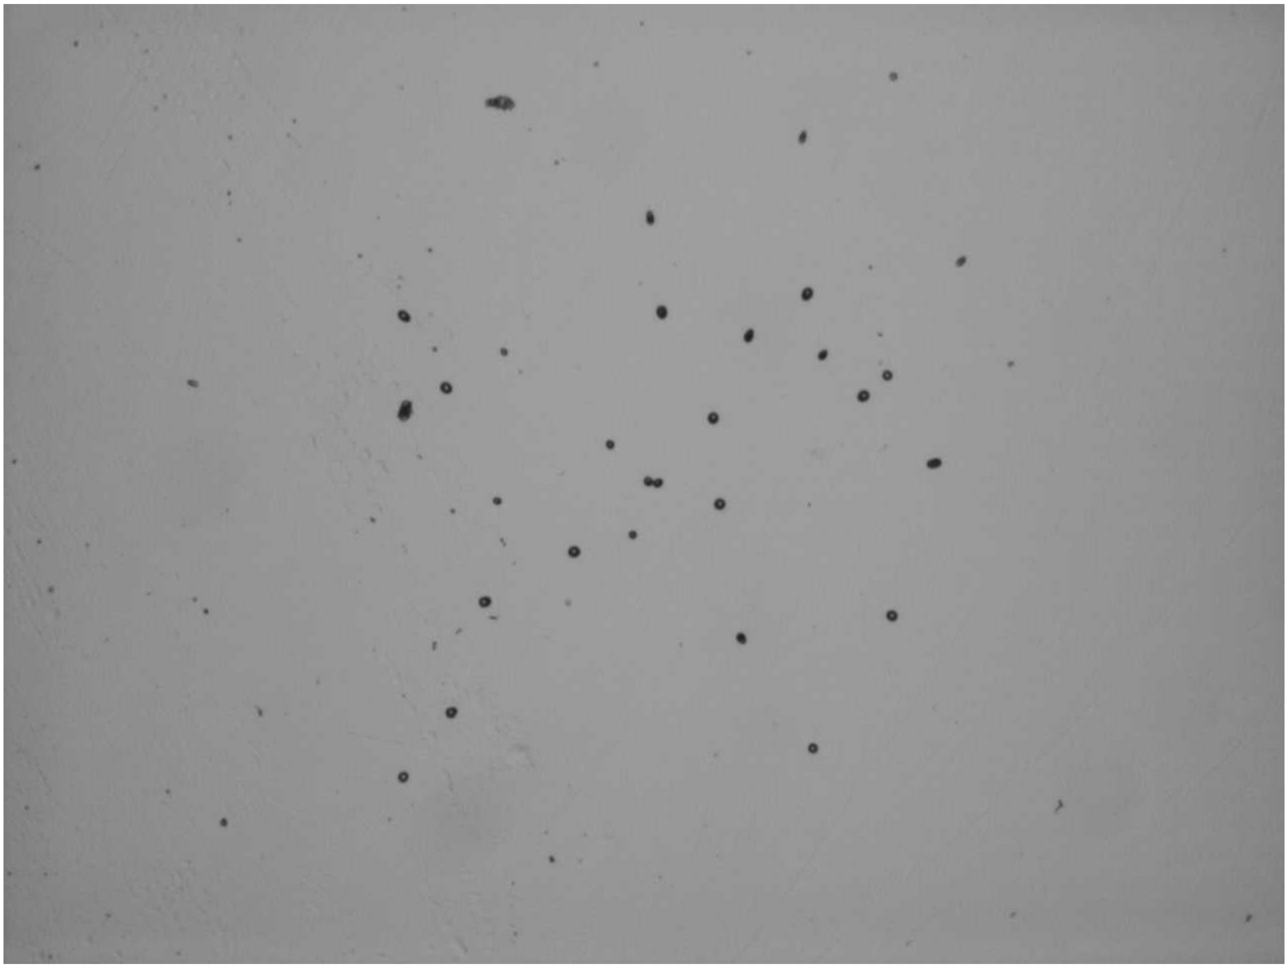

Figure 1
A small cluster of tracks. Magnification 40. The photographed area is about 1.3 mm by 1.0 mm
= =

The figure above is a cluster of 29 tracks which could be due to alpha particles, and several smaller tracks that can be due to protons. What is remarkable is that the cluster is surround by fields without tracks. The mean track density, over the area of Figure 1 is close to 23 tr/mm^2. This is 2300 tr/cm^2. The track density in the surrounding area is only about 6 tr/cm^2. The next figure shows tracks due to alpha particles from the Am-241 source, under identical etching conditions.

= = = = = = = = = = = = = = =

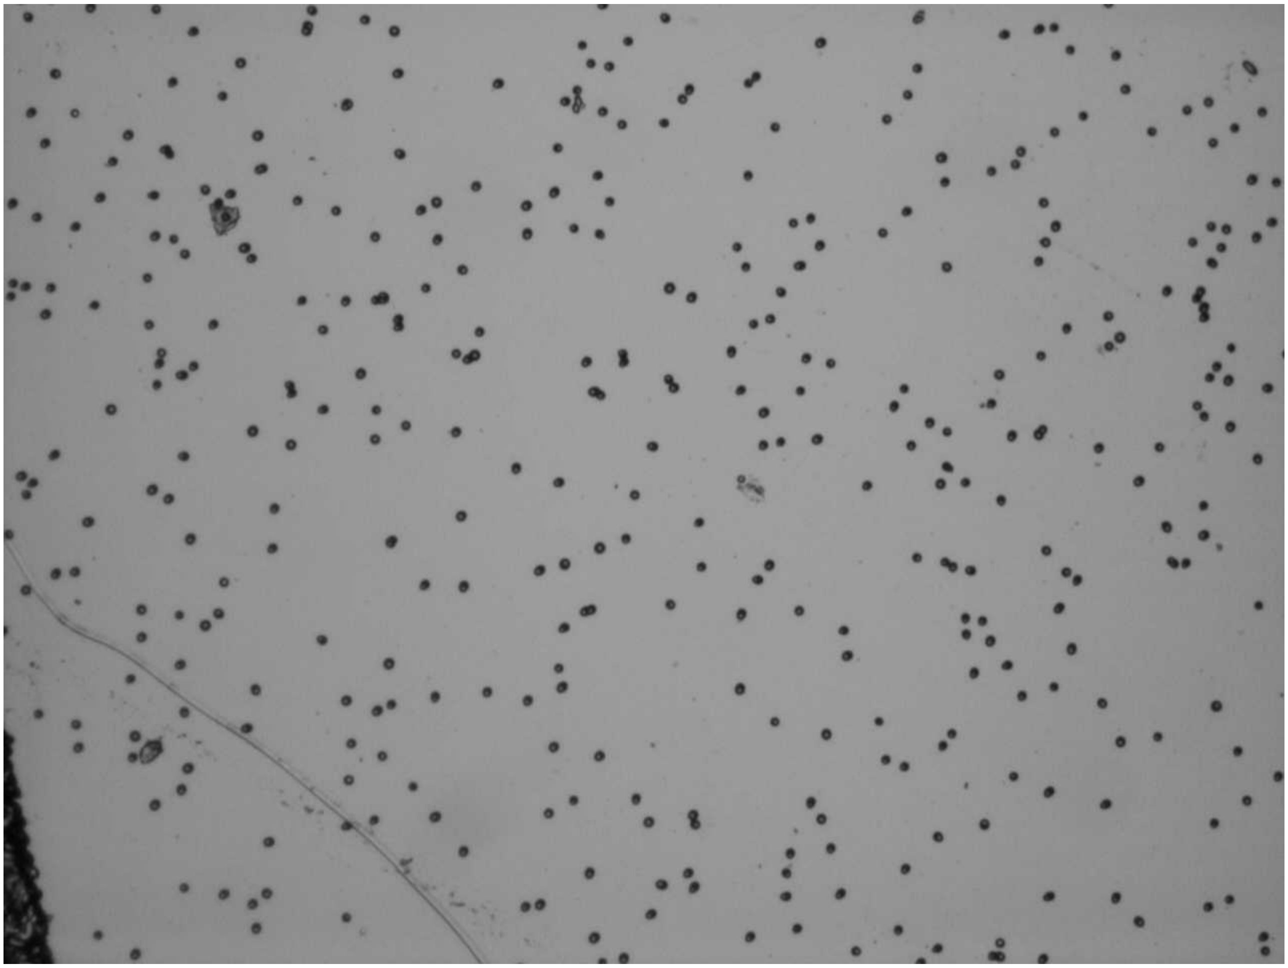

Figure 2
Tracks due to alpha particles. Magnification 40. The photographed area is about 1.3 by 1.0 mm

= =

A much larger cluster is shown in Figure 3 and Figure 4. In fact, tracks in the lower part of Figure 4 also appear in the upper part of Figure 3. The area of this larger cluster is nearly 2 square millimeters.

= = = = = = = = = = = = = = =

Figure 3
A larger cluster. Magnification 40. The photographed area is about 1.3 by 1.0 mm

= =

In that case many tracks have considerably smaller diameters than tracks on pervious figures. Furthermore, tracks on Figures 3 and 4 seem to be more shallow (as revealed by the effect of focusing).

= = = = = = = = = = = = = = =

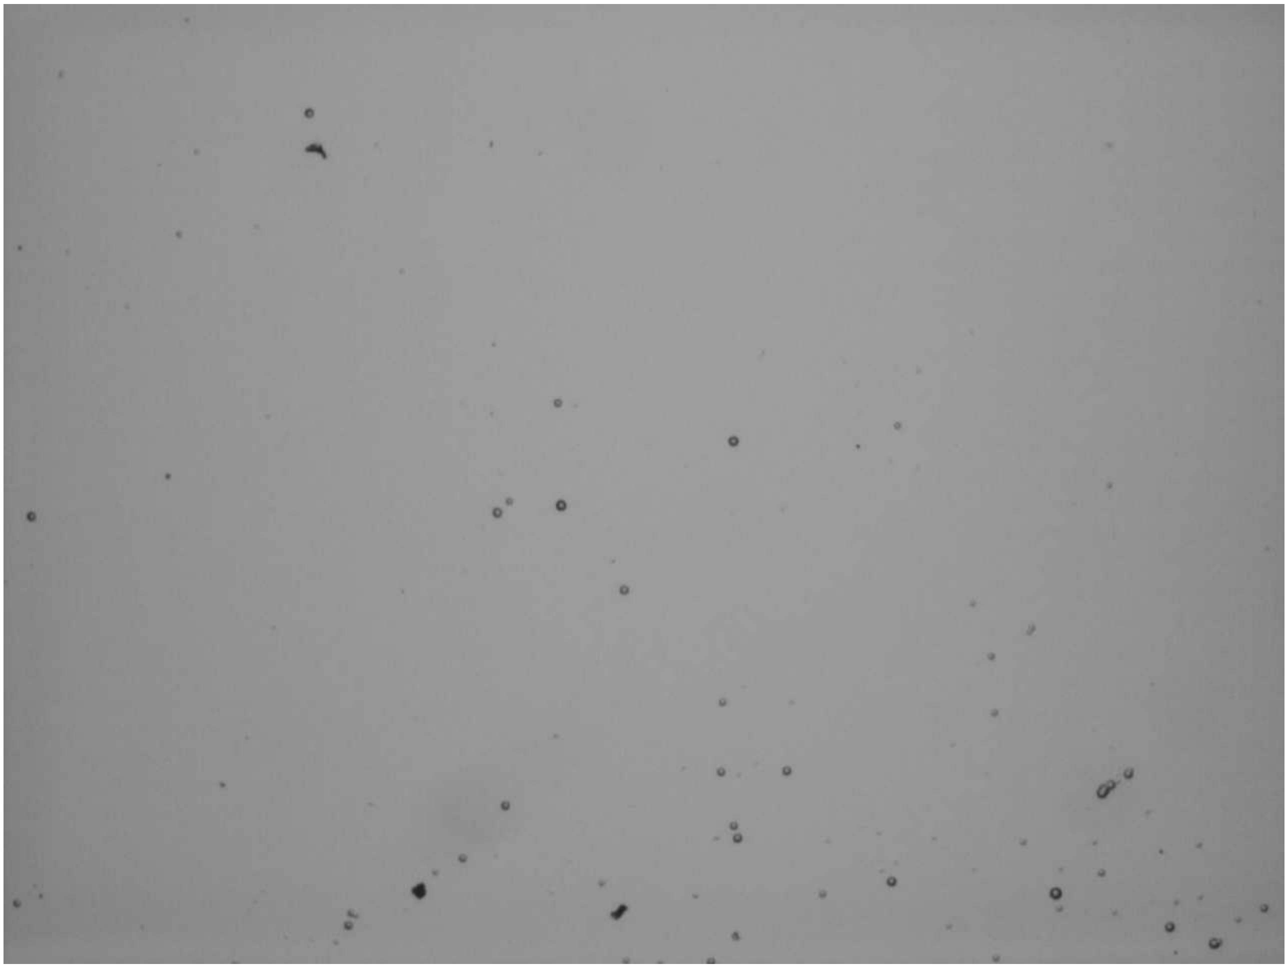

Figure 4
A small cluster of tracks. Magnification 40. The photographed area is about 1.3 mm by 1.0 mm. This figiure shows what is above Figure 3.

= =

The next figure shows a spectacular cluster of tracks that seem to be due to nuclear particles moving from a point source. Oriani already reported similar clusters on the private list for CMNS researchers. Someone might think that tracks are due to cosmic rays. What kind of cosmic ray collision can produce such a tiny cluster? How frequent are such collisions? Perhaps some cosmic rays experts will answer these questions.

= = = = = = = = = = = = = = =

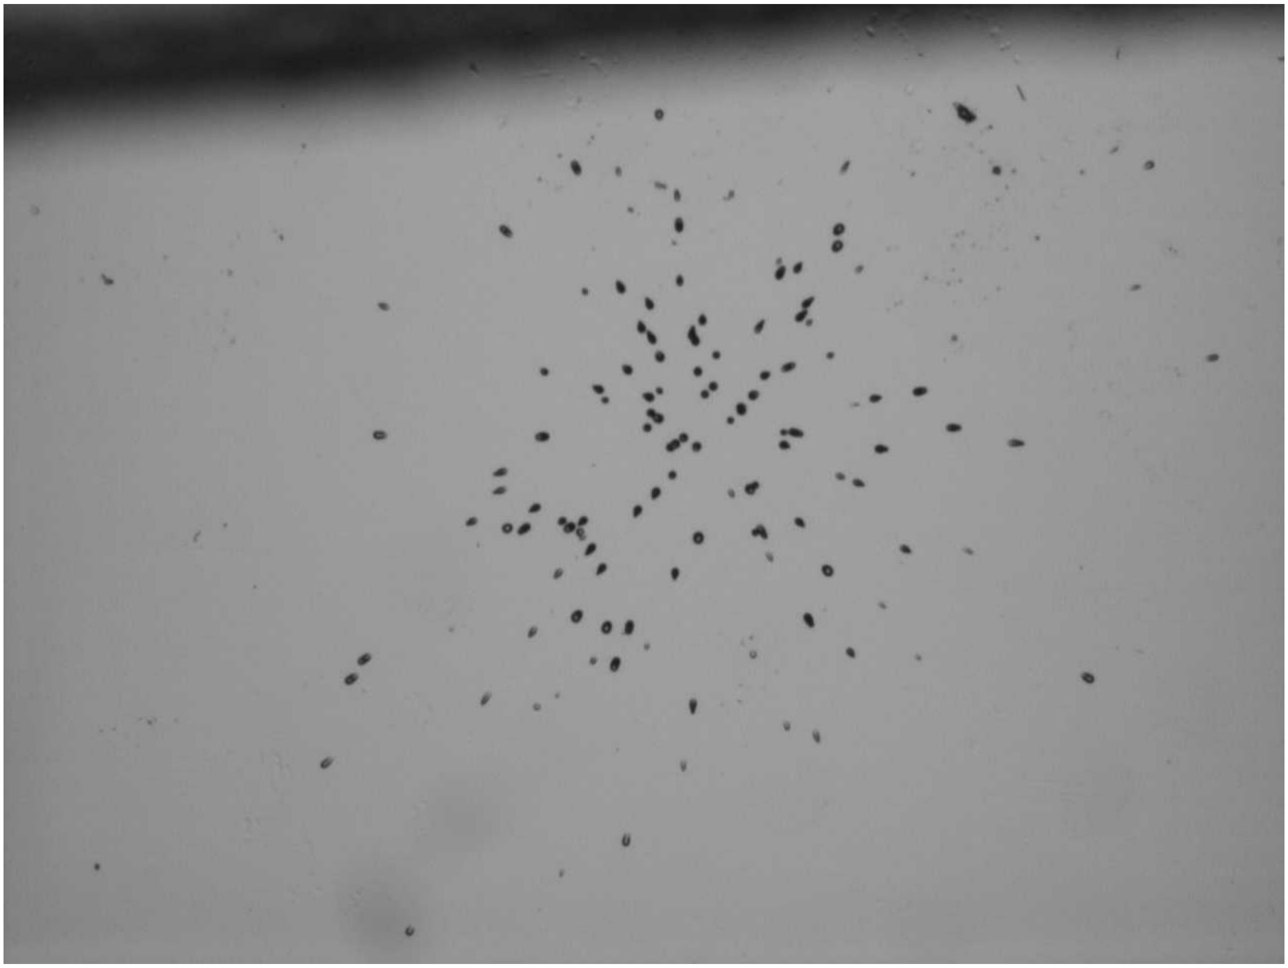

Figure 5
A small cluster of tracks. Magnification 40. The photographed area is about 1.3 mm by 1.0 mm Some of the tracks of this figure are also shown in Figure 6, at much higher magnification.

= =

= = = = = = = = = = = = = = =

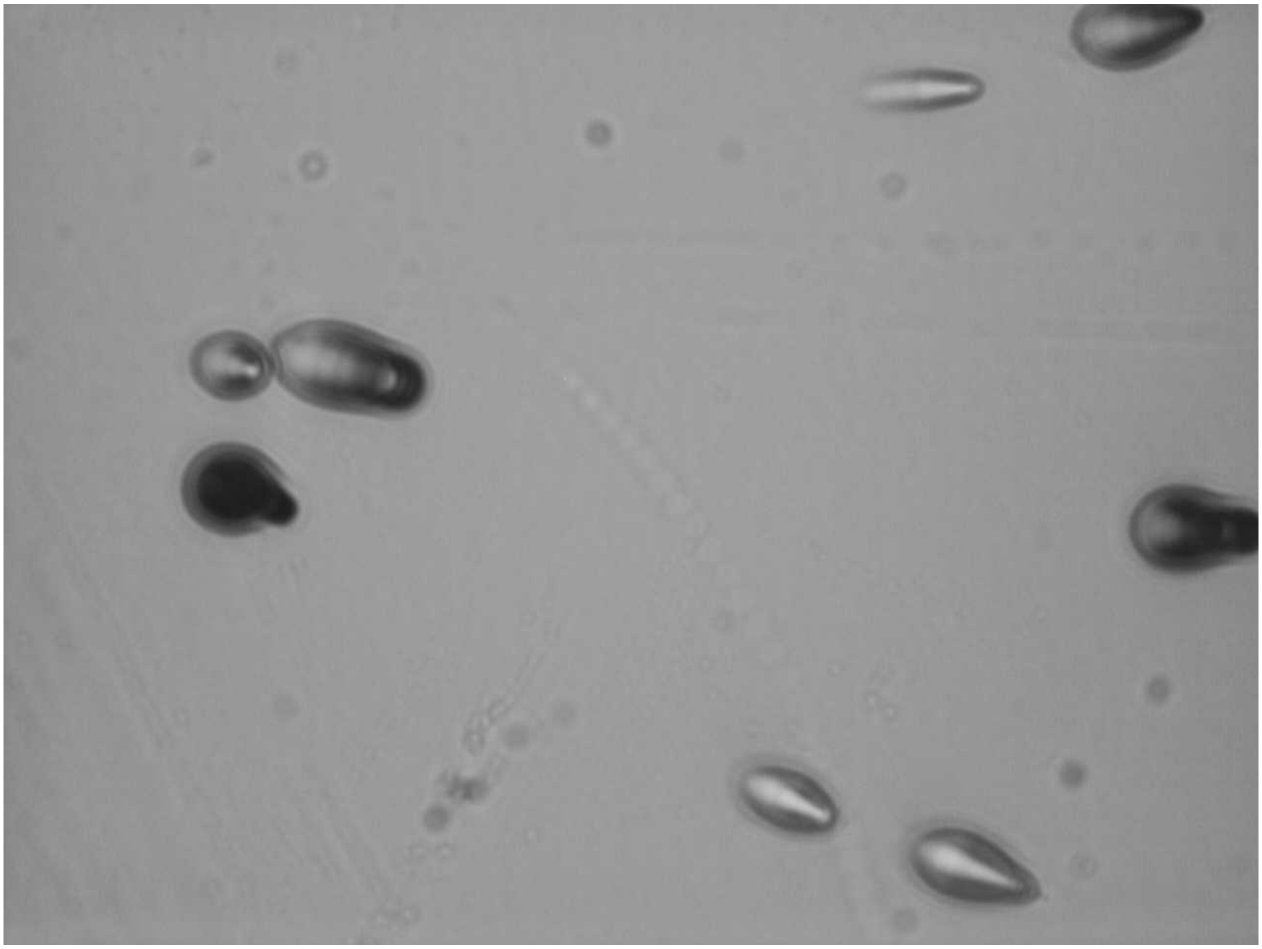

Figure 6
A small cluster of tracks. Magnification 400. The photographed area is only about 0.13 mm by 0.10 mm. Tracks seen here belong to the cluster shown in Figure 5. In fact, one can identify them in Figure 5 by looking along the "one o'clock direction" from the center on the cluster. More than one half of track in Figure 5 are elliptical.
= =

How can there be any doubt that most of tracks on my figures are indeed due to nuclear projectiles? Oriani told me today that he now has twenty consecutive successes. My first experiment seems to confirm the idea that a starter of some kind (seeding, kindling, etc.) does play an important role. My attempts to replicate his results failed without a starter and succeeded with the starter. Three cascades in one experiment ! Let us see what the next two experiments will bring, my experiment and Marissa's experiment. Marissa is a very young researcher; that is very important, considering ages of most CMNS researchers.

5) In a private message a nuclear physicist wrote: "Cosmic rays cannot be responsible for small clusters. A number of arguments can be used to support this opinion. Here is one of them. CR-39 chips are widely used as dosimeters. That application would be impossible if the number of tracks observed in only 100 hours was as large as on your pictures." I agree; dosimetrists would discovered small cosmic ray clusters long time ago. Note that my control CR-39 chip, of same size, that was etched at the same time, showed zero clusters. In fact, it had practically no tracks at all, as described in unit #327. Also most of the 1.3 by 1.0 mm areas, away from my three clusters, are practically without tracks (less than one track per field, on the average).

6) On the CMNS list Scott Little wrote: "Your cluster is wonderful. It closely resembles a photo Richard shared with us a while back. Frankly, it looks to me like the result of placing a small particle of radioactive material on the CR-39 for a while. There are hundreds of tracks which all appear to originate from a common point. How could a single high-energy particle (i.e. cosmic ray) produce such a shower?" Primary cosmic rays contain relativistic heavy ions. But such ions are very rare, I think. Collisions between relativistic heavy ions, such as gold, have been studied intensively at BNL (Brookhaven National Laboratory) for at least ten years. My understanding is that nuclear projectiles produced

in such collisions have much longer ranges than particles responsible for tracks in Figure 6. .....BNL is only two hours away (driving) from my home, and I have friends working there. It would not be difficult to consult with them. But first we need more data.

7) Time=15 hours, 9:15, 5/8/07 (Second experiment started at 18:15 on 5/7/07)
All is fine with the ongoing experiment. I=41 mA, cell potential is 5.93 volts. I will keep this current till the end of the experiment.

8) Time=27 hours, 21:15, 5/8/07
I=41 mA V=5.97 V

I forgot to mention something very important; the cluster shown if Figure 5 is located at edge of my CR-39 detector. That edge was actually in air, outside the cell. Why do we put the cathode in contact with the CR-39 chip? Because that was in the SPAWAR protocol. Richard Oriani modified that protocol by placing a very thin mylar film between the cathode and the CR-39 chip. The purpose was to protect the chip from a chemical attack of the electrolyte; hence the acronym PACA: Protection Against Chemical Attack. The film was sufficiently thin to transmit alpha particles.

This morning I read Oriani's and Fisher's papers presented at ICCF10. Their clusters were observed above the electrolyte, in the escaping gasses, as illustrated on page 568 (of the conference proceedings). That was several centimeters away from the cathode. Below is their Figure 2 (from page 571 of the ICCF10 proceedings). The upper photo is the chip before the electrolysis while the lower photo shows the same chip -- exactly the same location -- after the electrolysis. What a difference! A surface deffect near the lower left corner proves that the same area is being photographed.

= = = = = = = = = = = = = = =

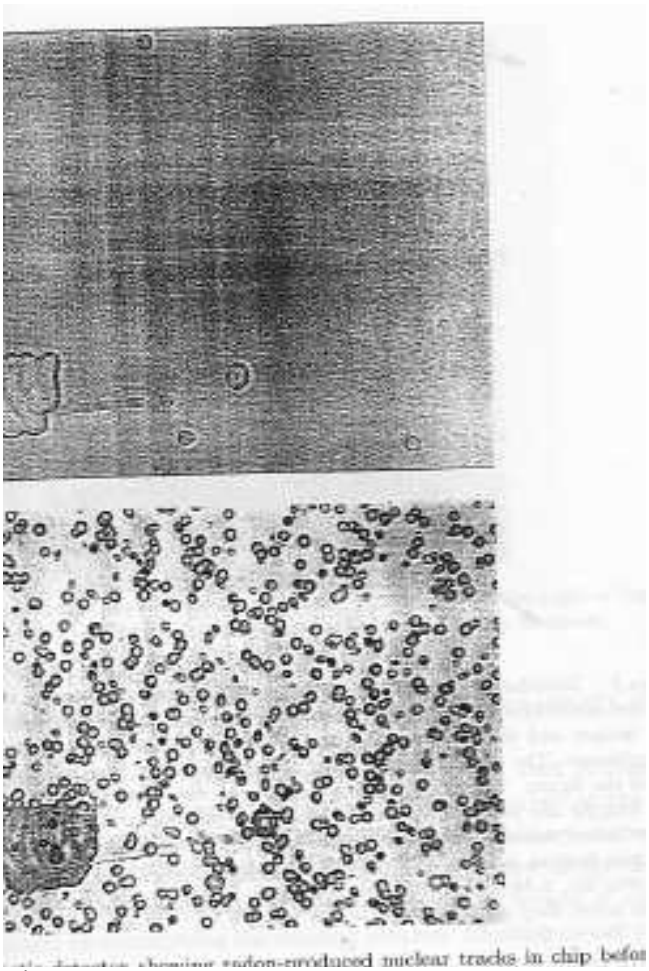

Figure 7
An illustration from the 2003 paper of R.A. Oriani and J.C. Fisher.

= =

9) On the basis of Oriani's table (which was posted before his additional successes, and before my one replication) I tend to believe that experiments are reproducible. Taking this for granted I just decided to run my experiment for much longer than five days. In a reproducible situation, an experiment that is run ten times longer should produce ten times more cascades, subject to usual statistical fluctuations. I do not have another large CR-39 chip to start another experiment. Is there any good reason for me to stop after five days?

And here is another reason for very long experiments. A success, according to Fisher and Oriani, is highly unlikely, unless "a starter" is provided. We do not know what the starter (seed, NAE, etc.) is. But we know that it is in the O-rings and/or in mylar from a successful experiment. We use it as kindling to start another fire. We also do not know how long the kindling will remain effective. Therefore, for the sake of future experiments, we must keep the fire going on continuously. In other words, running very long experiment, one after another, is desirable, till a reliable "igniter" is invented.

10) How solid is the evidence that kindling is essential? To answer this question one should perform several consecutive experiments with new O-rings, mylar and the electrolyte. Would five or more such experiment produce negative results? If so then the essential effect of a starter (or a combination of starters ?) Would be established. My failures to replicate Oriani's results without a starter might be due to the fact that the CR-39 chip was too small and not in a right location. After all, the central part of my large CR-39, the one with three clusters, has no tracks in the central region.

11) The beauty of Oriani's method -- squeezing the entire sandwich (mylar + CR-39) rather than squeezing mylar only -- is its mechanical strength. The electrolyte is no longer supported by mylar; it is supported by the entire sandwich. I can push down the anode-cathode setup without being afraid to puncture mylar The only precondition for this is that the cathode wire, the foot, should have no sharp points. In fact, I pushed that setup down several times, to make sure the cathode is really in contact with the sandwich. Fortunately, no complications are introduced by squeezing the CR-39 between two O-rings.

12) Time = 37 hours, 7:15, 5/9/07
I=41 mA, V=5.73 volts.

13) One scientist on the CMNS suggested a theoretical explanation of what is going on. That interpretation is not at all obvious, or easy to defend. Responding to this, also on the private list for CMNS researchers, I wrote: What is the best strategy to convince mainstream scientists that CANR are real? I think that the issue is worth discussing. My advice would be to ask all theoreticians not to inject theoretical interpretations until facts are recognized as real. Remember what happened in 1989. Instead of focusing on real experimental facts (generation of excess heat) discussion quickly shifted to theoretical considerations, such as coulomb barrier, expectations based on wrong models, etc. It would be much better if the F&P phenomenon was called UEH (unexplained excess heat) rather than CF (cold fusion), until the reality of UEH were recognized by all scientists.

If it were up to me I would recommend focusing on our new experimental facts. Let us agree that clusters of tracks are not due to artifacts, such as radioactivity or cosmic rays. Let us agree that clusters are likely to be due to unexplained nuclear projectiles (UNP). Then let us try to convince others that UNP are real. Trying to mix experimental facts with theories might backfire again. We want people to look at our experimental data; we want them to perform experiments; we do not want the debate to shift toward the as-yet-unaccepted ideas.

I know it is a touchy issue. Theoreticians do not want to be told what to do, what to publish and how long to wait. And we all believe that pure empiricism is not science. Theoretical debates are essential. But, like other powerful tools, theories can have both positive and negative effects. I am afraid that premature theoretical considerations can produce more harm than good at this delicate stage. What do other people think?

14) Time = 52 hours, 22 :15, 5/9/07
I=41 mA, V=5.47 volts.

15) John Fisher informed the CMNS list that he also replicated Oriani's experiments. He tried three times and each time he saw clusters. In two of his experiments small CR-39 pieces (probably 2 by 1 cm) were entirely in air, at the level of O-rings. He is going to send me one of his chip and I will make pictures of his clusters. Inspired by this, I just placed four small chips (each of 2 by 1 cm) on little wooden pedestals, also at the level of O-rings. Each chip is along a diagonally of my large CR-39, which has been under the electrolyte for 52 hour (when four additional chips were positioned). Each of these four chips has a scratch on the facing up surface. The distribution of chips is shown in Figure 8 below.

= = = = = = = = = = = = = = =

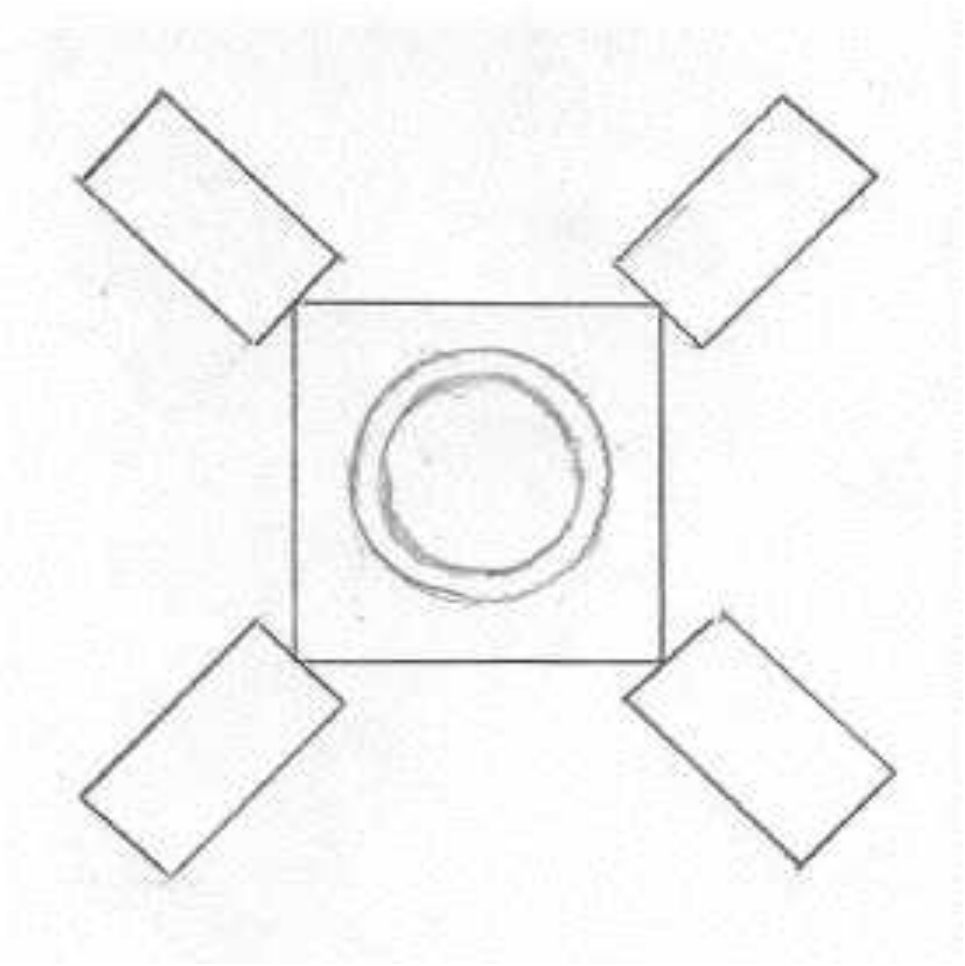

Figure 8
Configuration of five chips in the second experiment. The cirle represent the O-rings, the large square represents the 3 by 3 cm CR-39 chip, and diagonally oriented rectangles represent four smaller CR-39 chips (each 2 by 0.9 cm). Note that the total CR-39 area is nearly doubled. Small detectors are supported by pieces of wood. They are in the same plane, approximately, as the large rectangular detector.

= =

16) Time = 72 hours (3 days), 18:15, 5/9/07 I=41 mA, V=5.43 volts.

17) Today my large post-electrolysis chip (9 cm^2) was examined again. Here are some additional observations and suggestions: a) Three clusters were observed in an experiment that lasted 5 days. That corresponds to the detection rate of 3/5=0.6 clusters per day. Let me assume that 0.6 is typical. How many cascades would be observed, after 5 days, on a chip whose area is only 0.9 cm^2, as in my unsuccessful experiment? The answer is 0.3. This might be an explanation why my experiments described with small chips were not succesful. To replicate Richard's clusters I should have used the detector of the same size he used. My suggestion is that Marissa runs her experiment for much longer that the anticipated 92 hours. How can this hurt? Tracks created during the first 92 hours would not go away.

b) It is desirable to report numbers of clusters, and to show that areas surrounding clusters have no tracks. That is likely to be more meaningfull than mean track densities, as in Oriani's table above.

c) The cluster shown in Figure 3 and 4 is much larger than clusters shown in Figure 1 and 5. But it does not contain many times more tracks than smaller clusters. Is this typical? We need more data.

d) It turns out that the large cluster is on the side of the CR-39 chip that was facing down (away from the electrolyte). Larry would say it was on the “back side.” Two smaller clusters, on the other hand, were on the side facing up (toward the electrolyte). Is this a coincidence? We need more data.

e) Also note that all pits in the large cluster (a) are mostly round, (b) have a broad distribution of diameters and (c) appear to be more shallow than in the two smaller clusters. Is this a coincidence? We need more data.

f) Richard performed twenty experiments. I would very much like to know if his observations about clusters are similar to my observations.

g) From the public relation point of view, displaying pictures of clusters is highly desirable. The more the better, at this stage of the battle.

d) If the mean number of cascades is 3, and if the distribution of results is Poissonian, as in the case of Geiger counts, then the probabilities, P, for the number of n clusters (in 5 days on a 9 cm^2 chip) are as follows:

```
n = 0,    1,    2,    3,    4,    5,    6     etc.
P = 0.05, 0.15, 0.22, 0.22, 0.22, 0.10, 0.04, etc. (the tail where P-->0)
```

In other words, good replicability is not expected in experiments lasting only 5 days, even for 9 cm^2 chips. About 5% of results are expected to be failures. We need either a large number of short experiments, like those performed by Oriani, or a small number of much longer experiments. The second seems to be less demanding.

18) Time = 92 hours (four days) 18:15 5/11/07
I = 41 mA, V=5.26 V. About 40% of water was lost; the level is about 1 cm above the anode. I will replace the lost water tomorrow.

19) Time = 107 hours 9:15 5/12/07
I = 41 mA, V=5.15 V. About 50% of water was lost; the level is about 0.5 cm above the anode. It is time to replace lost water. I did this and the potential difference on the cell became 6.19 V. A correlation between the concentration of the electrolyte and the cell resistance is obvious. But the potential difference did not decrease by the factor of 2 when the concentration is doubled. It is clear that the measured potential difference is not only I*R.

20) Time = 144 hours 18:15 5/12/07 (end of day 6):
I = 41 mA, V=5.88 V.

* *

21) What follows are five microphotographs from the CR-39 that John Fisher sent me. Each picture covers an area of 1.3 mm by 1.0 mm (magnification 40). The photos would be much more informative if they could be compared to pits due to alpha particles of known energy under identical etching conditions. Unfortunately, a source of alpha particles was not available to John.

- - - - - - - - - - - - - - -

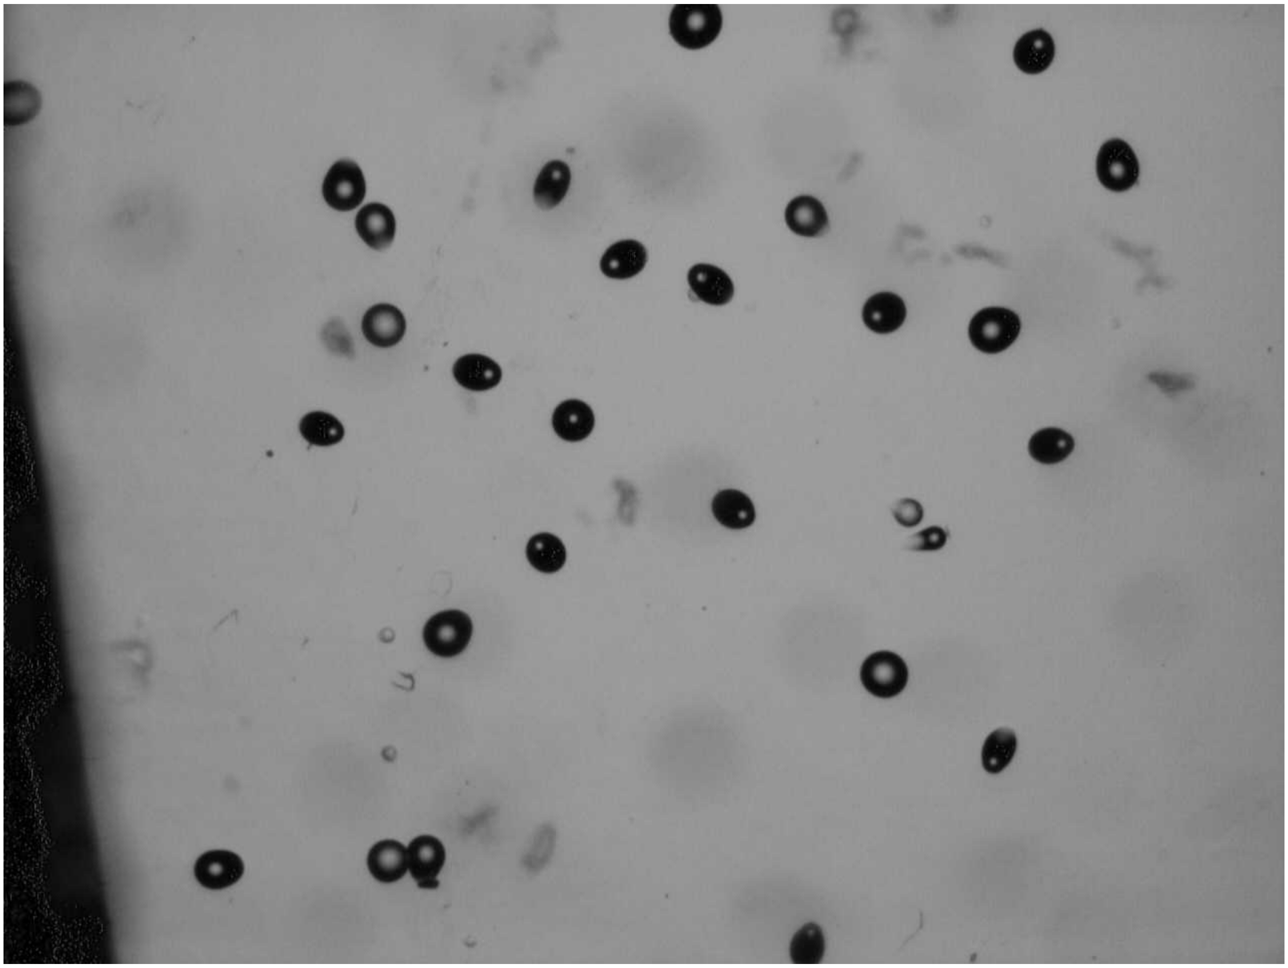

Figure 9
A cluster of very large pits. Very large pits were observed on the back side of the chip only (back side means facing away from the electrolyte).

- -

Please note that most of the 1.3 mm by 1.0 mm fields contain no pits at all. On the average a background pit can be found in one out of five fields.

- - - - - - - - - - - - - - -

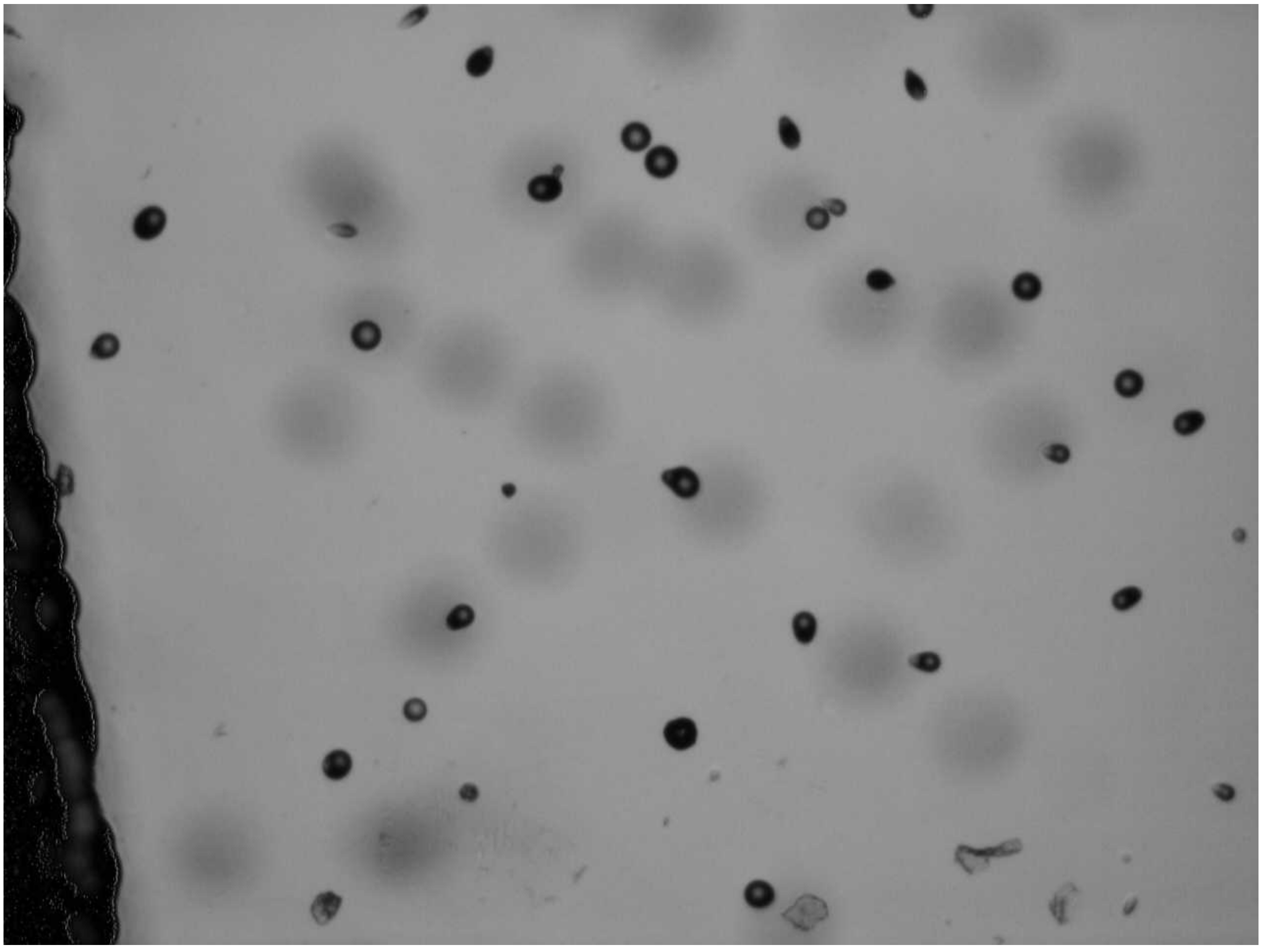

Figure 10
A cluster of medium-size pits on the top side of the chip (front side was facing the electrolyte). All pits, except for the background, are located near the margin of the chip. More than 99% of pits turn out to be located on less than 5 % of the total area.
- -
Large dark areas are due to pits on the oppsite side. Being out of focus these back side pits appear to be larger than in the previous figure.

- - - - - - - - - - - - - - -

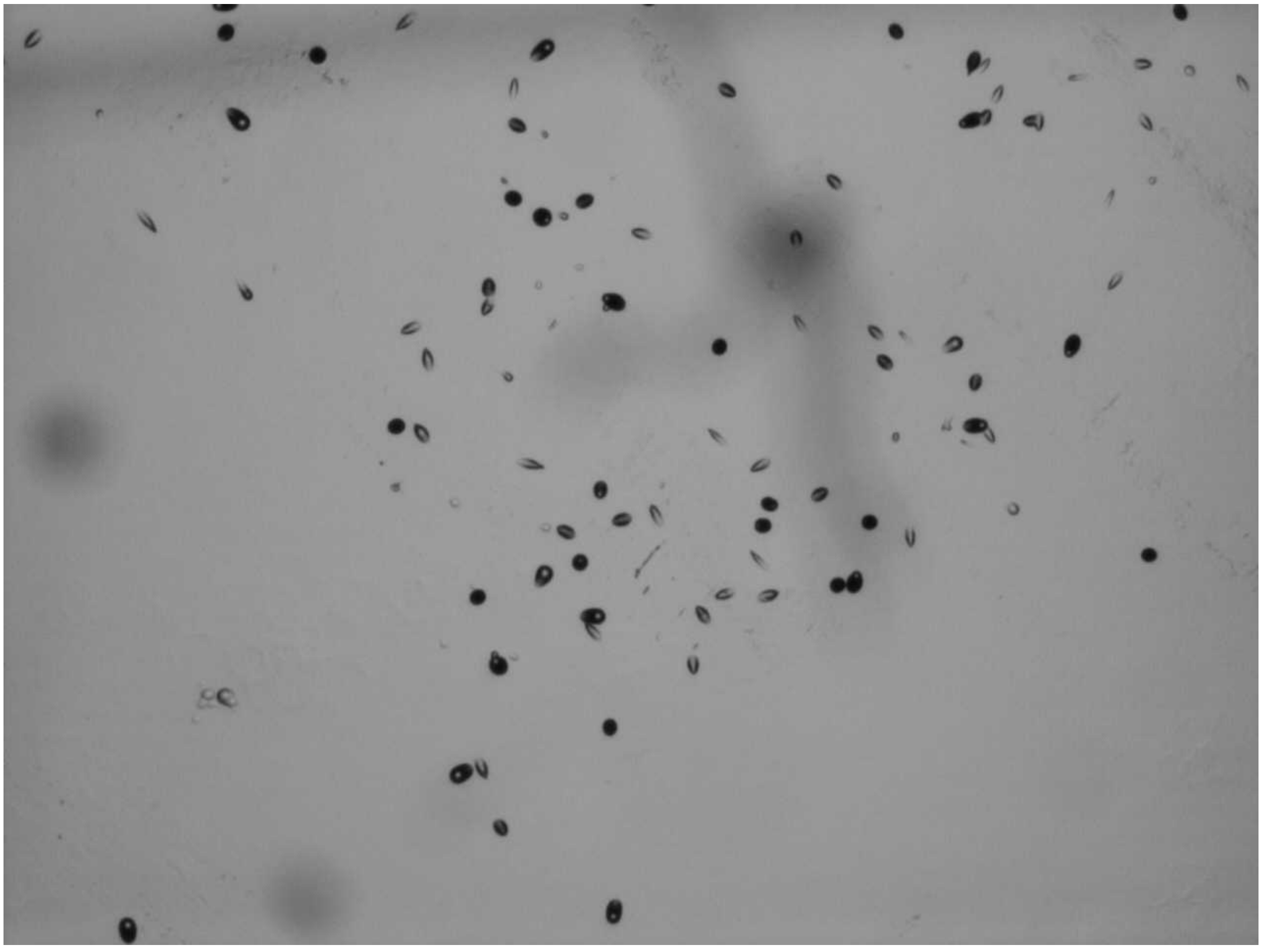

Figure 11
A cluster of small-size pits on the top side of the chip (top side was facing the electrolyte).
- -

Large dark areas are due to pits on the oppsite side. Being out of focus these back side pits appear to be larger than in the previous figure. - - - - - - - - - - - - - - -

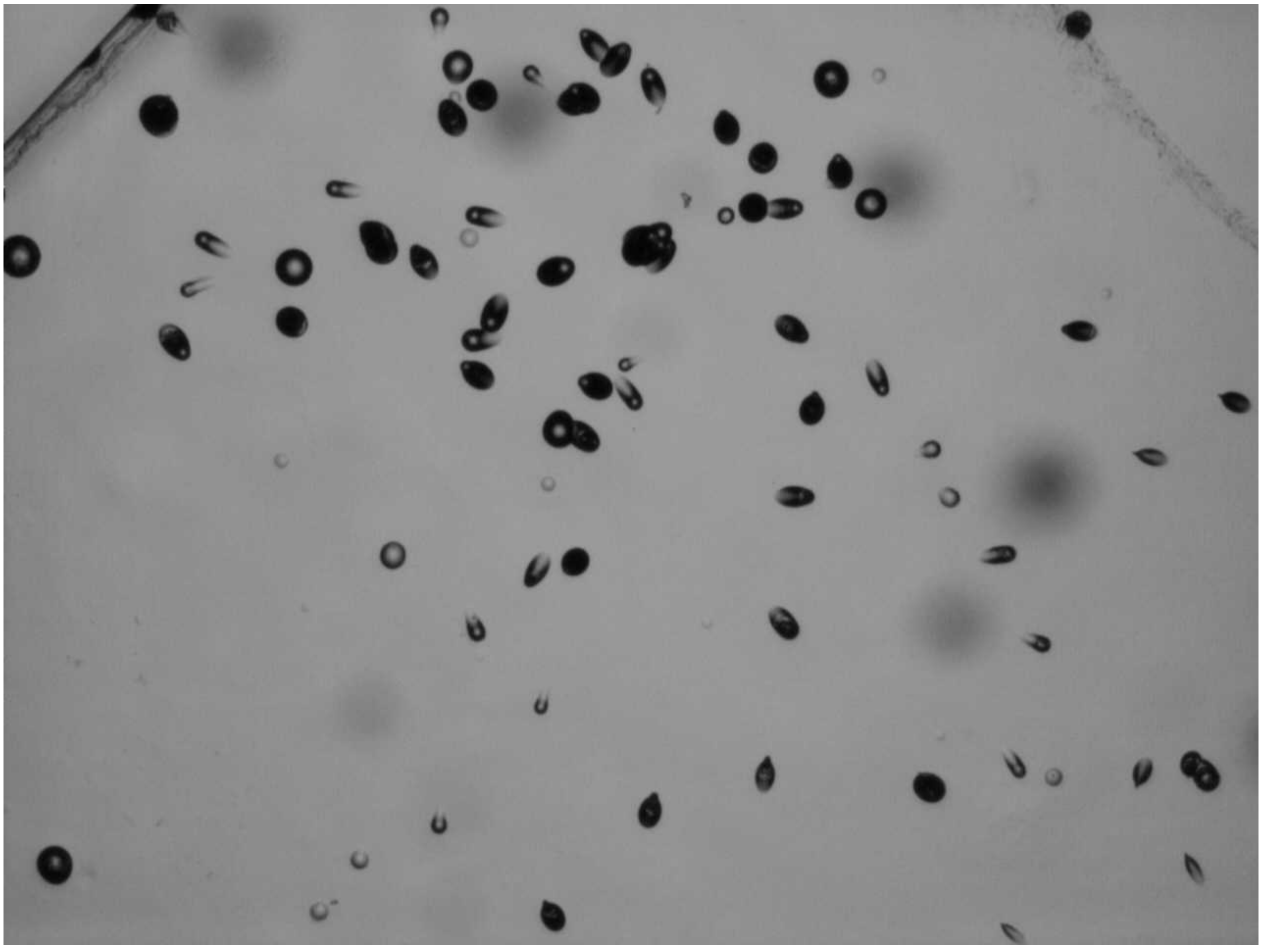

Figure 12
Another cluster of medium-size pits on the top side of the chip. -

* *

22) Time = 195 hours 21:15 5/15/07 (8 days +3 hrs):
I = 41 mA, V=5.55 V.

23) Time = 226 hours 4:15 5/17/07 (end of day 9 + 10 hrs);
I = 41 mA, V=5.40 V. Time to add water. After adding water potential became 6.35. Yes, the level is slightly above where I started.

24) A suggestion was made, on a private list for CMNS researchers, that excessive pits might be created by mylar. This prompted me to set up another control experiment. It started at 4:00 on 5/17/07.

a) A microscopic slide (glass) is resting on the box. About 6 mm of glass is actually in air, outside the box.
b) Protective films were removed from my CR-39 chip (~2 by 1 cm) and the chip was discharged (by touching it with salty-water-wet fingers.)
c) The chip is placed on the glass slide. About 6 mm of the chip is actually in air, outside the slide.
d) All is covered by the mylar film. About 6 mm of the film is actually in air, outside the CR-39 chip.
e) The small beaker (about 40 cc) is turned upside down and placed on mylar. That is my fake cell.
f) One rim of the cell is close to the edge of the box, actually, it is about 3 mm outside the box.
g) A scratch was made on the lower side of my CR-39 (to recognize it later).

Note that one end of the mylar film is totally in air, more of less as in my main experiments. The "null hypothesis" is that mylar becomes charged, creating an electrostatic field near the cell. That field attracts radioactive ions (always

present in air, due to cosmic rays, radon, etc.) into the region in which my CR-39 is in contact with air (at the lower side). Will this create excessive pits ? I will know in two or three weeks.

25) Time = 240 hours 18:15 5/17/07 (end of day 10)
I=41 mA, V=6.09 V

26) Time = 265 hours 19:15 5/18/07 (day 11 days + 1 hour)
I=41 mA, V=6.05 V Note: The current I=41 is the nominal value, as measured with a digital ammeter then the current stabilizer was built. I know that the actual current can fluctuate slightly due to fluctuations of temperature. In other words, the cell potential depends not only on how much water was lost but also on the temperature. In this experiment an old analog millimeter (full scale 500 mA) and vary accurate measurements are not possible. The instrument is used to indicate that the current is flowing. I plan to use higher currents (80 mA and 150 mA) before ending the experiment in June. Why? Because these currents were used in the experiment in which clusters were first observed. I do not know at what current the clusters were actually recorded.

27) Time = 293 hours 23:15 5/19/07 (12 days + 5hours)
I=41 mA, V=5.94 V

28) Time = 306 hours 12:15 5/20/07 (12 days + 18 hours)
I=41 mA, V=5.88 V

29) Time = 336 hours 18:15 5/21/07 (14 days)
I=41 mA, V=5.63 V

30) Time = 352 hours 10:15 5/22/07 (14 days + 16 hours)
I=41 mA, V=5.54 V
The level of the electrolyte is again about 1 cm above the anode. I will water now. After adding water V=6.57 V

31) Here is a message I posted on the CMNS list last night.
Scott Little wrote: “When examining the etched CR-39 under the microscope, each track you find always raises the question, "Is this a nuclear track or not"? The ones that are elliptical and have a distinctly conical shape have a high probability of being of nuclear origin. The ones that appear to be perfectly round but still have a conical shape are likely to be of nuclear origin. The ones that are perfectly round and relatively flat-bottomed are disturbingly ambiguous.”

**) One should expect a large fraction of tracks to be elliptical when the source of alpha particles is very close to a CR-39 chip. But nearly all alpha particle tracks are circular when the distance between the source and the detector is larger than 5 or 10 mm.

**) Looking at my three clusters, I see that the smallest one (Fig 5 and 6) has many elliptical pits. This could be interpreted as an indication that a nuclear process we want to replicate took place somewhere very close to the CR-39 chip. But pits in a larger clusters (Fig 1) are mostly round. This might be an indication that the process is taking place several millimeters away from the CR-39. The same can be said about the even larger cluster (Fig 3 and 4). In this case the distance might be even larger because the cluster is much larger, and because tracks diameters are widely dispersed. (Small diameters would be expected for particles which lose most of their kinetic energy before being intercepted by CR-39.)

**) In my opinion, it is too early for this kind of speculations, and for experiments suggested yesterday by X. In my opinion we must first agree that "seeded experiments" are reproducible on demand. As far as I know, each team that received seeds (recently-used Oriani's O-rings and mylar) observed clusters of pits. These pits are similar to tracks of charged nuclear particles.

**) What will happen when seeds are no longer available? In other words, what will happen when Richard Oriani stops performing experiments, one after another (to keep the NAE fire going)? I do not know how to answer this

question. For the time being as many researchers as possible should ask Richard for seeds (in order to replicate his results). The issue of possible artifacts, systematic investigation of parameters, and theoretical explanations, can wait till we agree on a high level of reproducibility. That would be a fantastic accomplishment (of turning protoscience into science?). Do not wait too long, please.

32) Tomorrow is day 16 of my second seeded experiment, as far as the current 41 mA is concerned. That will be four times longer than the duration of my first seeded experiment. Will I find more clusters than before? I hope so. But that remains to be seen. It is reasonable to expect 3*4=12 clusters, plus or minus 7. Why 7? Suppose I used a Geiger that registered 3 random particles from a radium source in 4 seconds. Then, the expected result, after 16 seconds, would be 12. For a mean value of 12 the distribution of possible outcomes is essentially bell-shaped and its standard deviation is close to 3.5. To be 95% confident that my expectation is correct, I would bet on the result that can differ from the mean value by two standard deviations. I expect to see at least 12-7=5 clusters because I assume that things are reproducible. (But my first experiment also contained 1 day of electrolysis with I=80 mA and 2 hours of electrolysis with I=160 mA. That is why I will run my second experiment for 4 additional days at 80 mA and for 8 additional hours at 160 mA. I have no idea at what currents were my clusters recorded.)

33) Time = 376 hours 10:15 5/23/07 (15 days + 16 hours)
I=41 mA, V=6.21 V

34) The statistical reasoning in 32 has a mistake. The 95% certainty would be valid if 12 clusters (or 12 Geiger counts) were really discovered in my first experiment. But the number 12 was an extrapolation. How to evaluate the level of confidence based on an extrapolation? I will ask a statistician. Meanwhile let me follow the intuitive approach. Three counts were recorded in a random sample drawn from a large Poisoning population. Thus the expected mean is 3 while the expected standard deviation is 1.73 (the square root of 3). Multiplying this by 4 one gets the mean of 12 and the standard deviation 6.97. The new standard deviationis nearly twice as large as the value I used above. Therefore the level of confidence, that the result will be between 5 and 19 is only 68% and not 95%. But even this is questionable; a Poisoning distribution with the mean of 3 is not bell shaped. Well, it is not difficult plot that distribution and to calculate probabilities of various intervals. But why should I waste time on this? Note that I totally ignored the fact that 21 consecutive experiments of Oriani, plus three consecutive experiments of Fisher, plus one to-be-confirmed (probably today or tomorrow) experiment of X, were successful.

35) Time = 386 hours 20:15 5/23/07 (16 days + 2 hours)
I=41 mA, V=6.07 V
Removing the current regulator and increasing the cell potential to 9.00 V. The current is 80 mA. I will use this current for 4 days (4 times longer that in the first experiment).

36) Time=386.25 hrs 20:30 5/23/07
I=82 mA V=9.02 V. I lowered the current back to 80 mA by lowering the potential difference to 8.73 V. Something is probably happened on the surface and lowered the overall cell resistance. About 15 minutes later the potential became 8.70 V; the current agin increased but very little. I should not pay attention to small voltage fluctuations. Next voltmeter reading will be tomorrow.

37) Last night the TGP beta team 2 (Marissa Little) reported that they also observed a cluster of about 70 tracks in the first seeded experiment, as illustrated in Figure I will say more about this in Figure 13 below.

- - - - - - - - - - - - - - - M

Figure 13
A closter reported by Marissa Little. Note that the cluster is surrounded by the area that has a negligible track density. The magnification was 40; the diameter of the displayed field is 2.5 mm.

- -

The etching temperature of the beta 2 team was 65 C. That is why sizes of pits are smaller than those shown in my Figure 1. Here is a brief message that Marissa just posted on the private list for CMNS researchers. "I've organized all of the experimental data for our PACA replication into an online logbook that I will keep up to date from now on. You can read about the first two experiments we completed and the two that are running now.

http://www.earthtech.org/PACA/logbook.html

Just a brief summary, our first experiment showed nothing anomalous. While waiting for additional o-rings from Richard, we ran a second experiment with what we thought were "dead" o-rings. The second experiment produced a cluster and a higher than background track count. Exp #3 and #4 are currently running (with fresh o-rings from Richard). Let me know if you have any questions of comments."

37) Time=387 hrs 21:15 5/23/07
I=81 mA V=8.76 V. I lowered the current back to 80 mA by lowering the potential difference to 8.24 V. Something is probably still happened on the surface and lowers the overall cell resistance.

38) Time=389 hrs 23:15 5/23/07
The current is about the same. V=8.40 V.

39) Time=396 hrs 6:15 5/24/07
The current is about the same. V=8.31 V.

40) Time=402 hrs 12:15 5/24/07

I =86 mA, V=8.22 V. To bring I back to 80 mA the V had to be lowered to 7.85 V. So I will continue with I=80 mA and V=7.85 V

41) Time=410 hrs 20:15 5/24/07
I=83 mA, V=7.84 V. To bring I back to 80 mA the V had to be lowered to 7.70 V. So I will continue with I=80 mA and V=7.70 V. How much of this is due to the progressive loss of water and how much to the instability of my simple d.c. power supply?

42) There was an interesting discussion, on a private list for CMNS researchers, about publishing our excitning results in a mainstream journal. Responding to someone, I wrote: " Yes, establishing repeatability should be the highest priority. I would not worry about possible artifacts, or about testing of the seeds hypothesis. Let us first reach the stage at which each of us, not only Oriani, can say, with confidence, 'do what I do and you will probably observe clusters, and excess tracks.' This can be accomplished in June, if we are lucky with the three ongoing experiments, my #2 and your #2 + #3. Also experiments of three other people on whose help Richard is counting. A paper Oriani suggested, with appendices from four or five teams, would be worth publishing, even if explorations of possible artifacts are still in progress. A protocol for a reproducible-on demand demo should be published as soon as each of us has additional replications. This will probably create a very favorable situation for new projects. But the seeding precondition should be part of the protocol, as I wrote yesterday."

Several hours later Marissa Little wrote: "I disagree. I think it is vital to investigate the possibility of artifacts before we publish. If the paper is published without evidence supporting the hypothesis that these tracks are indeed due to nuclear reactions occurring in the cell, it will be quickly dismissed by the scientific community at large. What if the effect turns out to be due to something mundane and not to nuclear particles? It would be very bad to have a published claim of a repeatable LENR experiment only for it to turn out to be an artifact. In order for LENR research to be accepted by mainstream science, researchers must be even more diligent with their investigations than those working in other fields. I don't think LENR scientists should publish early with preliminary results. I would not be comfortable publishing our results until a thorough investigation has been completed to rule out all artifacts and mundane causes for the effect. Only then will we be equipped to present a complete story that will speak for itself. At this juncture, I would have to 'argue' that the tracks were caused by LENR rather than the data "stating" that they were. I am not comfortable arguing any position in science. Let the facts speak for themselves."

43) Time=324 hrs 10:15 5/25/07
I =85 mA, V=7.61 V. To bring I back to 80 mA the V had to be lowered to 7.33 V. So I will continue with I=80 mA and V=7.33 V. I will have to add water this evening.

44) Time=435 hrs 21:15 5/25/07
I =89 mA, V=7.37 V. To bring I back to 80 mA the V had to be lowered to 7.08 V.
Add water. Current goes down to 54 mA at V=7.15 V. To bring I to 80 mA I had to increase the potential to 8.94 V. This 80 mA should be kept for 4 days. I started it at 20:15, on 5/23/07. So I have run it for 2 days and one hour. The end will be on Sunday evening (5/27/05). Then 8 hours at 160 mA and the end of this second experiment. Oriani is sending a chip to start another experiment. He thinks that another experiment will have more value that runing the current experiment for much longer.

45) Time=436 hrs 22:15 5/25/07
I =88 mA, V=8.89 V. To bring I back to 80 mA the V had to be lowered to 8.43 V.

46) Time=4446 hrs 8:15 5/26/07
I =80 mA, V=8.28 V.

47) Time=455 hrs 17:15 5/26/07
I =88 mA, V=8.27 V. To bring I back to 80 mA the V had to be lowered to 8.01 V.

48) Time=472 hrs 10:15 5/27/07
I =91mA, V=7.97 V. To bring I back to 80 mA the V had to be lowered to 7.51 V.

(ending 80 mA after 4 days)
Go from 80 mA to 160 mA
V=11.48 V before adding water and 13.30 V after adding water.

50) Time = 481.50 hrs; 20:45 5/27/07
I=200 mA, V=13.2 V. Lower V to 11.30 V to go back to 160 mA

51) Time = 482 hrs; 22:15 5/27/07
I=169 mA, V=11.49 V. Lower V to 11.03 V to go back to 160 mA

Use this current for 8 hrs (to match the 16 days at 40 mA) and then for 0.5 hrs (to match one extra day of 40 mA). Then go to 80 mA for 6 hours (also to match the extra day at 40 mA) and finally to 40 mA for 24 hours. End the experiment on Tuesday, 5/29/07, provided the CR-39 for the next experiment arrives. If not then keep running for another short 40, 80, 160 cycle.

52) Time = 506 hours; 22:15 5/28/07
I=41 mA, V=5.86 V. Experiment proceeds as planned; I am in the middle of the last 24 hours, unless the CR-39 chip for the next experiment does not arrive tomorrow. The mean background on that chip, as specified by Oriani, is 16.6 tr/cm^2; st.dev. 9.7. hat is about the same as he wrote about the previous chip. But that chip actually had about ten times lower background.

53) Time = 514 hours (21.5 days since the beginning); **6:15 5/29/07**
I=40 mA, V=5.89 V.

54) Time = 518 hours (the end of electrolysis is not far away) 10:15 5/29/07
I=40 mA, V=5.76 V

55) Time = 523 hours (ending the electrolysis at 15:15 5/29/07)

56) Summary
Experiment #1 lasted 5.08 days (~79% at 41 mA, ~20% at 80mA and 1.7% at 160 mA)
Experiment #2 lasted 21.8 days (523 hours, with the same percentages as above). I expect to see about 12 clusters, plus or minus several, depending on the fluctuating level of optimism.

57) Experiment #3 started at 16:50 on 5/29/07, less than an hour after the end of the experiment #2. The electrolyte was the same as used in experiment #1 (in which three clusters were found) and reused in experiment #2, which just ended. But new mylar is used in the experiment #3.

58) About exeriment #2:
Results from the experiment #2 will be posted below, as I did after the experiment #1. One thing should be mentioned. In taking apart the cell used in the experiment #2 I noticed some moisture on the CR-39 surface below the mylar. That surface was dry at the end of the experiment #1. I suspect some tiny holes in mylar (used by Oriani and then by me in two experiments) were responsible. It was not a leak; only a very thin layer of moisture. And only near the center. I do not think that the layer of moisture could create interpretational problems, especially if clusters are found outside the O-ring area. No visual sign of any kind could be seen on the surface after the moisture was wiped out. I will examine the surface under the microscope, before etching, as well. Tomorrow I will probably etch the chips and have the first look at them under the microscope.

What has been done today (5/30/07)? The chips from the experiment #2 were etched for 6 hrs (NaOH 6.25 N at 73 C). At the same time the already-etched chip from the experiment #1 (with three clusters) was etched again for additional 5 hours. I will start examining the chips from the experiment #2 tomorrow. Today I examined the chip from the experiment #1. Perhaps longer etching will tell us something important. What did 11 hours of etching did to tracks of alpha particles? Tracks became much larger, as shown in Figure 14 below.

- - - - - - - - - - - - - - -

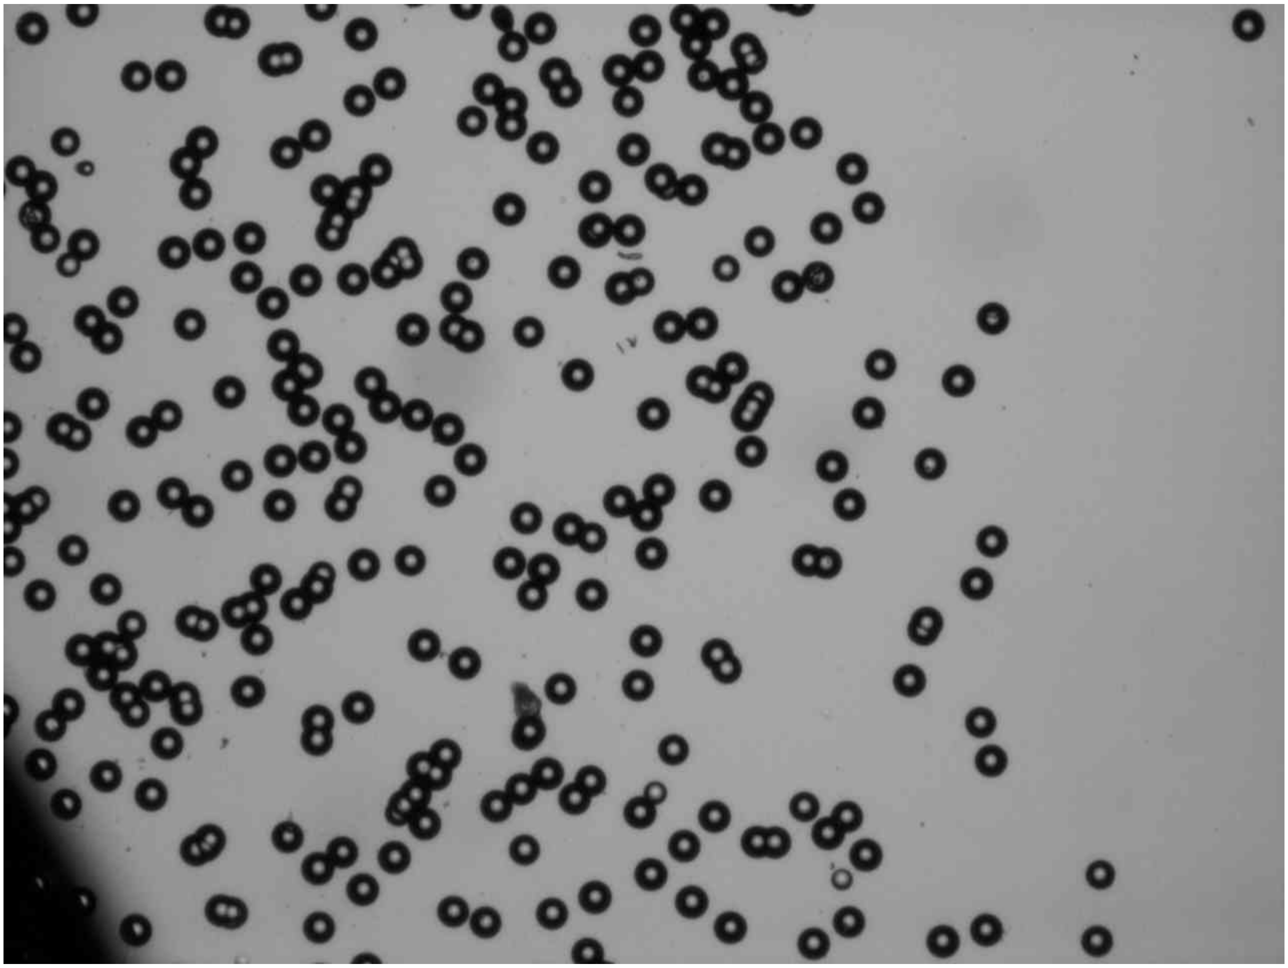

Figure 14

Tracks of alpha particles from Am-241 after 11 hours of etching. Compare them with tracks after 6 hours of etchin, in Figure 2. Magnification 40. The field shown is about 1.0 by 1.3 mm.

- -

The Figure 15 below shows a cluster which I though was the same as in Figure 1, except the tracks are larger. But now I am not sure. Perhaps it is a cluster I missed before. Or it can be the same cluster as in Figure 1 except that some tracks were washed away. Unfortunately, it is not easy to find exactly the same spot. Missing a cluster on this chip is easy because it became twisted.

- - - - - - - - - - - - - - -

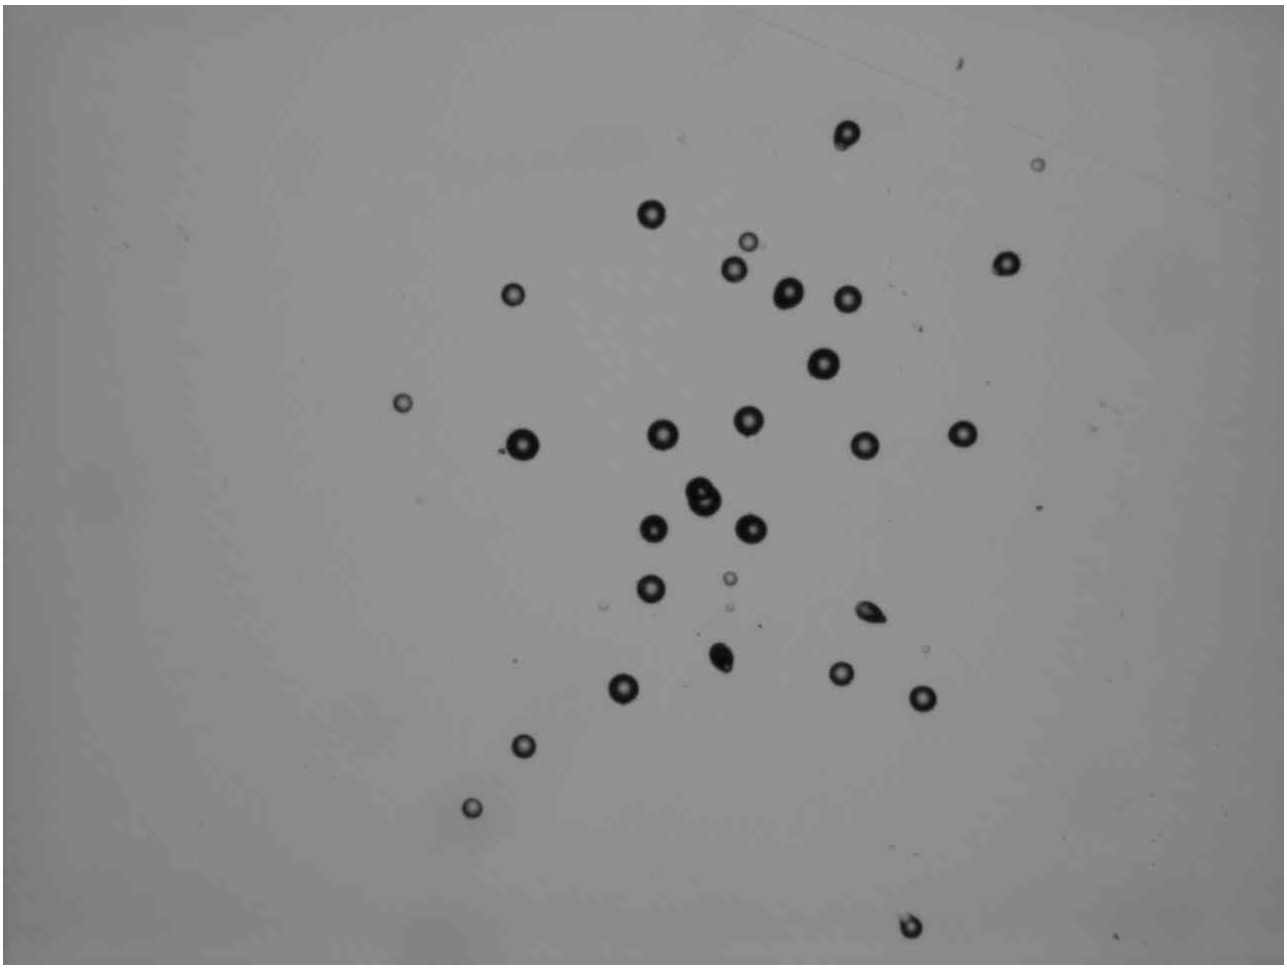

Figure 15
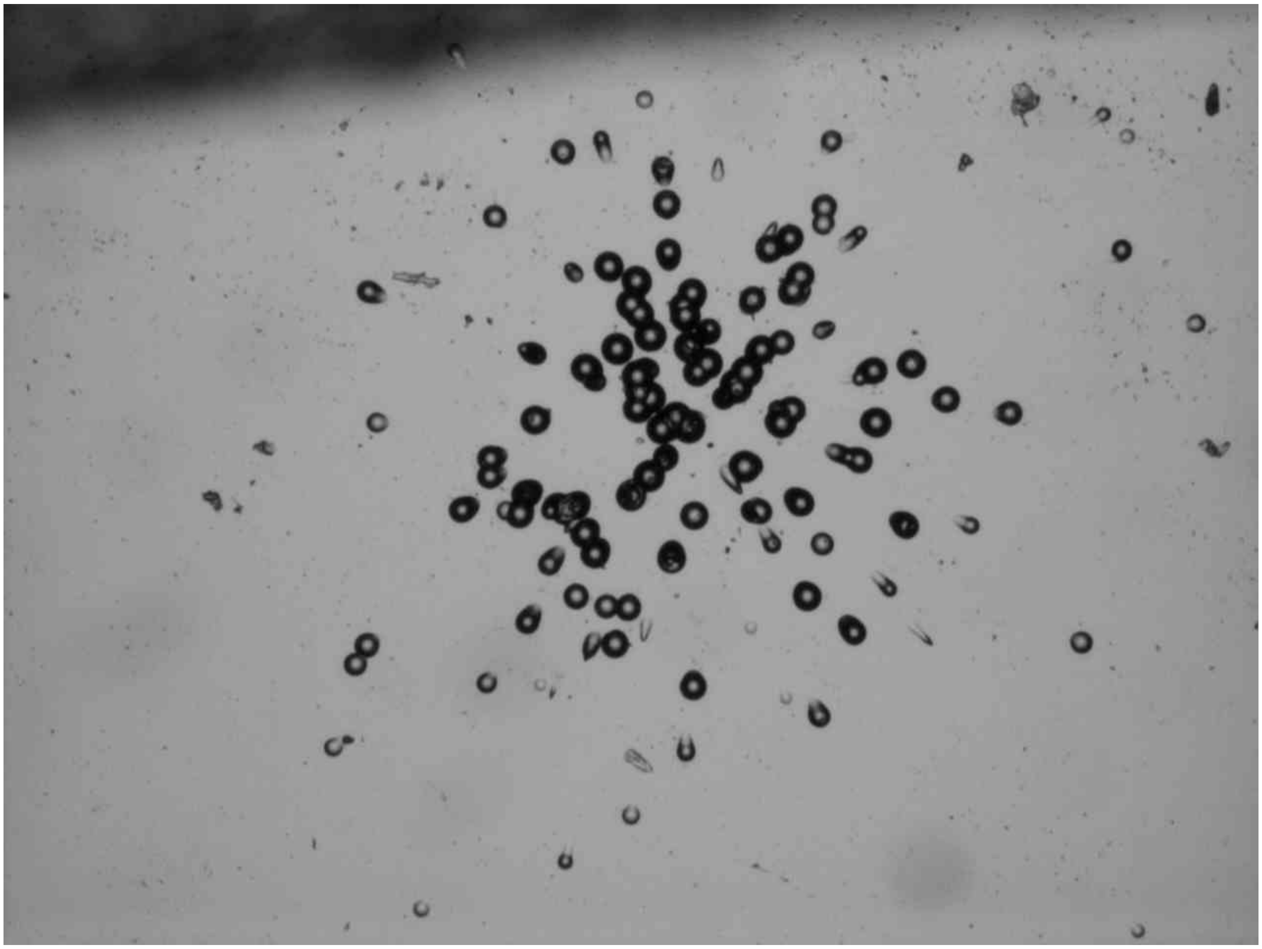
Is this a cluster I missed before or is it a cluster that lost some tracks due to additional etching? Magnification 40. The field shown is about 1.0 by 1.3 mm.
- -

The figure 16 below shows the same cluster as in Figure 5, except that tacks are larger. One thing becomes clear; many tracks that were elliptical before became round. That is good to keep in mind. Large tracks are easier to count but loosing elipticity might not be desirable. Another undesirable thing is that tracks are overlapped more often.
- - - - - - - - - - - - - - - -



(BR> Figure 16
A cluster that was shown in Figure 5, after additional 5 hrs of etching. Magnification 40. The field shown is about 1.0 by 1.3 mm.

\- -

The large cascade, shown in Figures 3 and 4, already had a smalled and shallower tracks. In Figure 17 one can see some tracks from that cluster, after additional 5 hours of etching. They seem to be even more shallow (less dark) than before. The figure 17 shows an island of pits which I did not see before. I would not count them as tracks. But what are they? I saw several little island of such “foam” today. In any case, this question belongs to speculations; our task, at this stage is to either agree or disagree on reproducibility. What is reproducible and what is not? It is a waste of time to speculate about things which might turn out not to be reproducible.

\- - - - - - - - - - - - - - -

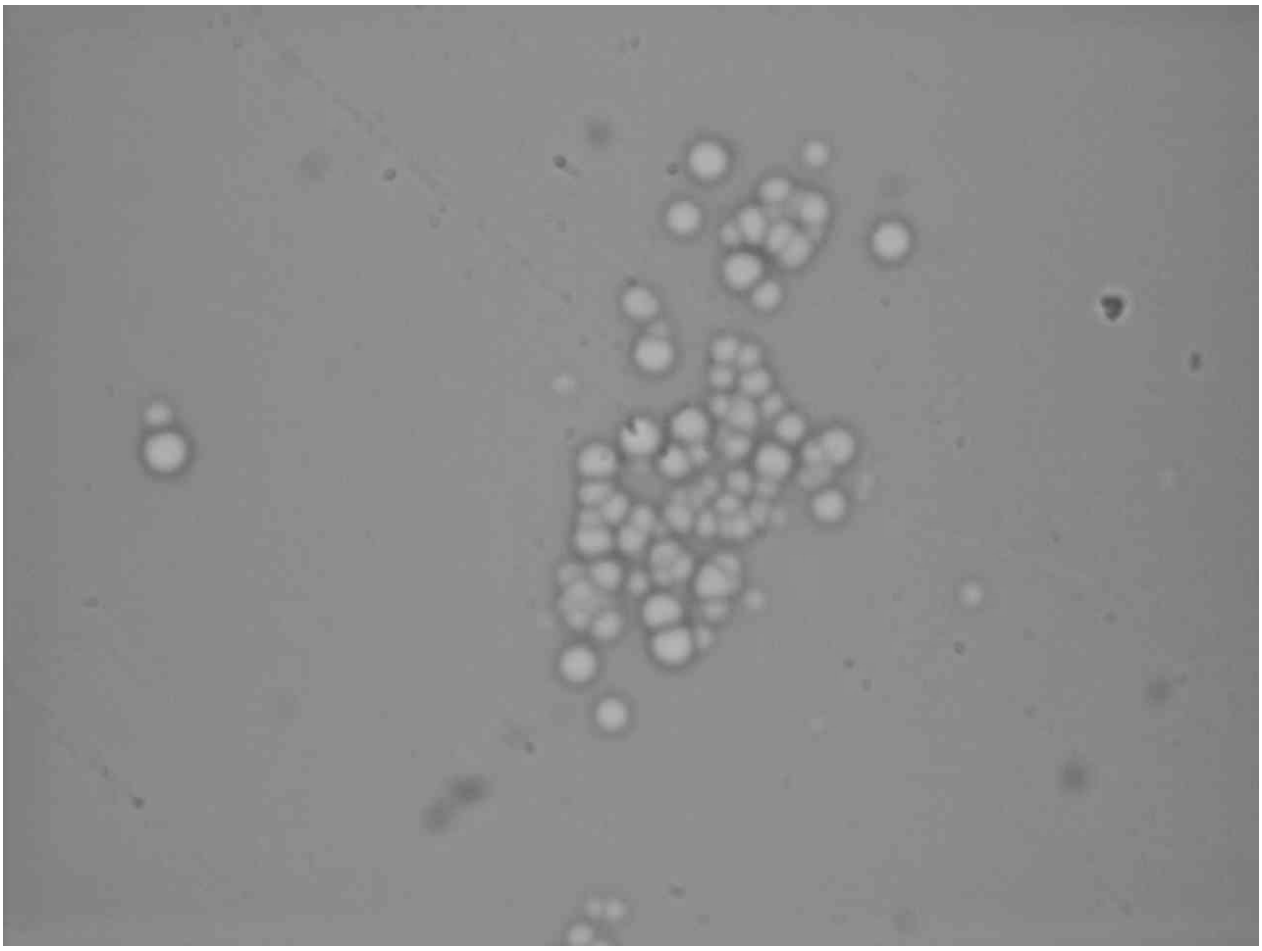


Figure 17
An island of very shallow pits that are very close to each other. Magnification 200. The field shown is about 0.2 by 0.26 mm.
- -

A smaller island of very shallow pits is shown in the Figure 18.
- - - - - - - - - - - - - - - -

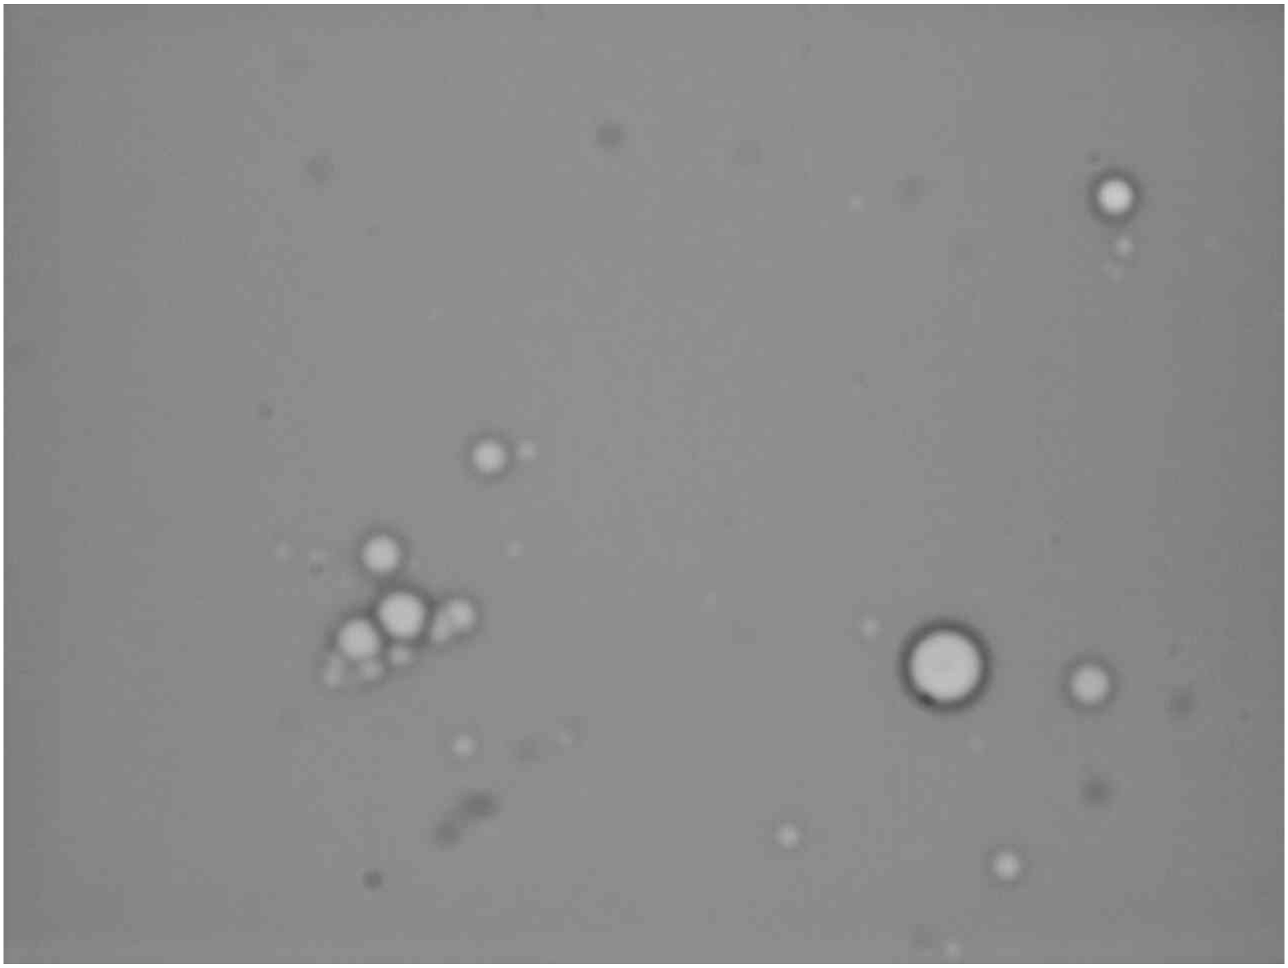

Figure 18
Another island of very shallow pits that are very close to each other. The field shown is about 0.2 by 0.26 mm. Magnification 200. At that magnification, pits due to alpha particles would be about two times larger than the largest pits below (toward the lower right corner). And they would have dark boundaries, as in Figure 14.
- -

Pits like those shown in the last two figures will not be counted when the CR-39 chips, from the experiment #2, are examined tomorrow. Keep in mind, in comparing pictures with each others, that the level of focusing and the level of illumination effect peak appearences. I am glad that Marissa found two large clusters. How many will I find tomorrow? The large chip will be easier to work with because it is not twisted. So I will not have to constantly refocus when the chip is scanned.

59) Other replications: Marissa Little also finished two experiments and clusters were observed in each of them. Preliminary results, and pictures, are already in her electronic logbook at:

http://www.earthtech.org/PACA/logbook.html

= =

60) My three experiments were #1 (5 days of electrolysis) #2 (21 days of electrolysis) and #3 (it has been running for over 2 days so far). The five chips from the experiment #2 (their locatios are shown in Figure 8 above) have been etched yesterday. Today I examined these chips. Figure 18 shows tracks of alpha particles, from the little corner of my large chip.
- - - - - - - - - - - - - - -

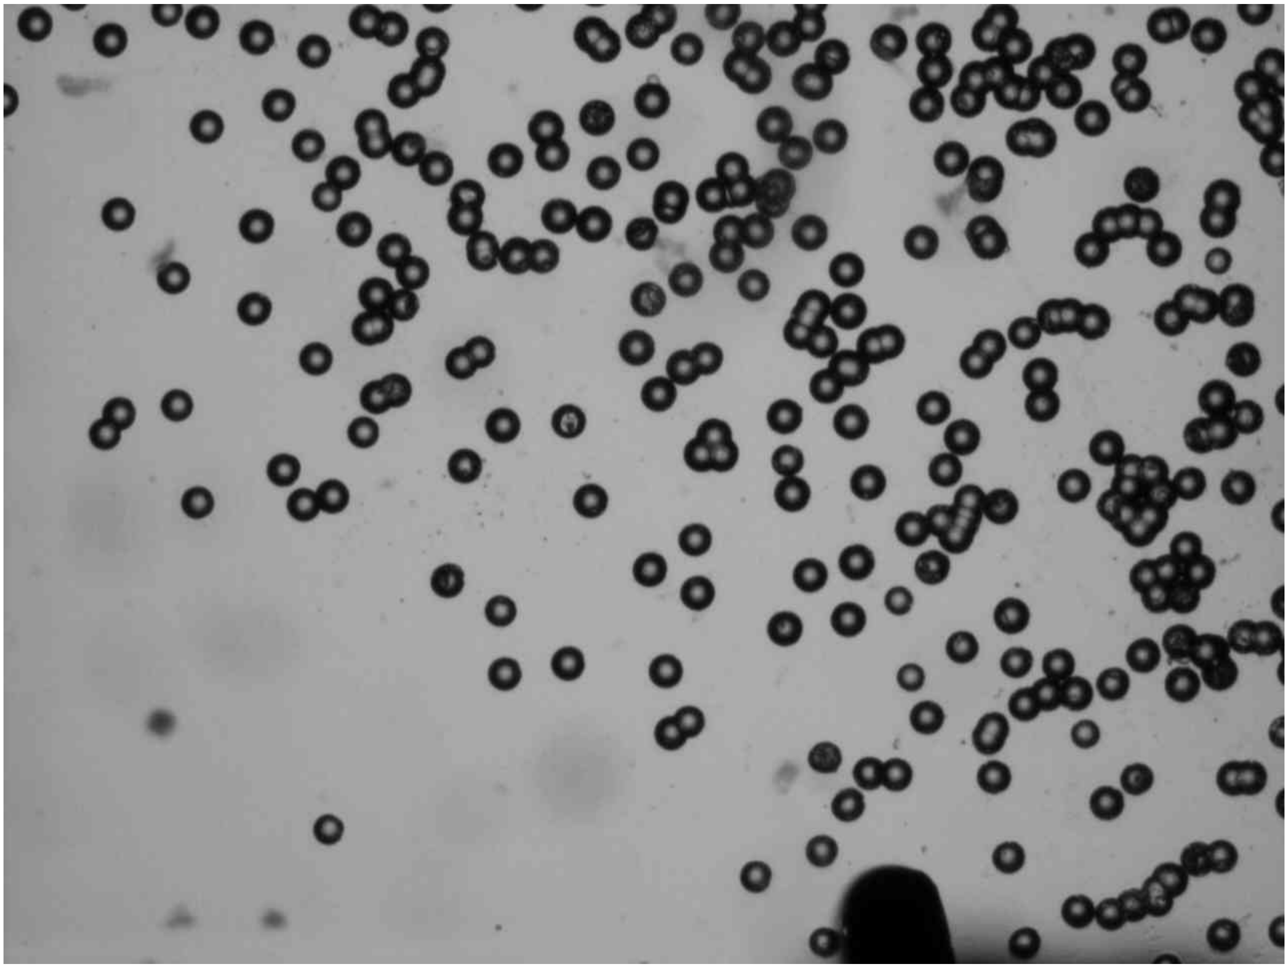

Figure 19
Tracks of alpha particles from Am-241 after 6 hours of etching. Magnification 40. The field shown is about 1.0 by 1.3 mm.
- -

Figure 20 shows the largest cluster I found. It has about 80 tracks. The average track density, over the field shown in this figure is 80/0.013= 6154 tracks per cm^2. The average background density is known to be close to 15 tr/cm^2.
- - - - - - - - - - - - - - -

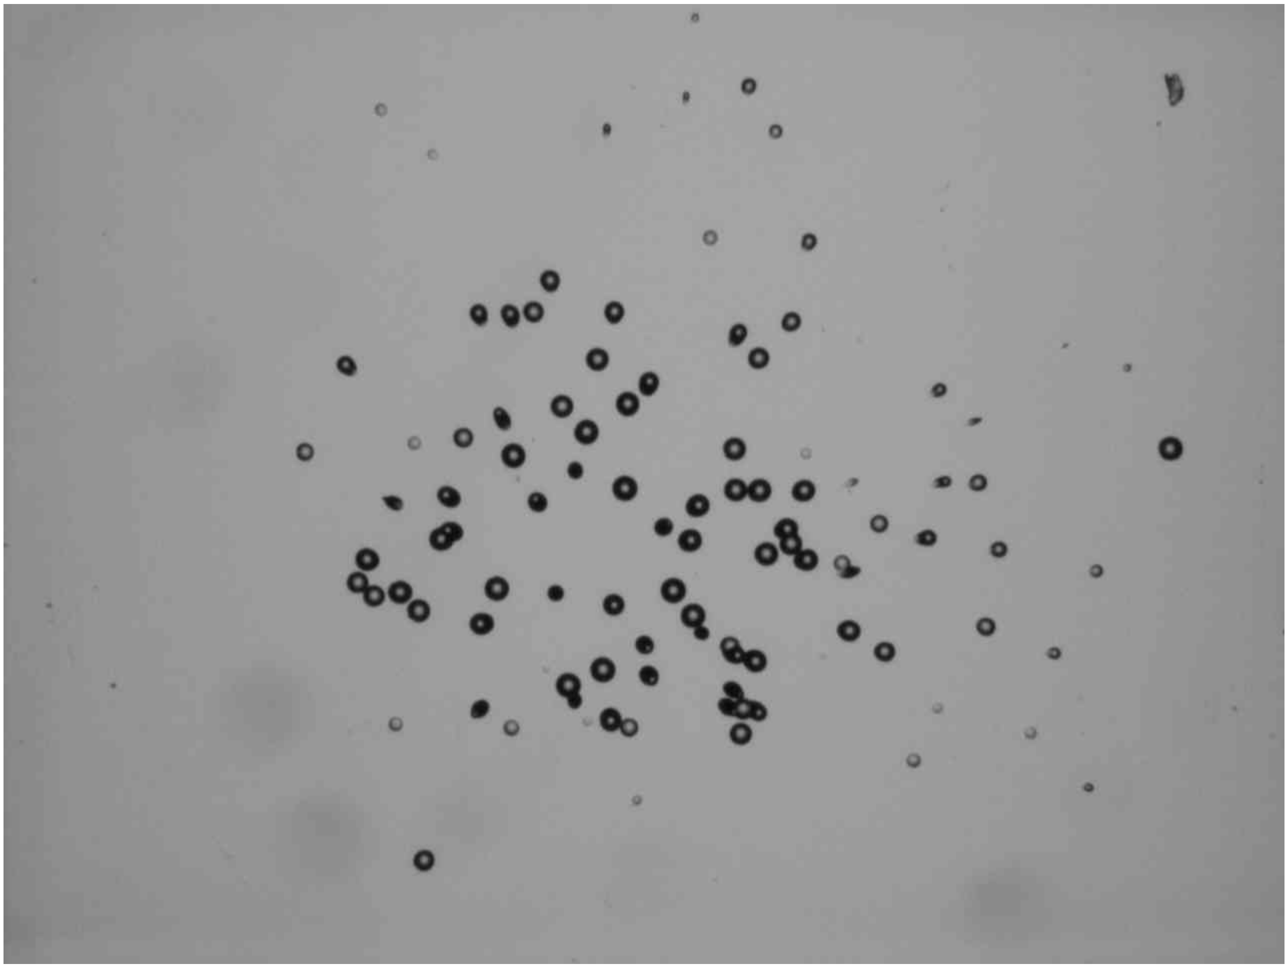

Figure 20
A cluster of about 80 tracks. Magnification 40. The field shown is about 1.0 by 1.3 mm. This cluster was found on the side of CR-39 chip that was facing down (away from the electrolyte). I looked at the corresponding circular field above it (the field looking up) and found only two tracks, on the field periffery. Visually seen circular fields have diameters close to 5mm, their areas are 3.7 times larger than areas of rectangular fields of the camera.
- -

Figure 21 shows a small cluster. Many more such clusters could be found. In this case one has 7 tracks on the area of 1.3 mm^2. This translates into 7/0.013= 538 tracks per cm^2. That is nearly 40 times higher than the mean background density.
- - - - - - - - - - - - - - -

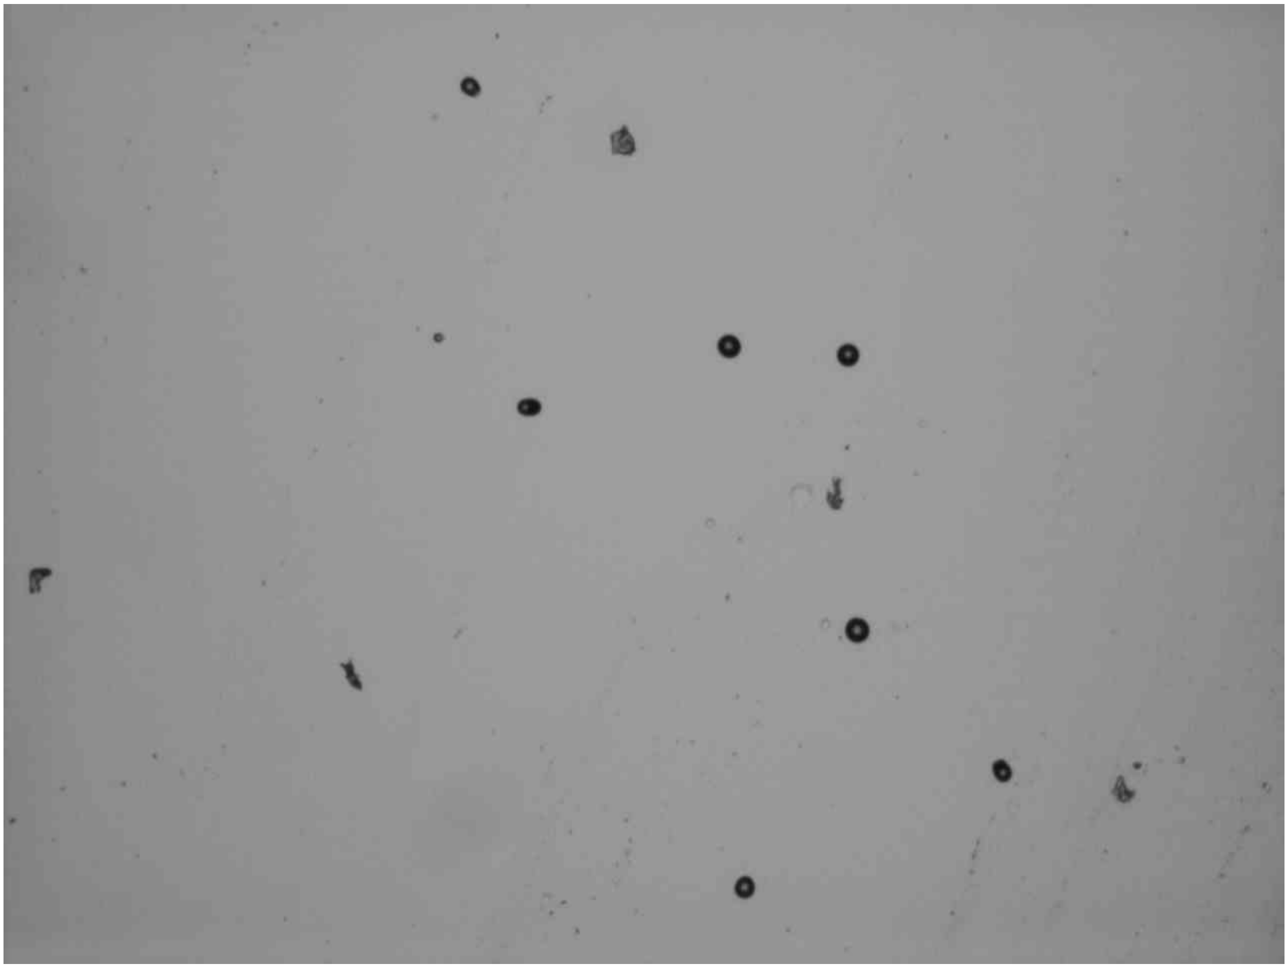

Figure 21
Tracks of a small cluster. Magnification 40. The field shown is about 1.0 by 1.3 mm. The local field density, 538 tr/cm^2 is still much higher than in the background (15 tr/cm^2). Clusters with small number of tracks, like the one above, could be found on each side of the chip.
- -

Note that diameters of pits in clusters are about two times smaller than the diameters at tracks due to alpha particles from Am-241. This is probably significant. I wish the exposure to alpha particles (at the corner of my large CR-39) had been done before the electrolysis and not after it. For the time being this issue should probably be ignored. Our goal is to establish reproducibility of clusters. Each experiment, so far, confirms Oriani's claim. In that sense, great progress was made in recent weeks. Figures 22 and 23 show a cluster that occupies two fields.
- - - - - - - - - - - - - - -

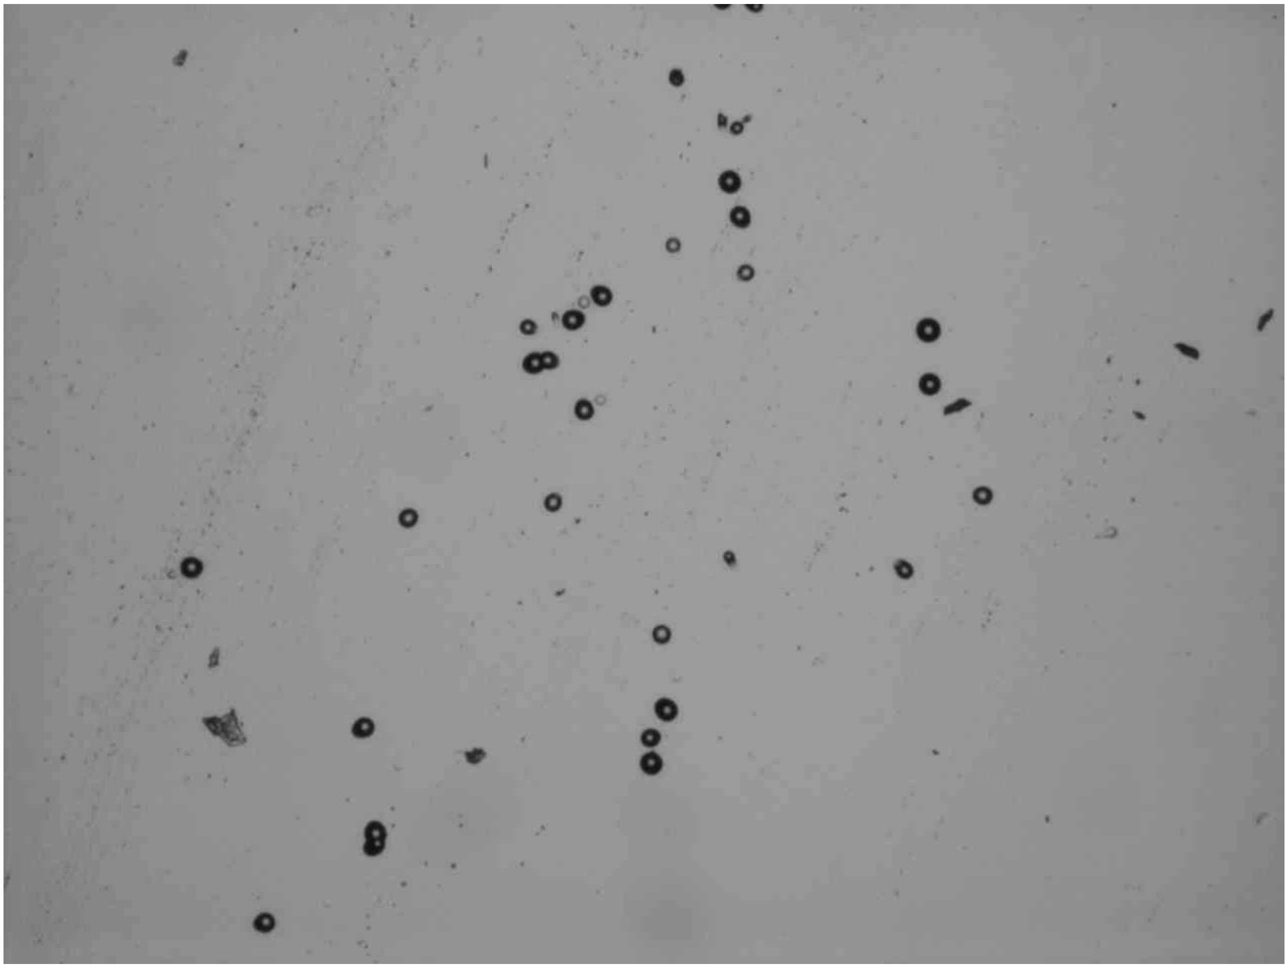

Figure 22
Lower part of a cluster (27 pits). Magnification 40. The field shown is about 1.0 by 1.3 mm. This cluster was found on the side facing the electrolyte. The circular field below it (the field facing away from the electrolyte) had zero tracks.
- -

Some tracks can be seen on both figures.
- - - - - - - - - - - - - - -

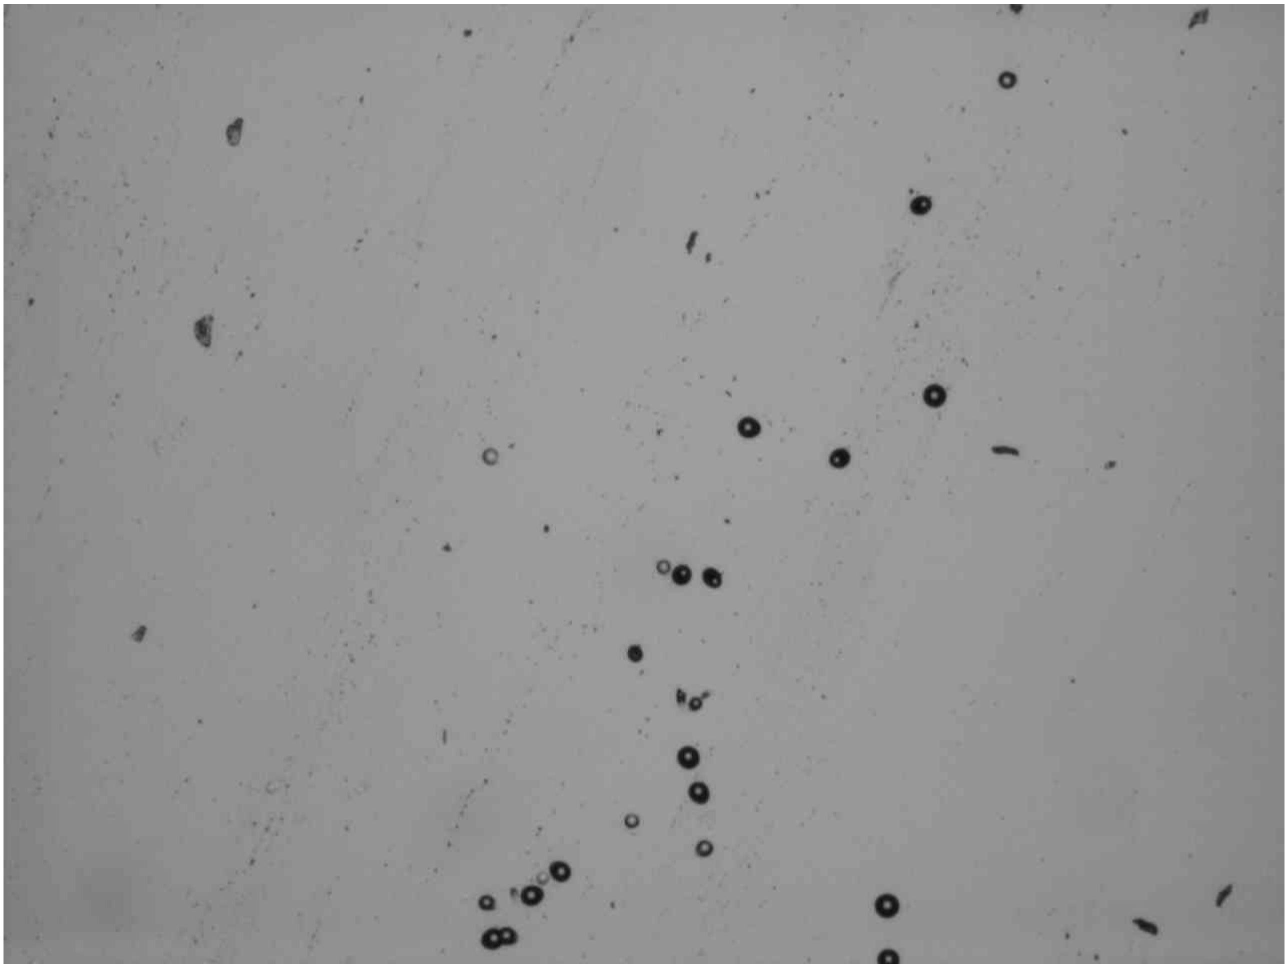

Figure 23
Seven additional pits of the cluster shown in Figure 22 can be seen in the upper part of this figure. Magnification 40. The field shown is about 1.0 by 1.3 mm. This cluster was found on the side facing the electrolyte. The circular field below it (the field facing away from the electrolyte) had one track.

- -

Figure 24 shows a mini-cluster, similar to that of Marissa.

- - - - - - - - - - - - - - -

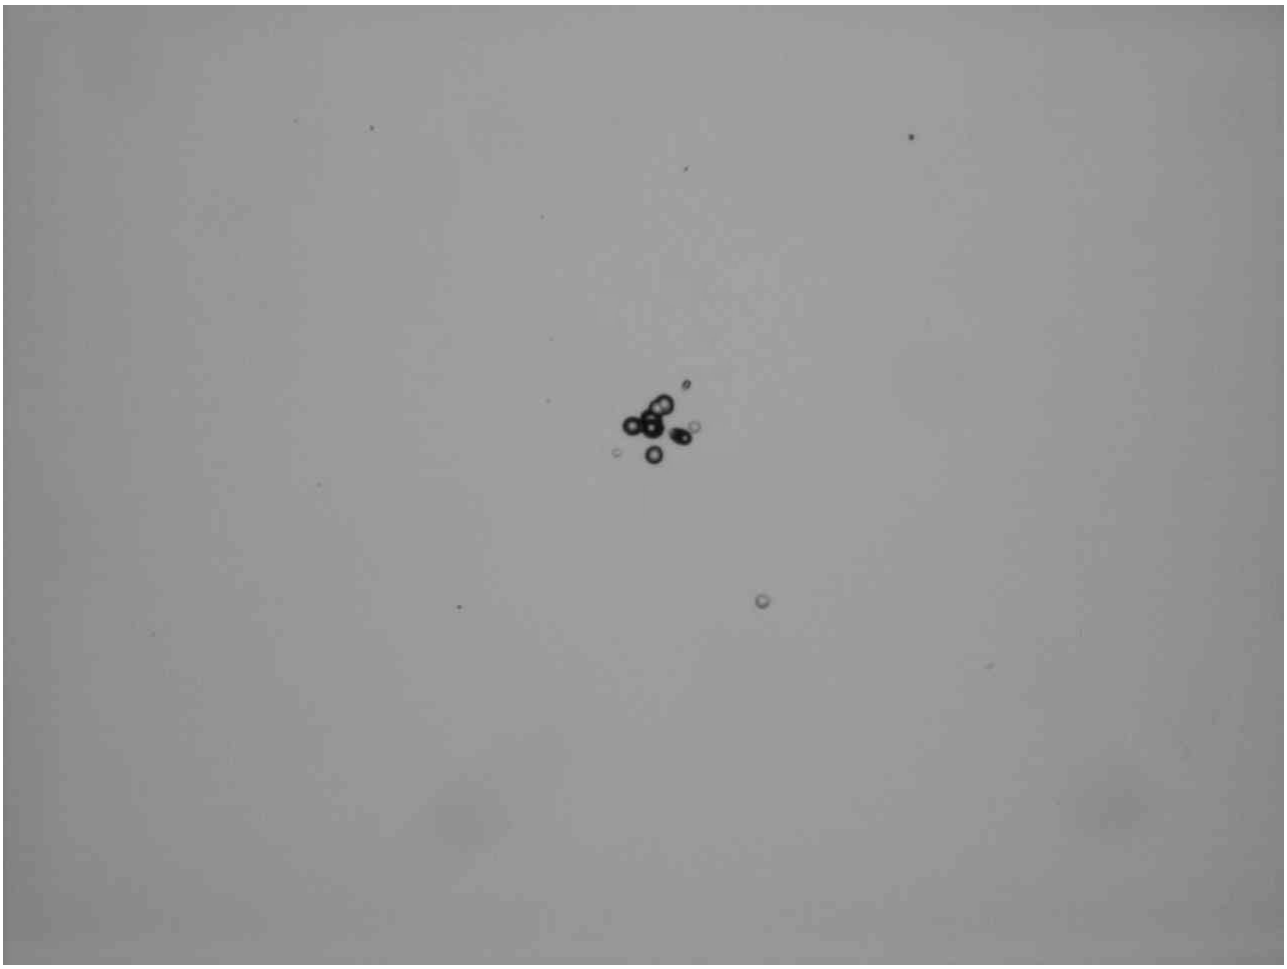

Figure 24
A tiny cluster. Magnification 40. The field shown is about 1.0 by 1.3 mm. This cluster was found on the side facing the electrolyte. The circular field below it (the field facing away from the electrolyte) had zero tracks.
- -

Figure 25 shows the same mini-cluser under a five times larger magnification.
- - - - - - - - - - - - - - - -

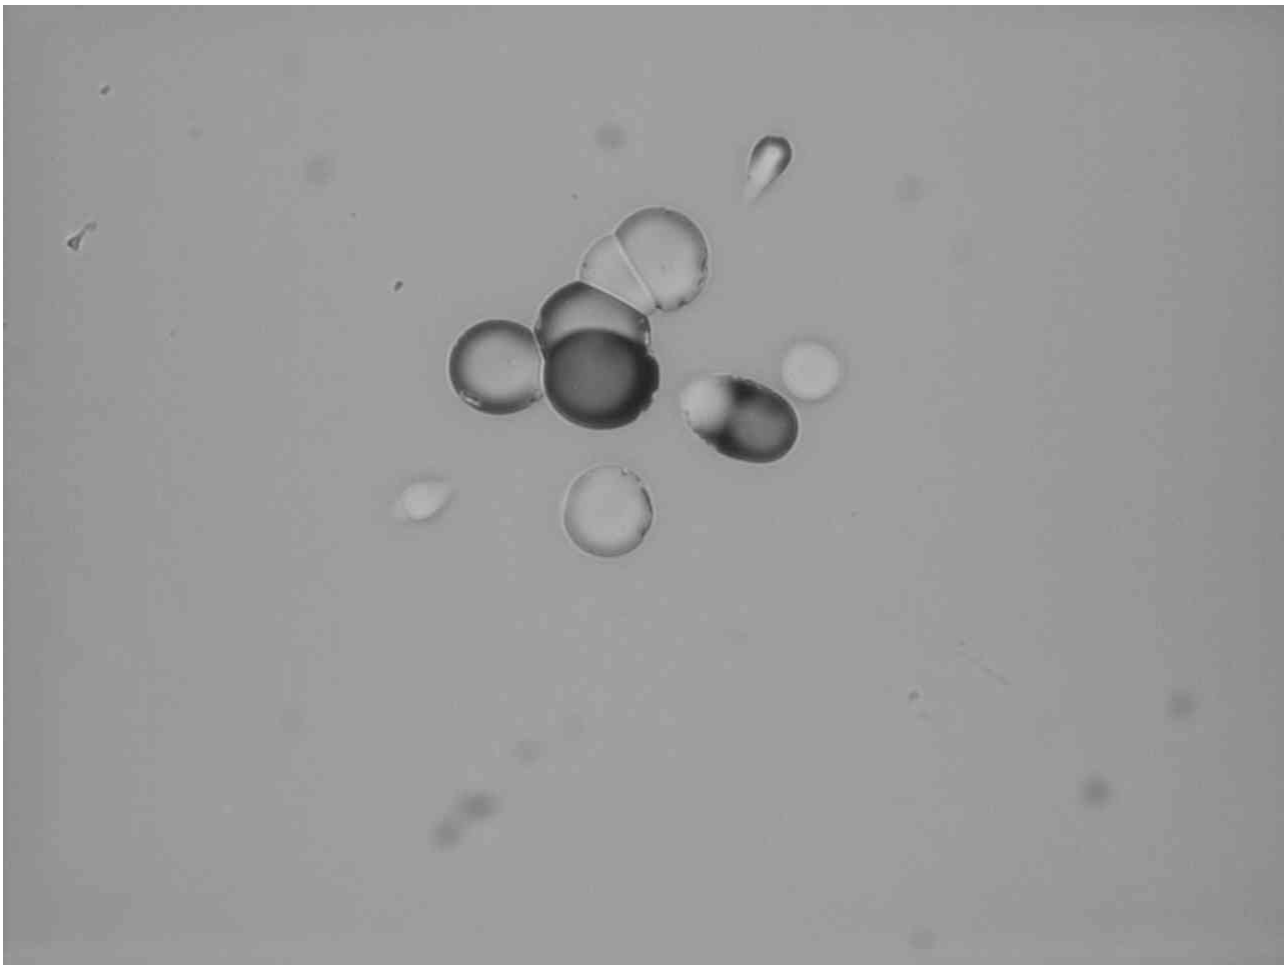

Figure 25
A tiny cluster. Magnification 200. The field shown is about 0.2 by 0.26 mm. This cluster was found on the side facing the electrolyte.
- -

No clusters were found on four smaller chips, placed as shown in Figure 8. The numbers of tracks on 8 surfaces of these chips (each 2 by 0.9 cm) are shown below.

41 tracks on Surface 1
22 tracks on Surface 2
36 tracks on Surface 3
34 tracks on Surface 4
35 tracks on Surface 5
32 tracks on Surface 6
33 tracks on Surface 7
26 tracks on Surface 8

These results are similar to the background, measured by Richard (who sent me the chips). The sum of tracks on both sides of the large chip, excluding those that belong to large clusters, turned out to be 396. The exclusion process was subjective. Dividing this sum by 2*9 cm^2 one gets 22 tacks per cm^2. This is not significantly larger than the expected background of 15 tracks per cm^2. Part of the difference might be due to small clusters (that were not excluded) but this cannot be taken for granted. Note that local track densities within some clusters, as in Figure 19, are orders of magnitude higher than in the background. For that reason we should emphasize clusters and not mean track densities (which include clusters). This reminds me of a famous saying attributed to E. Rutherford -- “if your experiment needs statistics, you ought to do a better experiment.” Clusters will be easier to sell than mean densities.

61) June 1, 2007

Experiment #2, that lasted 21 days, did not produce many more clusters that the experiment #1, that lasted only 5 days. Prompted by Richard and Marissa, I decided to end the experiment #3 after only four days of electrolysis, and to start experiment #4.

62) June 2, 2007

Experiment #3 was stoped at 15:50 today (after 95 hours of electrolysis at I=41 mA). That was only one hour less than 4 days. Once again some moisture was found on the CR-39 that was supposed to be protected from the electrolyte. The mylar had no rupture but the imprit of the spiral nickel cathode (the foot) was clearly visible. That is where, I suspect, was the leakage. Instead of starting experiment #4 at once I removed the O-rings and applied the CR-39 chips to them. Motivation for this was in what I know about Oriani's results (a lot of tracks below the rings), and in what was reported by Marissa yesterday (also excessive track below the ring).

Figure 26 is very crude schematic representation of my O-ring testing arrangement. The two removed O-rings are labeled as Q and P while four 2 by 1 cm chips are labeled as A, B, C, and D. In the cell from which the two O-rings were removed the ring P was below the ring Q, as illustrated. The chip A stayed below the ring Q for 24 hours, the chips C and D stayed above the ring P for 24 hours, while chip B stayed between the two rings for 24 hours. The chip E has three areas. During the first 8 hours first area was between the two rings, during the second 8 hours the second area was between the two rings, and diring the last 8 hours the third are was between the two rings. This was accomplished by sliding the chip E from one position to another.

- - - - - - - - - - - - - - -

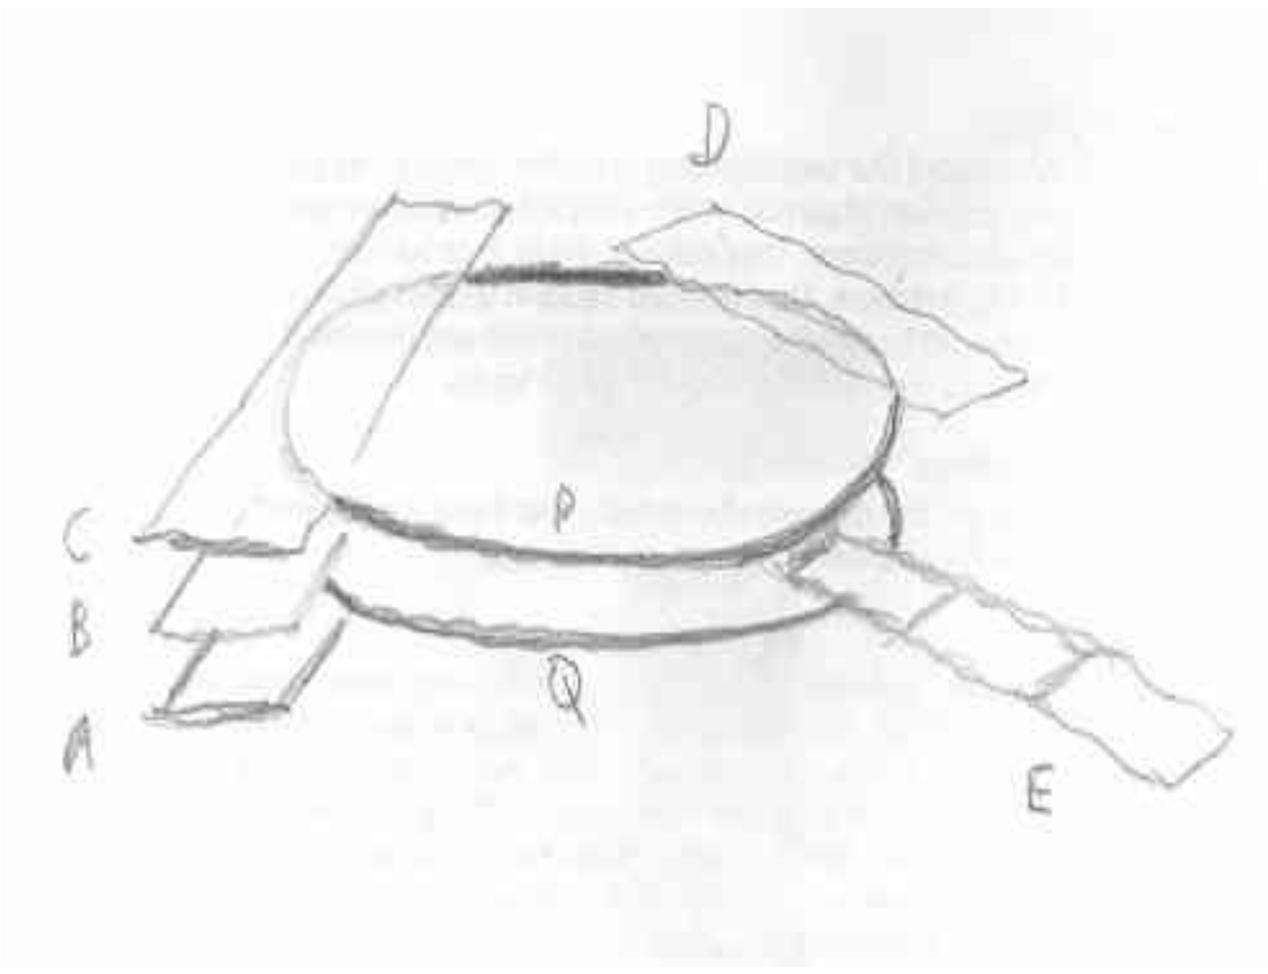

Figure 26

A tiny cluster. Magnification 200. The field shown is about 0.2 by 0.26 mm. This cluster was found on the side facing the electrolyte.

- -

Chips A, B, C and D are the same as those shown in Figure 8; they were used in experiment #2. I know that the average number of pits per surface, after the experiment #2, was 32. The chip E on the other hand was never used; it was the last one from a set sent to me by Pamela Boss. The expected background is 15 pits per surface.

63) Uranium dust?
Marissa's website:

http://www.earthtech.org/PACA/logbook.html

shows what happens when alpha-radioactive dust particles are deposited on the CR-39 surface. Each dust particle creates a set of tracks similar to our clusters. It might mean that the NAE created during the electrolysis is not deposited uniformly over the O-ring surfaces. But it can also mean that some kind of radioactive contamination, for example uranium or radium, is present on seeded rings sent to us by Oriani. If this were the case then a "seeded" ring would remain "seeded" for a very long time. Oriani wrote that seeded pieces loose their potency after several days. That seems to rule out uranium or radium. What about Rn-222 whose half-life is 3.8 days, or Po-218 which is constantly recreated from Rn-222 at the rate of 3.8 days? There are several such possibilities, such as Ra-224, Po-216, Bi-212 and Po-212. My ongoing test (see Figure 26 above) could be repeated but with time intervals longer than 8 hours. But a silicon detector would be a much better tool for this kind of investigations. It would show which isotopes are present and in what relative amounts (on the basis of energies and half-lives).

64) June 3, 2007
Chip E has just been moved to the third (last) position. The field that was on the right side in Figure 26 is now between the two O-rings. The test will end in 8 hours and the experiment #4 will be started. Meanwhile I was thinking about the radon-like contamination again. Which experimental facts is it consistent with and which facts are not consistent with it?

a) Experiment #2 lasted four times longer that experiment #1. But it did not produce about four times more large clusters. The might be interpreted as an indication of the radon-like effect. Clusters are due to dust particles whose alpha radioactivity goes down exponentially with the half-life of several days.

b) If that interpretation is valid then I should see even smaller number of large clusters in the experiment #4. After all, it will be started 27 days after the O-rings were received. Perhaps experiment #4 should also last several weeks. If clusters are due to original contamination with something that decays like radon then the experiment #5, stared two months after the experiment #1, should have no clusters at all. On the other hand, I should still observe large clusters, in the experiment #5, if they are due to something alpha-radioactive that is recreated in the cell during the electrolysis.

c) Oriani did observe large clusters in about twenty consecutive experiments, each lasting about 4 days. That would be a good argument that clusters are due to a nuclear process induced by electrolysis, provided one can be sure O-rings are not recontaminated with radon-like something, after each experiment. It would be interesting to know how many clusters were actually observed after each of his experiments. Fortunately, his CR-39 pieces contain this information. I am sure Richard keeps them well organized and labeled.

d) In a private message received today, someone wrote that an X-rays film could be used below the CR-39 chips during Oriani-type experiments. " If you see any pattern in the fogging that matches the damage (pits) in the CR39, it will be very difficult to explain the pits as chemical or mechanically induced artifacts." Logically this makes sense. But the X-ray film is not sensitive enough, unless one wants to detect millions of photons. Using thick nuclear emulsions, instead of CR-39 chips, could be useful. But this is not trivial. In any case, I have no experience in working with thick nuclear emulsions. Silicon detectors would be much more appropriate replacement for our chips.

65) The 24-hours-long test ended and the experiment #4 started at 16:30 (6/3/07).
Nothing is different in comparison with the experiment #3, except the cathode wire was slightly reshaped, to make sure the center column (in the heat shrink) is not the lowest point of the foot. I am concerned about the moisture. The nuts were turned a little tighter. I will now start etching all five chips used in this test, and three chips used in the experiment #3. The large chip (3 by 3 cm) used in the experiment #3 was squeezed between the O-rings while two small chips (2 by 0.9 cm), used in this experiment, were in the air, outside the cell. As in the experiment #2, they were slightly above the plane of the main chip (say 3 mm). One of them was 45 to 65 mm from the cell axis and another was 75 to 95 mm from the axis.

Only one large CR-39 is used in the experiment #4; it is my last CR-39 piece. New 6 micron mylar is used in experiment #4. And the exposure to Am-241, at the little corner, took place before the electrolysis. Before etching I will expose another corner as well. This might become important in comparing sizes of post-electrolysis pits with sizes of pits due to alpha particles from my Am-241. Starting voltages 12.1 V on the power supply and 6.4 V on the cell (because I am using 41 mA current regulator, as in experiment #3).

66) Time = 5 hours (Sunday, 6/3/07, 21:30)
The experiment #4 has been running nicely but I just discovered a mistake. The mylar film has been positioned below the CR-39 chip, rather than above it. In other words, the chip is not protected from the electrolyte, the cathode foot is resting on the chip. Should I stop the experiment and restart it after placing mylar into the desired position? That is what I would do if it was my first experiment. But it is my third one and I already believe that experiments are reproducible on demand. Why should absence of mylar prevent me from seeing clusters, even near the center? I will certainly be able to see clusters outside the O-rings, and between the O-rings. And I might learn something interesting from this mistake. The experiment #4 is not as important as the experiment #3; its main purpose was "to keep going' so that kindling will be available when I decide to do something else.

67) Time = 30 hours (Monday, 6/4/07, 22:30)
Chips from the experiment #3 Not a single large cluster (above 5 tracks) was found. The total number of tracks was also found to be much smaller that in the experiment #1. Each of the two small chips, that were positioned outside the cell, showed only 7 tracks on two surfaces. That is much less than the expected background. Note that the background is known to fluctuate a lot from one chip to another.

The total number of tracks on two surfaces of the main CR-39 chip was found to be 188. That corresponds to the mean density of about 10 tracks/cm^2. The expected background density is 15 tracks/cm^2. The corresponding number of tracks in the experiment #1, excluding about 100 in clusters, was 636 (mean density 35 tracks/cm^2. The test described in Figure 26 above also did not show excess tracks, in comparison with expected background. These results, and the fact that experiment #2 that lasted 21 days did not produce more clusters than the experiment #1, that lasted only 5 days, are rather significant. They seem to indicate that Oriani's seeded O-rings, responsible for creation of cascades in the first experiment, lost their potency shortly after the experiment #2 was started. The etching was for 6 hours at 74 C, as before, and alphas from Am-241 produced usual pits, But I will etch the big CR-39 for another 6 hours, together with the chip from the experiment #4 (that started yesterday). I do not expect any excess tracks from experiment #4. But I will look for them.

68) An overview of the situation:
a) Are Oriani-type experiments reproducible on demand? Ignoring my experiment #3 one should say yes. But there is vexing problem; the first step of the protocol calls for obtaining a set of seeded O-rings from Richard Oriani. We cannot say "start with commonly available components, follow our footsteps and you will observe clusters of tracks." The demonstration of an electrolytically-induced nuclear process cannot be said to be independently replicable unless preparation of seeded O-rings is also replicable.

b) Seeded O-rings are produced from virgin O-rings in Oriani's electrolytic cell. There is something peculiar in that cell; an attempt to make seeded O-rings in another cell has a very low probability of success. Richard thinks that something rare happened to the cell during one of many experiments conducted by him in the last five years. But he does not know what it was. Investigations of Richard's cell, and of his process of seeding the O-rings should be given high priority.

c) Numerous tests conducted by Richard demonstrated that virgin O-rings, placed on CR-39 chips for several days do not produce excessive tracks of nuclear particles. But seeded O-rings, under identical tests, show presence of excessive tracks. Oriani says that seeded O-rings acquired "residual radioactivity." What kind of track-forming particles are emitted? Is the residual activity permanent or does it decrease with time? Dedicated experiments to answer these questions must be designed. I take it for granted that nothing was alpha radioactive in Richard's cell before it acquired the ability to produce seeded O-rings on demand.

d) Suppose a replication experiment is conducted by a researcher who received a set of seeded O-rings from Richard, as I did. The total number of tracks, after the electrolysis is N(tot). Let N(electr) be the number of tracks due to the electrolysis in the replication experiment. Then

N(electr) = N(tot) - N(res) - N(b)

where N(res) refers to tracks due to residual activity and N(b) refers to tracks due to the background. To show that electrically induced emission of nuclear particles is real one must show that N(tot) is much larger than the N(res) + N(b). Showing that N(tot) is much larger than N(b) is not sufficient. But that is what I was doing so far. That is why investigations of residual activity must be conducted before investigations of electrically induced radioactivity. None of the replicators was able to succeed in a replication experiment without receiving a seeded cell from Oriani. But each replicator can study residual activity.

69) My new results and etc.:
a) Experiment #4 was terminated this morning, after 64 hours of electrolysis. Then the CR-39 chip was etched for 6 hours, as usual. As expected, nothing was found but very low background; only 24 tracks on one side and 20 tracks on the other side. That translates to the average track density of about 2 tracks/cm^2.

b) The already etched main chip from the experiment #3 was etched for additional 6 hours, as suggested by Oriani. The tracks became larger but the total number of tracks, on both surfaces, was found to be 222. This is not significantly different from 188, after the first etching.

c) Today I ordered a CR-39 sheet for a next sequence of experiments. These experiments will probably be started next week, after a fresh set of seeded O-rings is received from Oriani. Marissa and Scott Little also forging ahead with new experiments, as described at their logbook-webpage at:

http://www.earthtech.org/PACA/logbook.html

70) Continuation of this electronic logbook will be in unit #329.
Let me end this unit by describing what happened yesterday. I was etching CR-39 chips in the chemistry lab. A colleague said “you are wasting time on this project.” My reply was that trying to resolve a scientific controversy is not a waste of time. He looked at me and said: “this controversy has already been solved.” I asked: “Do you know what I am studying?” He said “yes, this is another study of cold fusion.” I said that what I am doing is not cold fusion. Then I told him about tracks of nuclear particles. Nothing of that kind was investigated by Fleischmann and Pons. After that he stared listening and admitted that this is not a waste of time. This little episode confirms that many mainstream scientists are preconditioned to reject anything that they associate with cold fusion. Our investigation of Oriani effect has nothing to do with excess heat, with fusion of deuterium nuclei, or other effects that are, unfortunately, labeled as cold fusion. Each effect should be studied on its own merit, till connections with other effects are demonstrated. Being labeled a cold fusion researcher is highly undesirable.

328) Recent observations and comments

Ludwik Kowalski; 5/14/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) My second replication experiment, described in the unit #327, is in progress. It will run for many weeks. It is remarkable how reproducible everything is, as far the experiment is concerned. The current remains stable, as it should, but the cell potential decreases slowly as more and more water is lost by the electrolyte. Relicability of that kind is expect from all experiments in physical sciences -- one does the same things and results are the same. Some fluctuations are unavoidable because of the limited precision of our instruments. But will I see at least as many clusters in my second experiment as I saw in the first? That remains to be seen.

2) Here is what Scott Little wrote, about ten days ago, about excess heat on a private list for CMNS researchers. "[Someone asked how confident are we that the high rates of excess heat are real and nuclear?] In our case, not confident at all. We have never seen a real excess heat signal in our lab. But we have seen plenty of calorimeter artifacts that could easily be mistaken for excess heat signals. In a depressingly small number of cases, we have had the opportunity to perform our measurements side-by-side with the original investigator. In these cases alone we were usually able to pinpoint the error that led to the original excess heat claim. In a few instances, "the effect" would not appear while we were waiting to measure it. In the rest of the cases, all we can really say is that the experiment didn't work when we tried it. Our website http://www.earthtech.org contains a number of reports of these null results. Some people have accused us of trying to disprove cold fusion. That's ridiculous. Cold fusion does not need any help from us to continue being largely ignored by mainstream science.

What cold fusion really needs is a reliable demonstration experiment. That's what Ludwik Kowalski has been trying to find for several years now. We worked closely with him to see if Mizuno's incandescent W experiment (a la Clauzon et al) would do the trick. It didn't. That's what the Galileo Project was trying to establish. It didn't...or hasn't yet. That's what we are still pursuing right now in cooperation with Richard Oriani who continues to see relatively low level positive results from his PACA CR-39 experiments. That's why we continue to maintain our high performance calorimeter, MOAC, in good working condition so that cold fusion researchers can take advantage of our standing offer to test promising cold fusion cells free of charge.

Why go to all this trouble if we've never seen any real signs of cold fusion? Simple. If cold fusion is real, it will be of enormous importance to mankind. Lots of discoveries in science have come only after years of searching. Despite all our null results we still have some hope. But I also think that there is a finite chance that all of the apparently positive results that have been observed in cold fusion experiments are erroneous. i.e. the result of various artifacts. I know, it's hard to imagine how so many intelligent researchers could all be making such measurement errors. But it would at least explain the notorious difficulty of replication that cold fusion suffers. "

3) In message, posted a little earlier, another CMNS researcher, Jacques Dufour, observed: "……..It is very difficult to make a table containing ALL the result, because researchers have a natural tendency not to take into account unexpected results, just because they think that their experiment has to be improved. This is apparently perfectly honest, but we cannot exclude that the unexpected results are in fact true. ……" I find this observation very interesting. Not reporting results which cannot be trusted due to mistakes is natural and desirable. But this should be true for all results, not only for results conflicting with expectations. Otherwise the "perfectly honest" is indeed only

apparent. It is very difficult to be perfectly objective. That is why all important claims should be checked in different laboratories.

4) At the end of his message John Fisher wrote " I certainly believe that Oriani's O-rings contained radioactivity. It is this radioactivity, occasionally releasing polyneutrons, that ignites a reaction in a new setup." Hmm, I have two comments about this. Here what I posted on the private discussion list for CMNS researchers:

(a) The term radioactivity is well defined. In the context of our task, it stands for the emission of alpha particles from substances such as radium, radon, uranium, etc. John is using the same term for something different. I have seen a lot of unnecessary debates due to the fact that people assign different meanings to the same word. Perhaps John's process (releasing of polyneutrons) deserves a different term, at least for the time being. My suggestion is to use the noncommittal term NAE (Nuclear Active Environment), invented by Ed Storms.

(b) What is the best strategy to convince mainstream scientists that CANR are real? I think that the issue is worth discussing. My advice would be to ask all theoreticians -- including John, whose theory inspired the protocol based on starters -- not to inject theoretical interpretations until facts are recognized as real. Remember what happened in 1989. Instead of focusing on real experimental facts (generation of excess heat) discussion quickly shifted to theoretical considerations, such as coulomb barrier, expectations based on wrong models, etc. It would be much better if the F&P phenomenon was called UEH (unexplained excess heat) rather than CF (cold fusion), until the reality of UEH were recognized by all scientists.

If it were up to me I would recommend focusing on our new experimental facts. Let us agree that clusters of tracks are not due to artifacts, such as radioactivity or cosmic rays. Let us agree that clusters are likely to be due to unexplained nuclear projectiles (UNP). Then let us try to convince others that UNP are real. Trying to mix experimental facts with theories might backfire again. We want people to look at our experimental data; we want them to perform experiments; we do not want the debate to shift toward the as-yet-unaccepted ideas, such as polyneutrons, etc. I know it is a touchy issue. Theoreticians do not want to be told what to do, what to publish and how long to wait. And we all believe that pure empiricism is not science. Theoretical debates are essential. But, like other powerful tools, theories can have both positive and negative effects. I am afraid that premature theoretical considerations can produce more harm than good at this delicate stage. What do other people think?

5) In another message I wrote: I am not suggesting another acronym but in the future CANR might be replaced by CEMANA (chemically, electrically and mechanically assisted nuclear activities). In my mind forced diffusion of deuterium, like in Iwamura's experiments, is a mechanical process. And the term "activity" is less restrictive than the term "reaction." Alpha radioactivity of uranium, for example, is not a reaction. I suspect that clusters are produced in bursts of activity. A silicon detector, connected to a scalar (or to a MCA) would be an ideal tool for checking this hypothesis.
P.S.
I my opinion elementary events should be clusters of tracks, not individual tracks. What kind of artifact can possibly be responsible for a cluster? Natural alpha radioactivity from point-like sources. Control experiments, to test for absence radioactivity, are not difficult and we make them routinely. As suggested by someone else, cosmic rays do not produce clusters at the rate of several per week. Such clusters would have been discovered by CR-39 dosimetrists long time ago. If it was not for the widespread prejudice, and for significance of our claim, our data would be sufficient to convince all honest skeptics.

6) Here is how John Fisher responded to my suggestion about short-term strategy: " The idea that neutral particles of a novel type play a role in CANR reactions has proved fruitful. It encouraged Oriani to look for and find charged particles generated in the vapor over the electrolyte in an electrolysis cell (ICCF11). It encouraged Oriani to look for and find charged particles generated in the air beyond the cell wall (ICCF11). It prompted the suggestion that a bit of material exposed to the reaction in one laboratory might serve as a starter for igniting a reaction in another laboratory. Whether or not polyneutron theory is correct, it has proven to be useful by suggesting these procedures. Progress is faster when theory and experiment go hand in hand. They learn from each other and they teach each other. It would be a mistake for theoreticians to remain silent."

7) Replying to the above, X wrote: “Well said John. Scientific method although surprisingly rarely employed in any field has pretty good parentage and has scored some notable successes. As I understand it one should operate with a tight and closed loop connecting experiment and theory; it is a symbiotic process. The only reason to perform an experiment is to test a(n) hypothesis*. I suppose that means that the only reason to formulate a(n) hypothesis is to define conditions of an experiment.”

8) And here is what I wrote about the above comment: In the final analysis, X is correct. The long-term goal is to know what happens, and to understand it in terms of what is already known and accepted. My suggestion had to do with strategy. It is better to first offer what is easier to defend. Experimental data are easier to defend than polyneutrons. But I am only an observer. Let us hope that the 1989 situation does not repeat itself. I am afraid that people will start discussing polyneutrons instead of performing and discussing experiments. I will be easier to defend polyneutrons after existence of clusters, predicted by John Fisher, is accepted by mainstream scientists.

9) Responding to my comment William Collis posted this message: “Yes it will indeed be easier to defend poly-neutrons. As someone who has defended that point of view since I first heard John Fisher's presentation on the subject at ICCF4 in 1993, that will be a relief! In those days, there were very few explanations other than variations on d-d fusion. I'll confess I was subject a certain amount of ridicule when I made a presentation on it in 1994 (at Siena, Italy)! Having said that, it may well be that the poly-neutron theory is wrong, almost certainly in detail, quite possibly in the basics. The theoretical question we need to ask is, "What are the minimum characteristics necessary for these neutral particles in order to explain clusters, hot-spots, seeding, transmutations, helium, tritium, neutrons and few penetrating Xrays / gammas? That's quite a tall order!

I've taken you up on your challenge to write a tutorial on another class of Exotic Neutral Particles (ENP) - Bazhutov's Erzions and I shall include in my ICCF13 paper. I dare say that come the Catania Workshop in October I shall make some drastic changes to the Bazhutov's parameters which will satisfactorily explain the lack of detectable beta decay (no Bremstrahlung, no gammas) which is currently a problem. No model is perfect. It may be that a fusion of multiple ideas will be closer to the truth. Or it may be that magnetic monopoles are the elusive ENPs we are searching for. What we need, is theoretical guidance on how to distinguish these models experimentally. Both Erzion and poly-neutron theory suggest that beryllium should be an excellent fuel and generate energetic alphas. (Why not place a Be foil on the CR39?). You can distinguish the 2 models by examining the Be with a geiger counter afterwards (I won't tell you what to expect!)”

10) Replying to a suggestion, made by another CMNS researcher, to modify our experiment, I wrote: “I think that this is a good idea, as far as trying to understand what is going on is concerned. But that is not what our primary goal should be at this time, in my opinion. The short-term goal should be to convince ourselves, and then to convince others, that what has already been discovered is a new kind of nuclear activity induced by a chemical process, rather than an artifact of some kind. In that context, attempts to replicate identical experiments by eight TGP teams, and by other CMNS researchers, seem to be more important. My suggestion is to focus on potential artifacts in existing setups. Knowing what is going on seems to be more important, in the present situation, than trying to understand it. The coordinated assault should continue. Do you agree?

11) Responding to the above, Andrew Muelenberg wrtote: “Yes and no! While confirming an effect is high priority in the present context, understanding what is going on may make a major impact of establishing the critical conditions for reproducibility. It may make a difference as to how the work is received. It is easy for us back seat drivers to make suggestions on how the experimenters should use their time. If we can usefully contribute time / money / moral support / theories, then we can make suggestions. The extra chips are cheap, easy to place, and would not change the present operations. However, they do require documentation and "reading." Both of those items cost the experimenter dearly. Are there areas in which the experimenters would like or could use assistance? “

12) Yesterday I suggested: let us produce a list of potential artifacts, as far as clusters are concerned. Then we can discussed experiments that will help us to demonstrate that what is observed is not an artifact. Clusters are "easier to sell" than uniform distributions (that are not much more intense than the background). . . .

13) I already commented on what William Collis wrote. Let me add to this. It is always more desirable to explain facts

in terms of what has already been accepted. Explaining facts in terms of unexplained ideas seems to be counterproductive. But this is not something unheard of. I am thinking about the famous paradox of missing energy in beta decay. Calorimetric measurements of mean energies per beta particle, conducted in 1930s, were not consistent with the law of conservation of energy. To explain these experimental results, Pauli invented neutrino, a particle of negligible mass that carries the missing energy. I suppose that many people had reservations about this, just like many of us resist explanations based on polyneutrons, erzions and magnetic monopoles. But Pauli's hypothesis was eventually shown to be correct by Cowan and Reins (1950's).

In my opinion, people who are not fluent in advanced physics, like myself, are not in good position to validate exotic theoretical speculations. But most of us are interested in what high caliber experts think about explanations based on ad hoc assumptions. Explanations will be validated not only on the basis of their logical correctness but also, and mostly, on the basis of experimental facts. But first reality and reproducibility of facts should be recognized by mainstream scientists.

329) Continuation: Oriani's effect in Phase 2

Ludwik Kowalski; 6/14/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Get ready for more experiments:
This is my electronic logbook for data reporting, and for related comments. It is the continuation of my electronic logbook from the unit #327.

2) Below is a message that I just posted on a private list for CMNS researchers. It describes a plan to continue replications of Oriani's experiments. Hopefully, some progress is going to be made to learn about two topics; (a) what is the time dependence of residual activity is seeded O-rings sent to me by Oriani, and (b) are clusters of tracks due to electrolysis or are they due to what Richard calls residual activity.

Richard is going to send me two seeded O-rings, each between two large CR-39 detectors. As soon as detectors arrive (next Tuesday, probably ~24 hours after they were applied to seeded chips) I will remove the chips, and start the experiment #5, with a fresh detector. At the same time two fresh detectors will be applied to the O-ring #2, for the duration of the electrolysis (4 days). During the electrolysis the O-ring #2 will be kept between two fresh detectors. After the electrolysis all seven CR-39 chips will be etched in the same bath for 7 hours.

Suppose I see clusters on CR-39 after the electrolysis and no clusters on CR-39 chips that were applied to the O-ring #2, at the same time. Then I would be able to say that clusters were electrolytically-induced. The other extreme would be "no significant difference between the three chips." This would mean that the electric current in the cell is not responsible for the formation tracks; I would conclude that all excess tracks are due to what Richard calls "residual activity." Information about time-dependence of residual activity (NAE?) will also become available. Does this logic make sense?

Comments, criticism and suggestions will be appreciated, as always. Details will be reported in the on-line logbook (unit #329), as they were when my first four experiments were in progress (unit #327). I am going to follow Richard protocol, as before. I consider this protocol to be preliminary because its first step consists of asking Richard for seeded O-rings. What is needed is a protocol which tells people how to produce seeded rings on demand.

3) Terminology and expectations:
Clusters of tracks on a post-electrolysis chip might be due to three kinds of processes: (a) natural background (cosmic rays and alpha-radioactve contamination), (b) residual activity discovered by Richard Oriani, and (c) electrolysis in a replication experiment (in a cell with seeded O-rings). Contribution of natural background was shown to be negligible in numerous experiments conducted by Oriani (see Table 1 in unit #327). Are alpha-like particles emitted during the electrolysis due to residual activity or are they due to a different process? Assuming that two different processes are involved, I am going to write

$$N(tot)-N(backg) = N(res)+N(electr)$$

where N(res) is the number of particles, or number of clusters of particles, due to residual activity and N(electr) is their number due to electrolysis. On the left side N(tot) represents the total number particles recorded during an experiment while N(electtr) represents the number of particles due to the electric current only. My experiment #5 is expected to

provide information about the N(res) and N(electr). Three distinct outcomes are possible:

(a) N(tot) is not significantly different from N(backg).
(b) N(electr) is negligible in comparison with N(res)
(c) N(electr) is not negligible comparison with N(res)

Note that (a) would exclude anything unusual while (b) or (c) would confirm that at least one CMNS process was taking place during my replication experiment. The outcome (c) would be a clear indication that two CMNS processes were contributing to emission of unexpected alpha-like projectiles.

What does the term "seeded O-ring" refers to? Oriani was studying emission of alpha-like particles, during the electrolysis, for many years. Then he discovered that such particles are also emitted from the O-rings removed from a cell, after electrolysis. That emission was named "residual activity." Why is an O-ring exhibiting residual activity is said to be "seeded"? Because it can be used to replicate Oriani's results in another laboratory, as recently demonstrated. Note that the word "seed" is used to describe an unknown prerequisite for a replication success. In that sense "seed" is not necessarily the same thing as "residual activity," or vice versa. A large number of reproducible-on-demand experiments would have to be performed before things become clear. Inventing names is not sufficient.

4) Replying to Scott Little; 6/17/07:
In a private message Scott Little wrote: "In my search for the sensitivity of CR-39 to radon, I saw several mentions of the problem of radon progeny (decay products) sticking to the CR-39 surface and influencing the track count. It is mentioned in this
paper: www.cityu.edu.hk/ap/nru/pub_j20.pdf . This raises the following question: Is it possible that active o-rings are o-rings that are contaminated with radon progeny? Here is my reply; the CC was sent to R. Oriani and J. Fisher.

"It is true that residual activity, that appears when a virgin O-ring is used in Richard;s cell, is likely to be the central issue raised by referees. Richard's task will be to convince them that what he named "residual activity" is a new CMNS process. They will probably ask "how do you know that it is not an alpa contamination activity?" Here is what I plan to do to address this question, in the next week or two.

a) The two seeded O-rings will probably arrive on Tuesday, each between two CR-39 detectors. Let me name these detectors D1, D2, D3 and D4. I will remove them from the O-rings after 36 hours of exposure (most of it during the delivery).

b) At that time I will start the electrolysis experiment, with a fresh chip, using one seeded O-ring. This will give me the detector D5, after 4 days of electrolysis. Hopefully, D5 will show several clusters, as in my first experiment .

c) During the electrolysis I will study residual activity of the second seeded O-ring. That O-ring will be kept between two fresh chips for two days, and then with two other fresh chips for the next two days. This will give me chips D6, D7, D8 and D9.

d) After four days I will start the second electrolysis experiment, also lasting four days. This will give me the D10 chip, after eight days. Hopefully clusters will again be seen in D10.

e) I will continue studying residual activity during the second electrolysis experiment (applying two fresh chips to the second seeded O-ring every two days). This will give me chips D11, D12, D13 and D14.

f) All chips will be etched at the same time, and in the same bath, after eight days. Will the rate of excessive track formation (tr/cm^2 per day) remain the same or will it be decreasing exponentially with time? To rule out a possibility that Rn-222 is responsible one must show that experimental data are not consistent with the 3.8 days half-life.

g) Unless nothing but the background is observed after the second electrolysis, I plan to continue. Details will depend on results. For example, another 4 days of electrolysis with D15 and two additional data points on residual activity, with D16, D17, D18 and D19, during the same time. The goal will be to learn about the time dependence of residual

activity, using the O-ring #2, and to collect data on clusters during consecutive electrolysis experiments. What else should I do, or how should the plan be modified, to maximize the amount of useful information? P.S. Scott, you asked about Rn-222 atoms sticking to CR-39. That could produce a star with four nearly overlapping tracks (from Rn-222, Po-218, Po-214 and Po-210). But large clusters of separated tracks cannot be explained in that way, unless sticking atoms are clustered, for example, on electrically charged islands. ”

5) The seeded O-rings will arrive today (6/19/07):
a) I will be studying two things at the same time: residual activity (outside the electrolytic cell) and electrically induced activity (in the electrolytic cell). There will be many chips and I must be able to correlate relative positions of chips with respect to O-rings. A system to accomplish this has been invented. This is particularly important in studying of residual activity (because some parts of O-rings might be more active than others.

b)Another important thing is to minimize contributions of radon. This should not be a problem on 27th floor, unless cement walls contain uranium. According to a 2005 Korean paper -- “Construction of an environmental radon monitoring system using CR-39 nuclear track detectors;” by Gil Hoon Ahn and Jai-Ki Lee -- a CR-39 chip exposed to air gains 4 tr/cm^2 each day, when the radon concentration is 1 pCi/L. At a typical 3 pCi/L concentration, the excess would be 60 tr/cm^2, after five days. In my experiment, the accumulation of tracks (both in air and in the electrolytic cell) will be near the open window, in a ventilated room, at the 27th floor. This is the best I can do to minimize the exposure to radon. I will measure the preexisting background in the newly purchased CR-39. Suppose it is 2 tr/cm^2. Suppose the control chip, exposed to air for five days, shows 10 tr/cm^2. That would tell me that the mean radon concentration is close to 0.4 pCi/L. I expect it to be lower than this. But that remains to be seen.

c) After removing a blue plastic, protecting a chip, I will discharge it in jar with salty distilled water. Then the chip will be rinsed in pure water and used in an experiment. And then what? Ideally, a chip should be etched as soon as possible, to prevent accumulation of post-experiment tracks. On the other hand, one may prefer to wait and etch all chips together. What is better? I think that etching as soon as possible is more important. That is what I am going to do.

6) Tuesday, 6/19/07 13:00
The experiment #5 was started. One hour later experiment #6 started. I am performing two experiments at the same time. To avoid confusion, measuring time dependence of residual activity, in the seeded O-ring, will be experiment #5. It is performed outside the electrolytic cell. Looking for clusters of tracks, in the PACA detector below the cell will be experiment #6.

The seeded O-ring #2, received today, had been in contact with two large CR-39 chips for 24 hours. I removed these D1 and D2 chips, and applied fresh D6 and D7 chips to it. These chips will be collecting tracks during the next two days. The seeded O-ring #1 was also in contact with two CR-39 chips, D3 and D4, for 24 hours. These chips were removed; they should give me information about the initial residual activity of the O-ring #1. That O-ring has already been mounted into electrolytic cell, above the mylar and the fresh D5 chip, to start the experiment #6. The current is 41 mA. That is where I am now. The first etching of removed chips will take place as soon as the hot plate, which I ordered today, arrives, probably on Friday. Chips ready for etching are suspended in air, near the open window.

How were the seeded O-rings created in Richard’s cell? They were created during 4 days of electrolysis, in his cell, at 40 mA. A small container with heavy water was in the tube below the CR-39. The lower side of the CR-39 (facing heavy water) was covered by the protective plastic. But a large cluster was found at that protected side of the chip, after the electrolysis. The track density on the other side (facing the mylar and the electrolyte) was only two times higher that the expected background. That is not significant to me, when the mean background and standard deviation are 16 and 9 tr/cm^2, respectively. But the large cluster is an indication that the unexpected process occurred and that the O-rings were seeded.

7) Wednesday, 6/20/07:
The hot plate was delivered today. But its temperature control thermostat is not working. I have to return it. Accumulations of tracks in two experiments are in progress. Nothing abnormal so far.

8) Thursday:, 6/21/07
At 10:00 the D6 and D7 chips were removed from the seeded O-ring #2, after 45 hours of exposure. Fresh D8 and D9 chips were applied to this O-ring at once. They will be exposed to the O-ring for 51 hours. The level of the electrolyte in the cell is still high (~1 cm above the anode). But I am adding distilled water, to replace loses, because I will be away till tomorrow evening. A chip measuring the background was unwrapped today and suspended in air, near the open window.

9) Friday, 7/29/07 (new experimental results):
The chips were etched (in 6.25 NaOH) two times for 6 hour; first without stirring and then with the stirrer. The etching temperature fluctuated between 69 and 79 C.

a) My chip D0' was exposed to the air near my window for 51 hours: The total area of 6 cm^2 (3 cm^2 on each side) had 43+32=75 tracks . This gives the mean density of 12.5 tr/cm^2.

b) My chip D0" was exposed to air for less than 2 minutes (between peeling off the protective plastic and beginning of etching). The total area (of 2*8=16 cm^2) had 104 tracks. This gives the mean density of 6.6 tr/cm^2. But why does one side has 86 tracks while another side, of the same chip, has only 18 tracks? In any case, even 86/8 is consistent with the mean density on the D0' chip. It is also consistent Oriani's background (mean 15 tr/cm^2 and standard deviation of 9 tr/cm^2. Using his standard deviation, I will assume that any mean density below 33 tr/cm^2 is background. That is the threshold of significance, for my chips.

c) Oriani's chips D1, D2 (exposed to the seeded O-ring #2 for the first 24 hours) revealed tracks whose diameters were larger than those due to my alpha particles. This was discovered after my first etching. The chips he applied to O-rings were probably pre-etched for background. Richard confirmed that he often reuses already-etched chips, expecting much stronger signals from residual effects. The first etching for my Am-241 tracks was actually the second etching for his old tracks. How else could the difference in diameters be explained? The chip D1 had 105 large tracks on the side facing the O-ring #2 and 66 on the opposite side. The chip D2 had 90 large chips on the side facing the same O-ring and 79 on the opposite side. This translates into the mean density of 19 tr/cm^2; it is consistent with the background. Smaller tracks, much less numerous, were not counted because I decided to count them after another etching. But distinguishing old tracks from new tracks became practically impossible after my second etching (two partially overlapping distributions).

g) My chip D5 was used in the electrolytic cell. As in the experiment #1 (see item #327), the electrolysis started 24 hours after the seeded O-ring was sent to me by Richard. The electric current was 41 mA and the duration of the electrolysis was 96 hours. No clusters were found on the D5 chip. The area of 9 cm^2, facing the electrolyte, had 107 tracks. The area of 9 cm^2, not facing the electrolyte, had 70 tracks. The mean track density, about 10 tr/cm^2, was not significantly different from the expected background. Absence of clusters on chips used in experiments #2, #3 and #4 was explained (see unit #327) in terms of decreasing "potency of seeds." But this explanation does not apply to the D5 chip; the timing of electrolysis, during which this chip was used, was not very different from that in the experiment #1. Let me add that the post-electrolysis chip D10 was also examined but no clusters were found, only randomly distributed tracks, consistent with the background. The D10 chip, like the D5 chips, was exposed to electrolysis for 4 days (at the constant current of 41 mA). Thus I no longer believe that creation of clusters is reproducible on demand, even when seeded O-rings are used.

h) My chips D6 and D7 were exposed to the seeded O-ring #2, as illustrated in Figure 1 below.

= = = = = = = = = = = = = = =

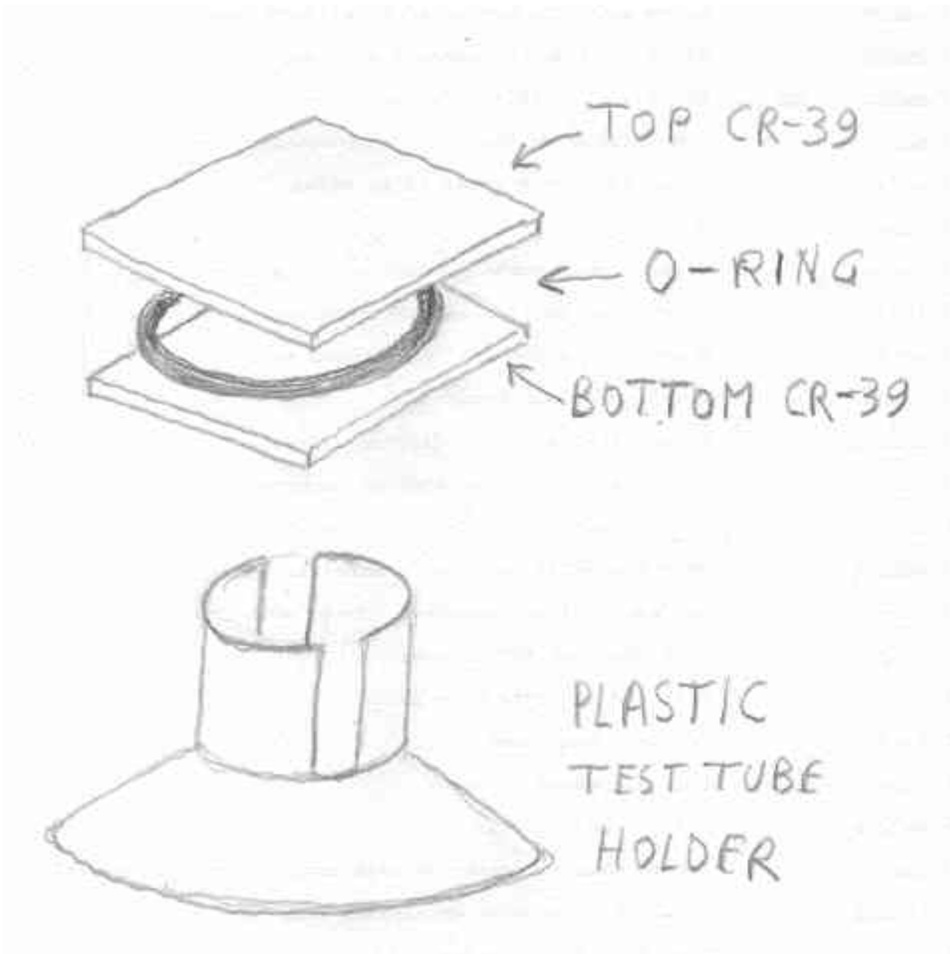

Figure 1
A simple setup to study residual activity in air (without any electrolytic cell).

= =

The D7 chip, supported by a plastic holder, was supporting the O-ring while the D6 was resting on that O-ring. The entire setup was about 15 cm from an open window in a ventilated room. The two vertical slots, in the plastic tube holder, were on the path of fresh air entering the room. This allows me to say that sides of the D7 and D6 chips, that were not in contact with the O-ring, were exposed to fresh air. This test started 24 hours after the seeded O-ring was sent to me by Richard. And it ended 45 hours later. The seeding operation was presumably successful; Richard observed a large cluster on the lower side of the post-electrolysis chip. His mean track density, however, “were in the range of 35 per cm^2.”

The D6 chip produced the following number of tracks: (a) The side in contact with the O-ring had 175 tracks on the surface close to 9 cm^2. This amounts to about 19 tr/cm^2. In other words, nothing significant in comparison with the background, was found. But the other side had many more tracks; I am certain that no mistake was made to identify which side was facing the O-ring. The side that was not in contact with the O-ring had 627 tracks. This translates into 70 tr/cm^2; well above the mean background. To map the distribution of tracks, the entire D6 surface was subdivided into 81 cells (9 rows and 9 columns). The area of each cell was 3.3 by 3.3 mm. The distribution of tracks was not uniform, as shown below.

```
...2...5...4...4...5...5...1...4    4
...5...8...9...3...3...9...4...3...3
..11...7..14...9..13..15...4...3...1

...2...2...2...1..36..41...5...2    2
```

```
...4...1...3...1...5...2...3...3...0
```

The chips D7, that was applied to the other side of the O-ring #2, had 149 tracks on the side that was in contact with the O-ring. This translates into about 149/8.1=18.4 tr/cm^2; it is not significantly higher than the background. The other side of the D7 chip had 355 tracks over the area of about 8.1 cm^2. This translates into the mean density of 44 tr/cm^2. Once again, it is above my threshold of significance. The distribution of tracks, this time in the form 8*8=64 cells, is shown below.

```
...5...4...6...3...1...5...1...0
...4...6...6..17  12   6   2   6

...4...8...7...4...4...2...1...1
```

My chips D8 and D9.
These two chips were applied to the O-ring #2 during the next 48 hours (after chips D6 and D7 were removed from the O-ring). The face of the D8 chip that was facing the O-ring had 95 tracks. This translates into the mean density of 95/9=11 tr/cm^2. The other side of that chip had 159 tracks; This translates into the mean density 158/9=17 tr/cm^2. Both D8 mean densities are likely to be due to the background. The chip D9 also had nothing above the background (114 tracks on the side in contact with the O-ring and 163 on the other side).

My chips D11 and D12.
These two chips were applied to the O-ring #2 during the next 46 hours (after chips D8 and D9 were removed from the O-ring). The mean density, from four surfaces, was 9 tr/cm^2. This is not surprising, considering absence of excess tracks on the D8 and D9 chips. The only conclusion one can make is that the half-life of residual activity is not very different from three or four days. This seems to confirm that the "potency of seeds" decreases, as suspected after the failure to observe clusters in the 21-day-long experiment #2.

10) Summary:
The overall situation, however, is far from being clear. My results seem to conflict with what Marissa Little posted in her electronic logbook yesterday.

http://www.earthtech.org/PACA/logbook.html

She thinks that Po-210 is the most likely candidate for tracks they observed. The half-life of that nuclide is 138 days. My track densities, on the D8 and D9 chips, would be about the same as on the D6 and D7 chips, if Po-210, whose half-life is 138 days, were responsible. Another mystery is that my excessive tracks appeared on CR-39 surfaces that were not in contact with the O-ring. Marissa wrote: "Additionally, we have shown that there is no significant change in the activity of the o-rings using the following sequence: run in a cell for two days, place on CR-39 for two days, repeatedly. This sequence was run for 5 iterations. The o-ring activity appears to be about the same for all 10 experiments." Why did my experiments, conducted in the air, yielded the results conflicting with what was observed in electrolytic cells? Additional experiments are needed to answer such questions.

11) Appended on 7/3/07:
Chip D15 was etched and examined yesterday, after 5 days of exposure to the cathode in my PACA electrolytic cell. The third exposure stared 8 days after the seeded O-ring was received from Richard. Neither clusters nor excessive tracks were found. This was expected because first two exposures (chip D5 and and D10) also produced negative results. The number of tracks on the side facing mylar was 106 while the number of tracks on the side facing down was 186. The mean track density, 292/19=16 tr/cm^2 is in good agreement with the background.

Why is my background so high? A proportional relation between the concentration of alpha radioactivity in air and track density has been studied. If the concentration is 1 pCi/L then each day of exposure to air increases the track density by about 4 tr/cm^2. My experiment was performed in presumably radon-free air (near an open window in a ventilated room at the 27th floor). The radon concentration was probably less than 0.1 pCi/L. The exposure to air was

no longer than several minutes (after the protective layer of plastic was removed and the electrolysis started). The radon in air could thus not be responsible for 16 tr/cm^2. The electrolyte I am using, the glass of my cell, and the wires from which the electrodes are made, were tested by me long time ago. Their contributions to the background, after several days of exposure, were found to be negligible. The only explanation I have is that the CR-39, received from Landauer, has higher than expected background. Perhaps airline companies randomly expose their cargo to neutrons, searching for explosives. The CR-39 chips received from Pamela, and then from Steven (to replicate SPAWAR experiments), had about ten times lower bacground.

Appended om 7/4/07)
1) The recent June 8 and June 26 entries in Marissa's logbook are probably not totally clear to everyone who read them at:

http://www.earthtech.org/PACA/logbook.html

What follows is my recent private messages to Marissa and Scott. It shows my thinking about Po-210. But first let me summarize their point of view. Scott and Marissa, please correct me, if necessary.

(2) Suspecting radon related contamination, and knowing that Rn-222 (and its daughters) can be identified by gamma rays, they sent a seeded O-ring to an expert on low-energy gamma rays detection, Dr. S. Landsberger, at the PRC laboratory. The ring was examined with a large high resolution gamma rays spectrometer. The “clean as a whistle” result indicated that gamma rays intensities were negligible in comparison with what would be consistent with the rate at which alpha particles are emitted from the O-ring. That was first interpreted as a very strong argument against the suspected Rn-related contamination. But then Marissa and Scott found out that one of the daughters, Po-210, nearly always emits alpha particles without accompanying gamma rays (actually, gamma rays of 0.80 MeV are emitted but only in 0.0012% of decays). Thus the “clean as a whistle” result cannot yet be used as an argument against a possibility of contamination. The alpha particles emitted by the O-ring, might be due to Po-210, the last radioactive element in the Rn-222 chain. That is the essence of what was posted by Marissa. I do not think that Po-210 is responsible for alpha particles from their O-ring. Here are extracts from my two private messages about this:

3) On Jun 30, 2007, at 8:26 PM, Scott Little wrote:
"The following calculations show that it is entirely possible that the activity of Richard's "hot" o-rings comes from casual contact with bench surfaces in his lab.....Please show me where I am wrong. I don't like this result any more than you do. But Occam's razor tells us that simple contamination with a known-to-be-present radioisotope is a more likely explanation for these tracks than nuclear reactions caused by ordinary electrolysis." Yes, the volume of a column of air whose base is 1 cm^2, and whose height is 250 cm, is 0.25 liters. Yes, if the activity of radon is 1 pCi/L then the column's activity, due to Rn-222, is 0.25 pCi. Each decay of Rn-222 actually leads to emission of three alpha particles (from Rn-222, Po-218, and Po-214) emitted shortly one after another. Then the Pb-210 is formed. The half-life of that isotope is 22 years. That brings a lot of complications.

The assumption that all single atoms of Pb-210 fall on the floor is questionable. I think that they also "fall" on other surfaces, including walls, ceiling, lungs of people, skin and cloth of people, etc. But that is not my main point. I question validity of Scott's idealization that the activity of Pb-210 is the same as that of Rn-222. I do not know what fraction of Pb-210 atoms, created in a room, actually decays into Po-210 in that room. Many things can happen to a lead atom during 22 years. Here is a hypothetical scenario. Suppose the probability that a lead atom reacts (chemically) with human hair is much higher than that it reacts with other surfaces in a room. In that case most of Pb-210 will be washed away when we take showers. The inert radon, on the other hand, does not react with other surfaces and remains in air. In that scenario the activity on Po-210, in a room, will be much lower than the activity of Rn-222. . . . My suggestion was that we focus on the half-life of residual activity, outside electrolytic cells. Is it consistent with that of Rn-222 (as my single result seems to indicate) or is it consistent with Po-210 (as described by Marissa and Scott)? If the residual activity does not change significantly during a week or two than their hypothesis (which might also be a referee's hypothesis) should be taken seriously. Speculations about what might happen to single lead atoms, created in air, will not help us in this context.

4) On Jul 1, 2007, at 12:45 AM, Scott Little wrote: At 10:44 PM 6/30/2007, Ludwik Kowalski wrote: "My suggestion

was that we focus on the half-life of residual activity, outside electrolytic cells." That seems like a very good direction to investigate, Ludwik. But we are going to have to be very careful not to physically alter the surface of the o-rings during this testing. Ideally, the o-ring should be held somehow and the CR-39 pieces placed very close but not touching. That way we would ensure that casual contact with the o-ring was not removing....or adding...radioactive material. The present method of handling o-rings with our fingers and placing them directly onto the CR-39 chips does not seem sufficiently well controlled for this half-life study. Don't you agree?

And we also need to protect the CR-39 from whatever is causing ~ 100 tracks/cm^2 in our lab on all 4 day background tests. Perhaps the o-ring should be placed in a very shallow, small cup so that, when the CR-39 square was placed on top of the cup, it would almost touch the o-ring and it would also completely cover the cup so that a small, static volume of room air would be exposed to the CR-39. We need one of Richard's super-hot o-rings that produces too many tracks to count in several days. That would allow us to make rather short exposures to the CR-39 and still get a statistically significant track count.

Adding 25 tr/cm^2 each day, especially in your low-radon environment (~ 0.6 pCi/L0), is an indication of something very unusual, as you already indicated. At your concentration only about ~3 tracks/cm^2 should be added each day. Therefore, "whatever is causing ~100 tr/cm^2 in our lab on all 4 day background tests" should be taken very seriously. This "whatever" may indeed be the UNA (unexpected nuclear activity) discovered by Oriani and Fisher. . . .

Appended on 8/2/07
Richard sent me a seeded O-ring with two CR-39 applied to it. I removed the CR-39 chips after 5.5 days and applied fresh CR-39 chips to the same O-ring. The second set was removed 6.5 days later. Then all four chips were etched at the same time (6.25 NaOH, 6 hrs, ~73 C)

1) Richard's CR-39 (labeled with one scratch):
a) side that was facing the O-ring had 49 tracks on 9 cm^2; 5.4 tr/cm^2, no clusters
b) opposite side had 42 tracks on 9 cm^2; 4.7 tr/cm^2, 4.7 tr/cm^2, no clusters.

2) Richard's CR-39 (labeled with two scratches):
a) side that was facing the O-ring had 32 tracks on 9 cm^2; 3.5 tr/cm^2, no clusters.
b) opposite side had 56 tracks on 9 cm^2; 6.2 tr/cm^2, no clusters.

3) Ludwik's CR-39 (labeled with a double cross):
a) side that was facing the O-ring had 32 tracks on 9 cm^2; 3.6 tr/cm^2, no clusters.
b) opposite side had 24 tracks on 9 cm^2; 2.7 tr/cm^2, no clusters.

4) Ludwik's CR-39 (labeled with a single cross):
a) side that was facing the O-ring had 21 tracks on 9 cm^2; 2.3 tr/cm^2, no clusters.
b) opposite side had 186 tracks on 9 cm^2; 21 tr/cm^2, no clusters.

Yes, 186 tracks! Should this be taken as a sign of an unusually large background or as a sign that some kind of a nuclear process that took place during the second exposure? The average from my first 3 surfaces is (32+24+21)/9 = 2.8 tr/cm^2. This is about 8 times less than on the last surface. But I did see large background fluctuations in the past. That is why I tend to attribute 21 tr/cm^2 to the background. Why would a seeded O-ring produce particles during the second exposure (on one side of the CR-39 chip only) and not during the first exposure?

330) Validations and relying on authority

Ludwik Kowalski; 5/25/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Trying to educate myself on the subject of "burden of proof," I went to Google and found <http://en.wikipedia.org/wiki/Burden_of_proof>. Scrolling to "Science and other uses, I found this short paragraph: "The less reasonable a statement seems, the more proof it requires. The scientific consensus on cold fusion is a good example. The majority believes this can not really work, because believing that it would do so would force the alteration of a great many other beliefs about thermodynamics." The author is wrong; validity of the laws of thermodynamics is not being challenged by cold fusion claims; it is a matter of using a new form of energy. In that respect cold fusion does not differ from fission already used to generate electric energy. The word 'thermodynamics" should be replaced by "nuclear physics."

2) A scientist who claims to discover something is expected to provide evidence for the validity of the claim. Other scientists evaluate the evidence and often challenge it in one way or another. That is how mistakes, when they exist, are discovered. A claim might be withdrawn, or additional evidence is provided before it is accepted. That is how things are supposed to work. Mother nature is not capricious; similar results are obtained when the same protocol is used in different laboratories. Suppose a controversy develops. Experimentalists from the camp A believe that pits are due to nuclear particles while experimentalists from the camp B believe that pits are due to a non-nuclear artifact, for example, a chemical effect. On whose shoulders is the burden of proof in this situation? We have two conflicting claims. The side A is expected to validate the nuclear claim and the side B is expected to validate the non-nuclear claim. The burden of proof is not on one side only.

Now consider a situation in which the team A claims to discover something potentially important and valuable while the rest of scientists, team B, prefers not to be involved. Those in team B say "it is not our claim and therefore it is not our obligation to show that the claim is not valid. The burden of proof is on A." I tend to disagree. Scientists are serving society; most often society supports them in one way or another. Evaluation of claims made by recognized experts is expected from all qualified scientists, not only from those who announced a discovery.

3) Another issue, related to the controversies in science has to do with faith in what experts say and write. The ongoing controversy about global warming triggered a debate, among physics teachers, about reliance on experts. In my opinion, one has no choice but to rely on experts, especially in dealing with topics with which one is not sufficiently familiar. A good example is Colorado2 experiment, described in unit #300. A clear explanation with references was needed to convince readers that our measured excess heat could not be attributed to a chemical reaction. I was not able to produce such demonstration. That is why help from an electrochemist was sought. The paper was not submitted because the expected help did not materialize.

The issue of relying on authority should not be confused with the issue of who is the authority. Some people think that newspaper articles and market analysis brochures are written by knowledgeable people. But this is not always true. What follows is an example of a nonsensical report about a scientific claim made by an ignorant writer. (How do I know that the writer is ignorant? Because s/he did not realize that the iESi technology would violate the law of conservation of energy. If s/he did s/he would address the issue. And also because s/he writes kW/hr. At first I thought it was a typing error. But the same "typo" appeared twice. The unit implies that the quantity described is the rate of the rate of the use of energy. This would probably be noticed by many high school students. But the author is obviously

not aware of this.)

Norwood Foundry, Innovative Energy Solutions agree to power up for clean energy facility.

Publication: Modern Casting
Date: Dec 2004
Subject: Internal combustion engine industry (Alliances and partnerships), Metal castings industry (Alliances and partnerships)
Location: United States

Norwood Foundry Ltd., Nisku, Alberta, Canada, and Innovative Energy Solutions Inc. (iESi), Las Vegas, entered into an agreement to begin the engineering, development and operation of iESi's first power generation plant utilizing iESi's clean energy technology. The new clean energy plant will enable Norwood Foundry, which employs 75, to generate six times (12 MW) more electricity than it consumes (2 MW).

iESi's technology will eliminate the need for fossil fuel-fired equipment, such as boilers, to generate super-heated steam required to drive turbines and generators to produce electricity. This will benefit Norwood, which currently uses induction furnaces to cast both ferrous and nonferrous green sand and nobake components.

The finished plant will apply iESi's clean energy technology to generate a power capacity of 12 MW/hr. for Norwood, which expects to market approximately 10 MW/hr. to external entities. The revenue created through the joint venture project is expected to exceed $6 million annually.

Under the joint venture, iESi will be responsible for the implementation of its technologies, while Norwood will finance the project. ACS Engineering, Calgary, Alberta, Canada, has been retained to provide engineering, procurement and construction services to the project. The plant is slated to be fully operational by the third quarter of 2005.

"As one of the largest consumers of electricity in the Nisku area, the implementation of iESi technologies will allow us to save money and continue our leadership position in the metal casting industry," said Norwood Foundry Director Bart Dornan. "iESi technologies will help us realize incremental income on the surplus power we generate, while being environmentally responsible, since no greenhouse gases will be emitted."

As far as In know, it was a fraudulent claim. The company no longer exists and millions of dollars were lost by naive investors.

Appended on 7/27/07:
What follows is a piece, probably more than two years old, that I found quoted over the Internet. The author is a Canadian nuclear scientist who was working for iESi.

Whitepaper On Plasma Heat and Hydrogen Generator

By Dr. Norman L. Arrison

iESi has acquired the most significant technology of the 21st century through Dr. Hyunik Yang and his team from around the world. Their technology draws on the energy of the atom and converts that energy into useful energy in the form of heat in one device and the splitting of the water molecule into hydrogen and oxygen in another device. Dr. Yang's team has varied in size and composition over a ten year period of research. The consistent aspect of the team has been their international stature and dedication to hard work under the leadership of Dr. Hyunik Yang. Dr. Hyunik Yang is 47 years of age and has a distinguished record beginning with his B.Sc. in Engineering from Korea followed by his Ph.D. and post doctorate degrees at Columbia University in New York. He then had a successful career with Hyundai where he was contracted out to NASA and where he won the Eastman Kodak Award for the best paper and an ASME conference. Dr. Yang then went to Russia where he became a member of the Russian Academy of Science.

With the distinguished scientists Dr. Yang had worked with, they decided to build a unit to produce power for mankind based on the energy in the atom.

The approach they used was brilliant. They used resonate harmonic frequencies to expose the nuclei of atoms so they could put the nuclei together to obtain the energy from the fused product. Their system is inexpensive, safe, and easy to operate and construct. The first plasma device will produce heat by taking water and converting it to steam. This device is expected to be working by late 2004 and an early prototype is already functioning. the early prototype produces 14 times the energy put into it and the final product is expected to produce 200 times the energy going into the unit. The second plasma device is expected in early 2005 and it will use it's energy to split the water molecule into hydrogen and oxygen. This device is already working in an old prototype which produces the hydrogen and oxygen and immediately recombines the two in a hot hydrogen and oxygen flame. The old hydrogen-oxygen device was the first proof that the team had successfully tapped the energy of the atom. It only produced 50% more energy out than went into the device but showed that the energy of the atom was being drawn upon.

iESi got control of this techology through the special relationsip which exists between Dr. [removed] and Mr. [removed] the founder of iESi. Mr. [removed] is married to a Korean attorney and through her got to know of Dr. [removed]'s work. Mr. [removed] was so fascinated with the techology that he helped Dr. Yang with his funding which up to that time had been carried by Dr. [removed] and his immediate family. Because of Mr. [removed]'s assistance for Dr. Yang's work, a close relationship blossomed which has resulted in the formation of iESi as it exists today. We at iESi feel very proud that we are the ones bringing this historical changing technology to the world. Plasma heat generation alone guarantees that the cost of electricity will be stable for all mankind. The hydrogen and oxygen producing technology guarantees a clean planet for humanity. the result is that iESi should be the most significant company of the 21st century.

An illustration of calibration

Ludwik Kowalski (August 5, 2007)
Montclair State University, Montclair, N.J. 07055

It often happens that a physical quantity in which we are interested depends on several quantities, x, y, z, which we measure. We say that the quantity is a function of (x,y,z). Sometimes this function is known. For example, the density of a cylinder can be calculated from D = mass/volume. In that case the formula is

D =4*m/(3.145*d^2*h)

where m is the mass, d is the diameter and h is the height. The m, d and h are measured and D is calculated. The well known rules of propagation of errors (1) can then be used to calculate the uncertainty (random error) associated with the calculated quantity. If the errors in m, d and h are, 2%, 3% and 1%, for example, then the uncertainty associated with the calculated density is close to 4.8%. A situation is not as simple when a formula to calculate the value of the quantity of interest is not known. In such case a researcher must depend on calibration. What follows describes an example of a calibration for a simple case in which the quantity of interest is a function of only one variable. I will ignore procedures used to deal with propagation of errors (via calibration) when the quantity depends on more than one variable.

Suppose we are studying an alloy of copper and zinc. We know that the resistivity, r, depends on the percentage of zinc, p. We want to be able to calculate p from r, after r is measured, But the formula for p(r) relation is not known. We also want to be able to calculate the uncertainty associated with the calculated p. To accomplish this we prepare six cylindrical samples of the alloys of known p. The values of p, for these standards of reference, are 5, 10, 15, 20, 25 and 30 percent. We measure r for each of these these samples and obtain the following set of data:

p(% of Zn)	5.0	10	15	20	25	30
r(nΩ*m)	31.2	32.7	38.1	53.1	58.4	52.4

For pure copper, at room temperature, r would probably be close to $1.68*10^{-8}$ Ω*m (16.8 nΩ*m) as reported in most textbooks. The linear regression line, for these six calibration points, happens to be:

p = 0.721*r - 14.5

as illustrated in Figure 1a. That is the end of calibration; the linear relation above becomes our formula to calculate p after r is measured. Details about the method used to measue r are not important in this context. The only important thing is the limited precision of measurements.

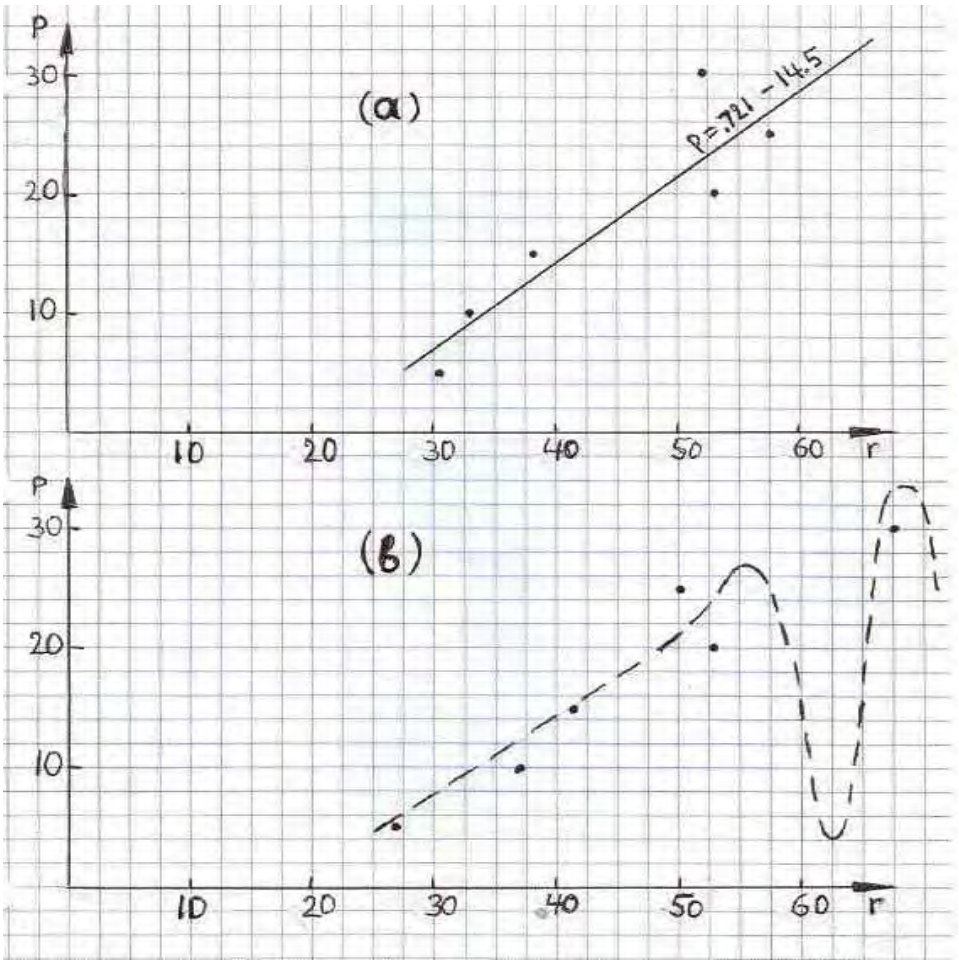

FIGURE 1ab
(a) Calibration scatter plot, p versus r, and the linear regression line.
(b) Another possible scatter plot, after remeasuring r for the same set of six standard alloys. The dashed line shows a possible nonlinear relation between p and r.

- - - - - - - - - - - - - - - -

For example, suppose a sample of unknown composition is given to us. We measure its resistivity and the result is 62.0 nΩ*m. What is the percentage of zinc in that sample? Using the above correlation line we find that p is 30.2 percent. And what uncertainty should be assigned to this results? Looking at the Figure 1a, we see that some data points are above the regression line while others are below it. This is due to random errors associated with measurements of r. The six numbers below are vertical distances between data points and the calibration line (see Figure 1a).

dp (% Zn): -3.04 +0.881 +1.98 -3.83 -2.66 +6.67

Such differences are often called residuals. Note that the mean value of residuals is essentially zero, as is should be according to the definition of the correlation line. Positive numbers refer to data points above the line while negative numbers refer to points below the line. It should be intuitively clear that the uncertainty in p would be larger if random fluctuations of data points, with respect to the correlation line, were larger. Smaller fluctuations, on the other hand, would indicate that the random error in p is smaller. The standard deviation, s, of the above six residuals is 4.00. The uncertainty in p, proportional to s, is thus 5.5, as illustrated in Figure 2.

The above method of inference, however, is not universal. Suppose the true relation between p and r is as shown by the dashed line in Figure 1b. That hypothetical relation has a deep minimum near r=0.62. Not being aware of the minimum we would say that p is 30, plus or minus 4 percent. But real p would be much smaller. The method described above should be used only when one is reasonably sure, on the basis of additional information, that the true relation between the variables is not very different from its linear approximation. (Any non linear function can be

approximated by a line segment for a sufficiently narrow range of independent variable.)

The six data points in Figure 1b is the result of another calibration, based on the same six standards as in Figure 1a. The new numerical data are show below.

p(% of Zn)	5.0	10	15	20	25	30
r(nΩ*m)	26.1	35.7	41.1	52.8	50.2	67.6

This time the calibration line turns out to be

$p = 0.622*r - 10.9$

It coincides with the dashed line in Figure 2b only when $r<4.5$. Why is this line slightly different from the one we obtained before? This is due to the limited precision of measuring r. Note that we are assuming that errors in p, for standards of reference, were negligible. According to the new calibration line, the value of p, assigned to 62 nW*m, should be 27.7 percent (plus or minus of approximately 1,5%Zn), rather than 32 percent (plus or minus approximately 4%Zn), as before. Ambiguities of that kind are unavoidable because results of measurements fluctuate around true values. Two kinds of related ambiguities can be recognized in our situation; one about the exact location of the calibration line, and another about values of p based on single measurements of r.

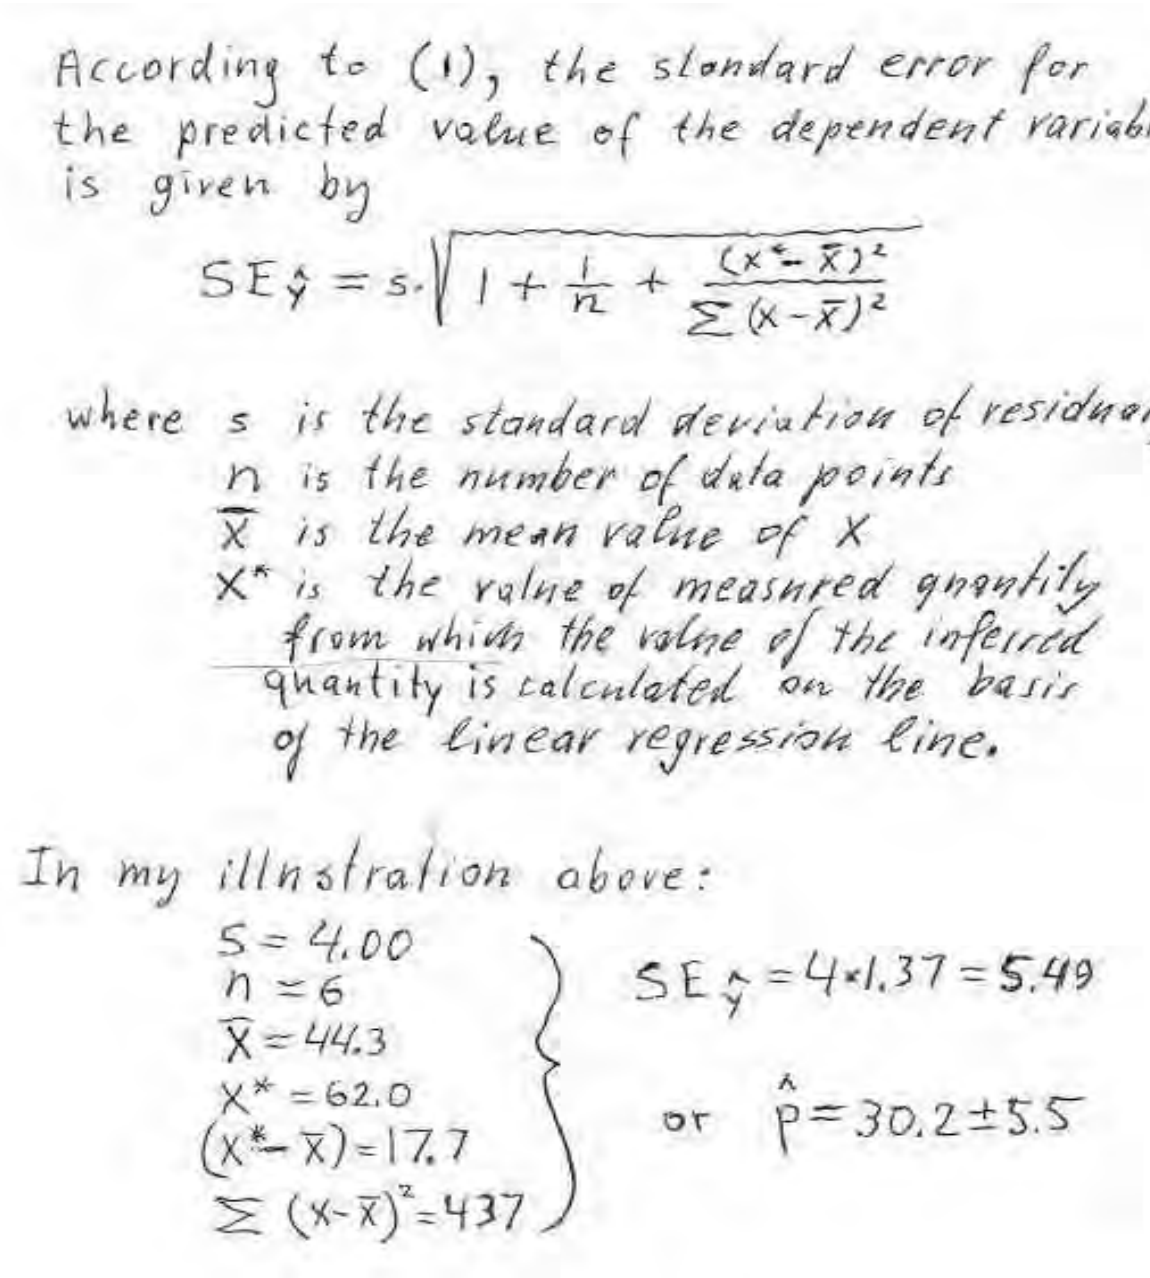

Figure 2
The term (x* - x_bar), under the square root, is the horizontal component of the distance of a particular value of x* from the central region. The uncertainty assigned to the inferred value is at a minimum when the measured value x* is closer to the center. Note that x*=62 is located near the right-hand margin of the scatter plot. For an x* close to 44.3, the third term under the square root would become negligible. Furthermore, the second term becomes negligible when n>20. Thus, for a large number of calibration points, the uncertainty in the inferred value approaches the standard deviation of residuals when x* approaches the mean x. This is intuitively acceptable; try to totate the regression line about the centroid of data points, (x_bar,y_bar). The range of calibration data points should not be limited to the range of expected values of x*, the wider the calibration range the smaller the uncertainty assigned to p, for any given n.

P.S.
This note was inspired by correspondence with Scott Little, a calorimetrist who uses linear regression calibrations. The correspondence, in turn, was triggered by Scott's paper (2), and by comments made by several CMNS researchers (3). Scott also critically examined my original draft and helped to improve it. But his method of calculating uncertainties is based on commercial software.

332) Krivit's Sonofusion Report

Ludwik Kowalski; 7/10/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Introduction:
Nonscientific factors, such as political and economic considerations, negative emotions, such as jalousie and vindictively, or desire to dominate, often influence scientific debates. Opposition to Galileo was ideological rather than scientific. The same can be said about opposition to the theory of relativity (Germany in late 1930s), and about opposition to genetics (Soviet Union in late 1940s). These are examples of well known, and highly organized, campaigns. Less known are contemporary feuds in various disciplines and sub-disciplines. A friend, Jed Rothwell, who created a wonderful Internet-based library of CMNS papers, wrote to me: "There is a lot of jealousy, rivalry and irrationality in this [CMNS] field, which is one of the reasons it has made so little progress. It is unfortunate." I believe Jed; he was following evolution of the CMNS field for much longer than I did. Jed's e-mail message came several days before the 23rd issue of The New Energy Times was published:

http://newenergytimes.com/news/2007/NET23.htm

Item 8 of that issue contains a link to an interesting report of Steven W. Krivit. The report is devoted to an ongoing feud in another field. Krivit is a professional journalist specializing in scientific reporting, and the editor of The New Energy Times. In the Introduction he wrote: "Society's general understanding is that scientists are objective, dispassionate, dedicated to serving the greater good of society, and held to a high standard of ethics." But then he describes situations which are quite different from what is generally expected. The feud he describes involves a nuclear engineer Rusi Taleyarkhan, Purdue University (where he is a tenured professor), his scientific opponents and some journalists.

In an overall comment about this ongoing feud (item 2 in the above URL), Christopher Purvis wrote "Purdue failed in that duty of care by leaving Taleyarkhan to represent himself among some of the most aggressive and manipulative international journalists, where, through no fault of his own, he quickly got out of his depth and walked into the trap they had prepared for him with the hired help of rival researchers." I have seen references to that episode but I did not read publications of involved scientists. I plan to read them; this unit is a place holder for future entries about sonofusion. For the time being I just want to share one observation.

Sonoluminscence and cold fusion: a common denominator
Taleyarkhan's claim is about sonofusion -- hot fusion taking place inside collapsing bubbles. In that sense the topic is very different from cold fusion claims. What do these two claims have in common? Both Fleischmann and Taleyarkhan made the same deplorable mistake. That mistake is partially responsible for subsequent rejections of what has been published. It would be better if claims were formulated in terms of what was actually discovered and not in terms of speculative implications. Fleischmann discovered non-chemical excess heat. It was a mistake to speculate that a nuclear process is responsible for excess heat, it was a mistake to accept the term cold fusion. The consequences are well known; instead of focusing on replications people started to discuss speculations, such as tunneling effect and emission of neutrons. Fleischmann should have refused to discuss nuclear physics concepts until reality of excess heat were recognized by most scientists.

Likewise, Taleyarkhan's claim should have been limited to what he actually discovered, generation of neutrons and production of tritium. He should have refused to discuss sonofusion until reality of nuclear particles was accepted by

most scientists. If he did this then subsequent debate would focus on detection of nuclear particles and not on wheather or not they are emitted from collapsing bubbles. Emission of nuclear particles would be interesting even if they were not emitted from collapsing bubbles. Putterman's emphasis on short time coincidences (between light and neutrons) was perfectly logical in the context of sonofusion but it would not be prematurely debated outside of that conext. Likewise, emphasis on coulomb barrier was perfectly logical in the context of cold fusion but it would not be prematurely debated in the context of excess heat. Decoupling facts from speculations would be initially beneficial in each of these fields.

Yes, tendencies to interpret experimental facts in terms of accepted theories is natural and desirable. Science is much more than factology. But waiting for general acceptance of new experimental facts, and refusing to speculate about theories, would likely be more effective, in a long run. Speculations about models should be based on will established facts while predictions about facts should be based on well established theories. And what to do in situations in which nothing is well established? In such cases it is probably better to address unexplained facts before addressing possible explanations. The issue of Fleischmann's excess heat, and the issue of Taleyarkhan excess neutrons, would probably be resolved long time ago if debates about explanations were postponed.

Appended on 7/12/07:
The first step toward sonofusion was discovery of sonoluminescence -- production of heat and light in tiny bubbles. Generation of heat in a rapidly compressed gas has been studied for more that a century; it led to many practical applications, such as ignition in a Diesel engine. In the case of small bubbles the temperature increases are often so high that substances are ionized and light is emitted. This was discovered by two German scientists in 1930's. But can the temperature be high enough to allow thermonuclear reactions? This question was asked in 1982, by an American scientist Hugh Flynn. The answer, according to Rusi Taleyarkhan (R.T.), is positive, as demonstrated by him in 2002, and in more recent experiments. But his claims have been challenged by several scientists. R.T. came to US from India, obtained his Ph.D. degree in nuclear engineering, and worked at Oak Ridge National Laboratory for may years. Then he became a tenured professor at Pardue University. Here is how his first sonofusion report was described in CERN Courrier (Apr 23, 2002):

". . . This is the latest apparent manifestation of sonoluminescence, whereby light is emitted by bubbles collapsing in a liquid excited by sound. Observations of the light suggest that implosions provoked by high-frequency sound could create extremely high temperatures and pressures - high enough, perhaps, to lead to conditions that could fuse two atomic nuclei. The researchers used neutrons to induce the formation of bubbles in liquid acetone in which the hydrogen atoms had been replaced by deuterium. Sonoluminescence resulted in the observation of light accompanied by neutrons. Tiny quantities of tritium were also detected. The researchers hypothesized that nuclear fusion had occurred, since the neutrons had different energies from those used to induce bubble formation, and tritium is an expected byproduct. When the experiments were repeated with hydrogenous acetone no tritium or neutrons were observed."

It is important to emphasize the basic difference between sonofusion and the so-called "cold fusion." The former is not different from the well known thermonuclear reactions, as in hydrogen bombs, except for the method by which bursts of high temperatures are generated in tiny bubbles. The later, on the other hand, are said to be due to unknown nuclear processes. The controversy about sonofusion has to do with generation of stellar-like temperature in collapsing bubbles; the controversy about cold fusion has to do uncharted areas of basic physics. The 2002 claim, for reality of sonofusion was based on production of tritium and on emission of neutrons, above the expected background level. These are two basic signatures of known thermonuclear reactions. But, as recognized by the first opponents of the sonofusion claim, D. Shapira and D. Saltmarsh, the neutron to tritium ratio in sonofusion was very different from what it is in known thermonuclear reactions. If sonofusion were real, they wrote, then it would be a totally new nuclear process. But these scientists from Oak Ridge National Laboratory did not believe that sonofusion was real. They, and other opponents, suspect that neither neutrons nor tritons, observed by R.T., were produced in compressed bubbles. An auxiliary neutron source, and tritium contamination, were said to be responsible for the reported results.

This morning I wrote the first two papers of R.T. and his coworkers:

(1) " Evidence for Nuclear Emissions during Acoustic Cavitation," Science , Vol. 295 , No. 5561, pp. 1868-1873 ,

March 8 , 2002.
(2) “Additional Evidence for Nuclear Emissions during Acoustic Cavitation”, Phys.Rev.E , Vol. 69 ,No. 036109 , March , 2004.

They are full of interesting details. Unfortunately, I am not sufficiently qualified to comment on everything. But I do understand some things. How was generation of tritium established? By counting electric pulses due to decay of tritium in a pre-calibrated liquid scintillation counter. One cubic centimeter of deuterated acetone could be removed from their cell and added to the liquid scintillator, ecolyte. Here are their results:

a) before sonofusion experiment (this is the background) -- about 53 counts/min.
b) after 7 hours of sonofusion --about 60 counts/min.
c)after 12 hours of sonofusion --about 69 counts/min.

Standard deviation associated with expected random errors were close to 2.5 counts/min. Yes, the amount of tritium does seem to increase with duration of an experiment but the rate at which accumulation of tritium increases is not impressively high. What is impressive, however, is the fact that no accumulation of tritium was observed when deuterated acetone was replaced by common acetone, or when deuterated acetone was exposed to seeding neutrons without acoustical waves. Numbers alone would be much more impressive if the rate of tritium production were several times larger.

According to R.T., sonofusion is greatly enhanced when acetone is constantly ionized by an external source of 14 MeV neutrons. These neutrons are delivered in pulses of short duration (about 10 microsecond). Each pulse arrives at a moment at which the applied acoustical wave is at the minimum. The bubbles collapse about 27 microseconds and that is when sonofusion takes place. Neutrons of 2.45 MeV are expected from the D-D fusion and that what said to be discovered by R.T. It is important not to confuse neutrons from sonofusion with neutrons from the 14 MeV source (a linear accelerator). The 27 microsecond delay seems to be sufficient for this. But this was not taken for granted by some critics. Statistical evidence for emission of neutrons is more convincing than evidence for emission of tritons, as illustrated in Figures 4a and 4b (see the second paper above). It is about 300 counts, when the acoustical wave is on, versus about 5 counts when the acoustical wave is off. In both cases the cell was exposed to the pulsating beam of 14 MeV neutrons. The hot fusion neutrons were detected with a scintillator counter that was blocking gamma rays. This was possible because shapes of electric pulses due to gamma rays were different from shapes due to neutrons. Actually, separation of gamma rays from neutron was not necessary to demonstrate presence of a nuclear effect. In a more recent experiment of R.T., described in

(3) “Nuclear emissions during self-nucleated acoustic cavitation,” Phys. Rev. Letters, Vol. 96, 034301, Jan. 27, 2006,

two additional kinds of detectors (BF3 and CR-39) were used to confirm presence of neutrons. But the most important innovation of the 2006 experiment was elimination of 14 MeV neutrons. This was done to show that 14 MeV neutrons could not possibly be responsible for hot fusion neutrons. Ionization of acetone, in the new experiment, was performed by alpha particles. To accomplish this a small amount of natural uranium salt was dissolved in acetone.

Inserted 7/14/07):
I also read two critical comments of this new experiment, one by B. Narango (a research associate of S. Putterman) and by a Russian Scientist, A. Lipson. Both comments, and rebuttals by R.T. can be found in

(4) “Comment on ‘Nuclear Emissions During Self-Nucleated Acoustic Cavitation,’“ Physical Review Letters, Vol. 97, p. 149403, (Oct. 6, 2006)

Narango analyzed the energy spectrum of neutrons, under assumed experimental configuration, and arrived to a conclusion that it was practically the same as that of Cf-252. Was he thinking about a possibility that a Cf-252 was present somewhere in the laboratory? If so then experiments with ordinary acetone would show about as many neutrons as experiments with deuterated acetone. But 2.45 MeV neutrons, according to R.T., were present only when deuterated acetone was used. Responding to Narango, R.T. showed that energy spectra of detected neutrons from his Cf-252 source and from his sonofusion cell were not identical. Even more convincing argument, against presence of a

Cf-252 source, was the comparison of energy spectra of gamma rays.

In Chapter 5 of his report, S. Krivit, tells us how the Cf-252 issue emerged, about half a year before Norango‘s paper was published, and how it was interpreted. It is important to be aware that neutron spectroscopy is a complicated business. Suppose that mono-energetic neutrons of 3 MeV are emitted. A plastic scintillation detector, exposed to these neutrons, will show energies of protons that neutrons create in plastic. These protons will have all energies from zero to 3 MeV. The shape of the recorded energy spectrum will depend on the size of the detector, on its shape, on its relative location with respect to the source, etc. etc. That is why neither the spectrum due to Cf-252 neutrons, nor the spectrum of neutrons attributed to sonofusion resemble the spectra of original spectra of neutrons from these sources.

Comments made by A. Lipson were about possible mistakes made in estimation of neutron detection efficiencies. Such mistakes, if real, would lower the neutron emission rate significantly. Was the rebuttal provided by R.T. (about e.m. noise) convincing? I think it was. But I am not sure.

Most people, including R.T.., seem to believe that sonofusion in deuterated acetone is the well known thermonuclear D-D reaction. But the R.T..’s data are not consistent with that interpretation. As noticed by D. Shapira and M. Saltmarsh, in

“Nuclear fusion in collapsing bubbles -- Is it there? . . . ” Phys. Rev. Lett., vol 89, p 104302 (2002),

the reported neutrons to tritons ratio in sonofusion and in thermonuclear reactions differ by four orders of magnitude. In other words, R.T.. observed about 10,000 less neutrons than would be expected for the reported amount of tritium. I do not remember this issue being addressed in subsequent discussion. That would not be important if the claim was limited to unexplained emission of neutrons and tritons. But the issue becomes essential when these particles are said to be produced in thermonuclear D-D reactions. In my opinion, arguments for reality of a nuclear activity are more convincing than arguments for the sonofusion nature of that activity. Let me add that according to Y.T. Didenko and K.S. Suslick, in

“Energy efficiency of formation of photons, radicals and ions during single-bubble cavitation,” Nature, vol 418, p. 394, July, 2002

Collapsing bubbles containing polyatomic molecules cannot possibly be heated to stellar temperatures. They wrote: “The temperatures reached during cavitation will be substantially limited by the endothermic chemical reactions of the polyatomic molecules inside the collapsing bubble. We therefore expect that the extraordinary conditions necessary to initiate nuclear fusion will be exceedingly difficult to obtain in any liquid with a significant vapor pressure. However, the possibility of such events in very low volatility liquids (for example, some polar organic liquids, molten salts or liquid metals) cannot be ruled out. The present results show that endothermic sonochemical reactions within a collapsing bubble are a major limitation on the conditions produced during cavitation.” This argument would also be totally irrelevant if the claim made by R.T. was limited to emission of nuclear particles.

The same observation can be made about very fast coincidences, between emission of light and emission of nuclear particles, requested by S. Putterman (see page 36 of Krivit’s report). Confirming such coincidences would indeed be a very convincing argument for sonofusion. Experiment of that nature, however, is not simple, and probably very difficult to interpret, especially if no dominant coincidence peak is found in the time spectrum. But such experiment is totally unnecessary in the context of a claim that does not include sonofusion. It would be better if attempts to confirm a nuclear activity were decoupled from attempts to confirm specific mechanisms, such as sonofusion or cold fusion.

Another overview of the sonofusion situation can be found in:

333) Richard's paper has been submitted to Physical Review C

Ludwik Kowalski (11/6/07)

When I was working on unit #335 (a paper describing my clusters) Richard Oriani submitted a paper to Physical Review C. This unit is a replacement of the draft of Oriani's paper that was posted here for several months. Unfortunately, the manuscript was rejected out of hand by the Editor without its being submitted to reviewers.

Note that figures and tables are below the main text.

Repeatable technique for the generation of a nuclear reaction during electrolysis

R.A Oriani

University of Minnesota, 151 Amundson Hall, 421 Washington Ave SE, Minneapolis MN 55455 email: orian001@umn.edu

Received 09/24/07

Abstract
A relatively simple technique using CR39 particle detectors has been developed that in 25 consecutive electrolyses has reproducibly produced charged particle tracks, showing unambiguous evidence of a nuclear reaction during electrolysis of heavy or light water solutions. Nuclear tracks can be produced upon the surface and beyond the 1 mm thickness of the CR39 detectors. Nuclear activity of some sort can persist in the Viton o-rings used in the electrolysis cell so that charged energetic particles can be generated subsequently without electrolysis.

I. INTRODUCTION

Since the ill-fated announcement by Fleischmann and Pons [1] that a nuclear reaction can take place during electrolysis of a solution of lithium sulfate in heavy water much work has been done in attempts to confirm the claim. Papers have been published that show the production of tritium, of ^{4}He, of the production of thermal energy far in excess of the inputted electrical energy, and the transmutation of some elements; see [2] for a review. These efforts have been met by assertions from the nuclear community of experimental error or naiveté, or accusations of fraud and deception. There are two main reasons for this repudiation: the claimed phenomena can not be understood in terms of currently accepted nuclear theory, and the lack of reproducibility of the phenomena. Any one experimenter cannot produce the claimed phenomenon on demand, and another experimenter often can not replicate the results.

Recognition of the latter difficulty has motivated the search for an experimental technique that is as transparent, simple, and irrefutable as possible to try to prove that electrolysis can be accompanied by a nuclear reaction, despite current understanding in nuclear physics. Energetic charged particles and very energetic neutrons can be detected and recorded by a high polymeric material called CR39, and its use is well known to the nuclear community [3]. A nuclear particle upon entering the plastic leaves a trail of disrupted chemical bonds which are more easily chemically attacked

than undamaged material. The pit that results from etching by concentrated alkali solution is unambiguous evidence that a nuclear reaction had occurred, since only particles of energies of 0.5 MeV or more can damage the bonds sufficiently to leave an etchable trail. Such energies are much larger than can be provided by chemical reactions.

The integrating character and the relative simplicity of this technique have led the writer to apply it to the problem. Control, or blank, experiments are necessary because radon in the air and the occasional cosmic ray produce etchable damage trails in CR39 detectors. Past work with this method in this laboratory has included immersion of CR39 chips in electrolyte solution, suspension of the chips in the vapor above the solution, placement of chips in air just below the metal plate that serves both as cathode and as the bottom of the electrolyte compartment, and placement of chips in air just outside of the glass cell, with each of these configurations maintained during electrolysis. From the numbers of nuclear tracks on the detector chips used in the electrolyses and those on chips used as controls can be calculated the probability, P, that the two sets of numbers belong to the same population, ie., that electrolysis has no effect on the number of pits. The results of prior research [4,5] are as follows. For detector chips immersed in H_2O/Li_2SO_4 electrolyte and Pd as cathode $P = 1.2*10^{-6}$, and with Ni as cathode $P = 5.8*10^{-4}$. With D_2O/Li_2SO_4 and Pd as cathode $P = 2.5*10^{-5}$. With detector chips suspended in the vapor over H_2O/Li_2SO_4 electrolyte and Ni or Pd as cathode material $P = 3.0*10^{-10}$. Although these results reasonably demonstrate that electrolysis can indeed generate energetic nuclear particles, it cannot be claimed that every electrolysis experiment will produce the nuclear reaction since the data sets for the electrolysis chips and the control chips partially overlap. Consistent reproducibility has not been achieved despite having kept constant all the controllable parameters. Therefore a different experimental approach has been adopted.

II. EXPERIMENTAL DETAILS

Investigators [6] at the SPAWAR Systems Center, San Diego, California, initiated the strategy of having the cathode and the CR39 chip in very close proximity. The metal wire serving as cathode was wound tightly around the detector chip. Unfortunately, this configuration produced copious chemical attacks on the detector by ions generated at the cathode. The huge number of chemical pits produced made it very difficult to ascertain the generation of nuclear pits. To maintain the desirable nearness of cathode to detector while avoiding the chemical attack, the obvious modification is the interposition of a thin Mylar film between the electrolyte and the detector chip. Preliminary experiments showed that 6 _ Mylar film permits the passage of nuclear particles emitted by pitchblende, energies of 4.1 to 5.8 MeV.

The cell design adopted is shown in Fig. 1. Squares, roughly 3cm x 3cm, of CR39 cut from a sheet supplied by the Landauer Corp. are overlaid by 6 microns Mylar foils obtained from Cemplex Industries, Inc., and the combination is pressed between Viton o-rings that fit into grooves in the glass o-ring joints purchased from Fisher Scientific Corp. The joint is held together by a pinch clamp. The anode is a platinum wire whose lower end forms a loop parallel to the plane of the detector chip. The cathode is usually a nickel wire whose lower end is bent into a shape like a W the plane of which is parallel to the plane of the detector square. The vertical portion of the nickel wire is sheathed in heat-shrinkable plastic tubing and spot-welded to a titanium rod inserted into a glass tube. The electrode assembly is held together by a rubber stopper through which a hole permits the escape of the gases produced by the electrolysis. This describes the electrolysis cell designated by S. Another cell designated by B differs from the S-cell only in that the platinum anode wire ends in a crude spiral the plane of which is perpendicular to the detector chip.

The current to cell-S is supplied and controlled by a potentiostat, and that to cell-B by a constant-current power supply. To begin an experiment a square of CR39 is cut from the sheet from the manufacturer, a small hole is drilled at a corner of the detector square to accommodate a wire for the subsequent suspension of the chip, and an identification symbol is inscribed at another corner. The surface on which the identifier is scratched is referred to as the front surface, and is the surface upon which the Mylar film is laid after the manufacturer-supplied blue film that protects the detector is removed. After the detector with its overlying Mylar film is clamped in the o-ring joint about 10 ml of electrolyte solution are poured into the cell and the electrode assembly is put into place. The cathode is then lowered carefully by sliding the supporting titanium rod within the supporting glass tube until the W-shaped foot of the cathode rests upon the Mylar film. Electrolysis is then started and the current is either kept constant for the entire duration of the electrolysis, or is increased once per day.

The electrolyte employed was usually of distilled H_2O with 0.022 g Li_2SO_4 per ml. To provide a comparison with the results of ref. 6 the first two experiments were done with silver cathodes in electrolytes of D_2O with LiCl plus $PdCl_2$. Water was not added during electrolysis to compensate for its loss by dissociation. Four days of electrolysis were the usual duration after which the cell was disassembled and the detector chip removed and washed. There was never any trace of pitting or abrasion on the detector plastic before etching. Stirred 6.5 M sodium hydroxide was the etching solution, held at about 70 C for about six hours. This was followed by examination at 100X and 500X, applying experience with pits produced by exposure of CR39 to ^{241}Am and to pitchblende to distinguish nuclear pits from artifacts caused by manufacturing defects in the detector plastic. The nuclear pits were counted on the front and rear surfaces of the detector chips within the outer perimeter of the o-rings, amounting to 4.5 cm^2. This procedure eliminated the counting of tracks that may have been produced by air-borne radon during the duration of electrolysis.

Control experiments of four kinds were carried out to account for the nuclear tracks already present in the detector as received from the supplier, as well as those produced during the entire experimental process caused by radon in the air, in the electrolyte, in the etching solution, and in the wash water. The control detector chips were handled in exactly the same way as were the experimental chips except that instead of being used in electrolysis they were either wrapped in Mylar film, immersed in stock electrolyte solution, pressed against as-received o-rings, or mounted in a newly constructed cell fitted with unused electrodes, electrolyte, Mylar film and stoppers, but in the absence of electrolysis. In each instance the same length of time as the duration of the electrolysis experiment was applied. The number density of tracks in the as-received detector sheet varies from one shipment to another, and is not a constant over any one sheet. Therefore it is appropriate to compare an experimental value of track number density to the mean value for the controls. The results for the controls are presented in Table I.

Consideration has been given to the possibility that the features seen after etching might have been caused by processes other than the alleged nuclear reaction. For example, radioactive dust particles floating in the laboratory air may adventitiously settle upon a detector chip and produce nuclear tracks. This possible problem has been examined by placing fine particles of pitchblende upon detector chips. Examination after etching has shown that such particles produce “rosettes” of tracks (Fig.2). These track configurations, reputedly also produced by cosmic rays, have very occasionally appeared on detector chips during our research. They were not included in the counting of nuclear tracks. One may suspect that electrostatic charges produced by peeling off the manufacturer-supplied blue protective plastic film from the CR39 might cause etch pits. This possibility was explored by adhering Scotch tape to a detector chip then peeling it off. After etching nothing was visible that could be attributed to static charges. However, it is recognized that if, after peeling off an adhering film the bare chip is allowed to remain exposed to dry air for many hours, the electrostatic charges on the chip will attract daughter products of air-borne radon so that nuclear tracks would be generated. This was prevented in our work because always immediately after peeling off the protective film the detector chip was mounted in the electrolysis cell.

Manufacturing defects can make it difficult to discriminate between nuclear pits and artifacts. The polymerization process can leave poorly polymerized regions. As etching proceeds the receding surface of the detector chip intersects with such regions which etch more rapidly than well polymerized material so that pits result. These pits are usually small, circular, shallow, and most of them appear in groups. They can be distinguished from nuclear pits by the much darker appearance of the latter in the microscope using illumination from above. Features whose identity remains ambiguous are not counted as nuclear pits. Scratches and other mechanical insults to the detector chips can also produce ambiguities. This problem was examined by a series of experiments in which various mechanical forces were applied to chips, followed by etching and examination. Light scratching produces linear arrays of pits usually of uniform diameter. For this reason pits in linear arrays are never counted as nuclear pits. Pits are not produced by hard pushes against the chip with the point of metal tweezers or with the handle of an Exacta knife. On the other hand a push with the point of an Exacta blade produces a very dark pit. Rubbing with a plastic rod has no effect, but rubbing with a metal spatula leaves a faint trace, and rubbing with the point of tweezers produces an etchable trail. But grasping a detector chip with metal tweezers using considerable force does not leave any effects. This is fortunate because the chips are manipulated with tweezers.

One other type of experiment was in some instances carried out along with the primary experiments. Prompted by the results of previous research [7] that the apparatus employed for electrolysis appears to retain some kind of nuclear

activity, it was decided to investigate whether the o-rings demonstrate this phenomenon. After the termination of an electrolysis the o-rings were removed and after drying were placed upon a CR39 square, and the whole was wrapped tightly in aluminum foil and stored for four days. Then the detector was etched and the nuclear tracks counted.

III. RESULTS AND DISCUSSION

Table II displays the results of consecutive electrolysis experiments the primary purpose of which was to validate the technique. The counts of nuclear tracks, either on the front or on the rear surfaces, (Table II) are always considerably larger than the counts per unit area for the controls (Table I). In every experiment the average number density of nuclear tracks found after etching is greater than the mean value for the controls. Hence it can be concluded that the present technique has consistently produced evidence that a nuclear reaction of some sort has been generated in the course of electrolysis. The present research does not identify the nature of the nuclear particles that produce the observed tracks, but Lipson et al, [8] claim that the particles are protons and alphas. Also, the present work does not attempt to establish the connection between the nuclear reaction here manifested and the excess thermal energy reliably measured calorimetrically by several investigators [2].

A second observation from the results listed in Table II is that tracks are found on both sides of the detector squares, and that often the average track number density on the surface facing away from the electrolyte is larger than at the surface immediately below the Mylar film. Charged particles that caused the observed tracks on the rear surfaces could not have been generated at the site of the electrolysis. The 1 mm thickness of the detector square is much too large to be traversed by charged nuclear particles with the energies established by Lipson et al. This leaves either neutrons of very high energies as the damage trail maker, or some other neutral particle that subsequently reacts or decays to produce alphas and protons.

It is significant that the nuclear pits are distributed bimodally, both as individual randomly located pits and as dense groups or clusters that are bounded by areas relatively devoid of nuclear pits. The number densities in clusters are much greater than the mean number densities listed in Table II. The clusters are of two sorts: one within which the pits are essentially randomly distributed as to position and shape (Fig.3), and one in which the pits of elliptical or conical shape are radially distributed (Fig.4). Pits of these shapes result when the path of an impinging nuclear particle is other than perpendicular to the surface of the detector. By focusing the microscope up and down one can determine the direction and sense of the path [3]. Doing this for all of the elliptical and conical pits one can determine that the nuclear particles that produced those pits emanated from a common origin away from the surface of the detector. In fact, by a careful analysis [9] one can estimate the distance above the detector surface where the shower of nuclear particles originated. This consideration leads to the surmise that zero-charge precursors, that themselves originated in the region of electrolysis, reacted with something in the air near the detector or in the Mylar film to generate charged nuclear particles that produced the nuclear tracks.

Early in the present work it became clear that the number density of nuclear tracks found along the circle of the o-ring was often considerably larger than elsewhere on the detector chip. Past work [7] had developed weak evidence that nuclear activity can persist after the termination of electrolysis. These two items combined to motivate exploration of what happens when an o-ring that has been used in an electrolysis experiment is removed from the electrolysis cell and is allowed to lie upon a new detector square for several days. Table III presents the results of these experiments. Whereas fresh o-rings that have never been used in an electrolysis experiment produce an average of 16.6 tracks/cm^2, once-used o-rings often produce a much larger number of tracks. In some cases the number of tracks is so great that counting becomes impractical, and the area of largest number density coincides roughly with the circular outline of the o-ring. Figure 5 is an unmagnified image of an etched detector square after a post-electrolysis o-ring had lain upon it for three days. Figure 6 is a 100X photomicrograph of a small portion of the circular hazy perimeter shown in Fig. 5. It should be noted that before etching no trace of pits can be seen. Similar circular haze rings, composed of a multitude of nuclear tracks, have been also found on detector squares used in electrolysis experiments.

The tracks produced by a post-electrolysis o-ring placed upon a CR39 chip cannot have been caused by an ordinary radioactive contaminant in or on the o-ring. First of all, new unused o-rings produce only small numbers of tracks (Table I). However, there is the possibility that the o-rings become radioactively contaminated during the preparation or the disassembly of the electrolysis experiment perhaps by contact with laboratory furniture. This idea was explored

by two sets of experiments. In the first set two new, as-received o-rings were suspended in the laboratory air for two days and then rubbed on the top surface of the laboratory bench. After this the o-rings were placed on detector chips for two days. This procedure resulted in 42.3 and 11.3 tracks/cm^2. The first value is for the o-ring suspended in air near an operating electrolysis cell. In the second set of experiments one side of each of two new, as-received o-rings was rubbed against the top of the laboratory bench on which many electrolyses had been carried out. The other sides of the two o-rings were not contacted to the laboratory bench. Then, each o-ring was clamped between two detector chips for two days. After etching the tracks/cm^2 found on the chip surfaces that had been in contact with the rubbed sides of the o-rings were 6.8 and 7.1. The two chip surfaces that had been in contact with the unrubbed sides of the two o-rings developed 5.0 and 13.6 tracks/cm^2. These results show that the track densities listed in Table III and displayed in Fig.6 can not be artifacts of contact of the o-rings with radioactive contaminants in the laboratory. Another unlikely source of radioactive contamination was explored. This is the high-vacuum grease applied to the grooves of the glass joints to facilitate assembly with the o-rings. Crosses were drawn on one side of each of two detector chips with the grease and one day later the chips were etched and examined. The track densities found on the greased sides were 11.7 and 13.4 tracks/cm^2, whereas on the clean sides the track densities were 11.1 and 9.3. The high-vacuum grease is not a source of radioactive contamination.

Although the number density of tracks along the perimeter of a post-electrolysis o-ring is larger than that within the area bounded by the circle of the o-ring, the number density within the circle is often larger than the track density of the controls. Figure 7 shows the etch pits near the center of the area of the detector chip bounded by the post-electrolysis o-ring that had been laid upon it (experiment number 1 in Table III). The detector area represented by the photomicrograph is about 1 cm away from the o-ring and measures approximately 0.008 cm^2, so that the number density of tracks is in the thousands. Furthermore, the largest angle at which a charged nuclear particle would produce a damage trail in the area of Fig.7 would be made by a particle leaving the o-ring from a point about 2 mm from the detector surface (see Fig.8). The tangent of this maximum angle would be about 0.2. However, this angle, about 11 degrees, is smaller than the critical angle [3] for a damage trail to be made visible by etching (about 36 degrees) so that particles coming directly from any part of the o-ring could not cause etch pits at 1 cm separation from the circle of the o-ring. This argument has been confirmed by the procedure of depositing a light coating of uranium acetate upon an as-received o-ring, keeping the coated o-ring between two CR39 squares for four days, then etching the detector chips. Examination showed that haze patterns following the circumference of the o-rings had developed, similar to that illustrated by Fig.5. However, the central regions of the areas bounded by the haze rings were clear. The track densities were 55 tracks/cm^2 on one chip and 70 on the other. These numbers are to be compared with the background value of 55 per cm2 and with over 2000 tracks /cm^2 found in the center of the chip pictured in Fig.5.

That a high density of etch pits can be produced near the center of the overlying o-ring is evidence that the nuclear tracks generated in a post-electrolysis experiment are not the result of contamination on the o-ring. The residual effect is a real phenomenon. One must conclude that something residing in the o-rings previously used in electrolysis caused the generation of energetic charged particles near the center of the area, and that these charged particles then impinged upon the detector chip at angles larger (ie.,closer to the perpendicular) than the critical angle for etching pits.

IV. CONCLUSIONS

Several definite conclusions can be drawn. First, a nuclear reaction can occur during electrolysis. A technique has been developed that consistently produces evidence of a nuclear phenomenon in the form of nuclear tracks made visible by etching. Second, nuclear tracks can be produced beyond the 1 mm thickness of the plastic detector. The inference may be made that at the site of electrolysis uncharged particles are created that are the precursors of the energetic charged particles whose damage trails can be observed after etching the CR39 detectors. It is further inferred that the precursor entity decays or reacts with an element in the air or with an element within the plastic of the Mylar film to generate charged particles. Third, the neutral precursor particle can persist for an as yet undetermined time in the materials that constitute the electrolysis cell and can react to produce charged particles in the absence of electrolysis.

Many questions are left unanswered. Chief among these is the nature of the precursor particle. Another important question is the relation between the nuclear reaction made manifest by the observed nuclear pits in the CR39 and the excess thermal energy that has been measured calorimetrically in other research. It is clear that the thermal energy

deposited by the formation of the charged particles observed in this research is much too small to account for the calorimetrically measured thermal energy. Much research remains to be done. The aims of the present work have been only to develop an experimental technique that reproducibly shows that a nuclear reaction can accompany electrolysis, to demonstrate some of the characteristics of the nuclear reaction, and to provide convincing evidence that justifies initiating extensive research in this new segment of nuclear physics not only because of its intrinsic scientific interest but also because of the possible development of a useful source of energy.

(A)

FIG. 8. Schematic diagram of the cross-section of a previously used o-ring resting upon a detector chip. Angle b, about 11 degrees, is the largest possible angle between the detector surface and the path of a nuclear particle going directly from the o-ring to the center of the area enclosed by the o-ring. Angle c is the critical angle (3) of particle impingement smaller than which etching does not produce a pit to mark the damage trail. This angle is about 36 degrees (9).

TABLE I
Results of Control Experiments, Tracks/cm^2

Configuration	First CR39 sheet Average	First CR39 sheet Std.Dev.	Second CR39 sheet Average	Second CR39 sheet Std.Dev.
Wrapped in Mylar	26.4	12.1	13.6	6.8
With new o-rings			16.6	9.7
In stock electrolyte solution			6.5	3.7
Within assembled unused cell			15.4	5.2

TABLE II
Summary of Consecutive Electrolysis Experiments. The first 11 experiments were done with the detector chips cut from the first CR39 sheet (see Table I), all of the rest were done with a second sheet.

Experiment Number	Cell	Current mA	Duration hours	Tracks/cm^2 Front	Rear
1 a	S	0.2-25	168	284	150
2 *	S	0.1-45	120	156 C	160
3 b	S	12-100	102	---	---
4	S	70-143	67	352	16
5	S	30-95	96	393 C	498 C
6	S	50	97	76	74
7	S	5-50	96.5	71 C	96
8	S	10-100	94	80	70 c
9	S	300	65	d	#
10	B	10,25	98	98	40 e
11	S	12,28	97	229 c	48 e
12	S	20	95	38 e	167 e,163 e

20	S	80	117	72 e	41 c
21	B	80	117	60 e	132 c,f
22	S	100	93	426	207
23	B	101	93	62	51 f
24	S	50	96	102	38 f
25	B	50	96	26	344 f

a The electrolyte in these two experiments was LiCl plus PdCl2 in D2O with Ag as cathode material. For all other experiments Li2SO4 in H2O with Ni as cathode was employed.
b In experiment 3, the detector chip was lost before a careful count of the clearly large number of tracks could be made.
c Some of the tracks appear in clusters.

d The number of tracks was so great that counting was impractical.
e The blue protective film supplied by the manufacturer was kept on the detector chip; in exps. 12, 16, and 17, only one-half of the detector surface was kept covered by the film.
f D2O was maintained within the closed air space below the detector chip.

TABLE III

Residual nuclear activity. The mean value of the controls for fresh o-rings upon detector chips is 16.6 with standard deviation of 9.7.

Experiment	Exposure (days)	Tracks/cm^2 Front	Rear
1	3	a,b	176
2	3	a,b	17.4
3	5	70	211
4	4	30	176
5	4	c	
6	3	16	c

a The number of tracks was so large that counting was impractical.

b The circle of the o-ring was followed by the swarm of nuclear tracks. See Fig. 5.
c A cluster of tracks appeared.

335) On emission of nuclear particles caused by electrolysis

Ludwik Kowalski; 9/20/2007
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Abstract:
Abstract: Numerous tracks of charged nuclear particles, emitted during electrolysis, were discovered by Oriani and Fisher (3). More recently, residual activity -- emission of nuclear particles after electrolysis -- was discovered by Oriani (5). This presentation, prompted by my participation in The Galileo Project, describes ten experiments conducted to replicate the reported results. Common CR-39 detectors were used in these experiments. A total of eight clusters of tracks were found in two out of six electrolysis experiments. Three clusters were also found in one of four experiments conducted to study residual activity. But track densities outside clusters were always essentially the same as on control chips. Arguments are presented against trivial explanation of clusters, such as natural radioactivity and cosmic rays.

1) Introduction
1) This is an investigation of claims (1,2,3,4) that charged nuclear particles are occasionally emitted during electrolysis. The accepted point of view is that chemical processes (interactions involving outer electrons in atoms and molecules) are too weak to produce emission of nucleons from atomic nuclei. Yet, several qualified researchers, such as A. Lipson, R. Oriani and S. Jones, have been reporting unexpected emission of nuclear particles, for many years. Experimental facts that conflict with existing theories should be studied rather than rejected. My study was prompted by a recent report of Richard Oriani (5), and by participation in The Galileo Project (6). Oriani discovered, by using CR-39 detectors, that nuclear particles are emitted during electrolysis. Later he discovered that particles are also emitted after electrolysis. I will refer to what happens during electrolysis as “Oriani effect” and what happens after electrolysis as “residual activity.” The first effect has been studied by Oriani for several years. In the spring of 2007, Oriani‘s recent results were posted on the discussion list for CMNS researchers. The report shows that unexplained effects were observed in more than twenty consecutive experiments.

2) High level of reproducibility, according to Oriani, is due to residual activity. Each consecutive electrolysis experiment presumably benefits from what happens during the previous experiment. The probability of triggering Oriani effect in a new electrolytic cell is said to be very low, but it becomes very high after the first success. That is why having a residually active O-ring became part of the protocol offered to researchers, like myself, who tried to validate the claims. The first experiment had to be performed with O-rings removed from Oriani's cell, shortly after electrolysis, and received by one of us about 24 hours later. Subsequent electrolysis experiments, with the same O-rings, were expected to reliably reproduce the effect. According to Oriani‘s paper (5), distributions of tracks left by nuclear particles on CR-39 detectors are mostly uniform, more or less. But sometimes tracks appeared in the form of small clusters. The following five nuclear phenomena were identified:

a) production of clusters of tracks during electrolysis
b) production of unclustered tracks during electrolysis
c) production of clusters of tracks after electrolysis
d) production of unclustered tracks after electrolysis
e) residually active (seeded) O-rings, in a cell, increase the probability of (a) and (b).

3) A spectacular cluster of residual activity tracks, shown in Figure 1, was recorded by Oriani during a recent

experiment. In showing this photo, Oriani, wrote; “this cluster was produced in a residual effect experiment. An o-ring previously used in an electrolysis run was placed upon a detector chip and the whole wrapped in aluminum foil, then etched after three days. The very interesting fact is that the cluster appeared not on the detector surface upon which had been placed the o-ring but rather on the opposite side of the chip. Furthermore the latter side had remained covered by the manufacturer-supplied blue plastic protective film throughout the experiment. Try to explain this as a result of radioactive contamination !” The blue protective film is thick enough to stop alpha particles from radioactive substances.

.

Figure 1
A cluster produced during Oriani‘s residual activity experiment lasting three days. The magnification is X100; the photographed area is approximately 950 by 760 microns.

= =

What follows describes my simple apparatus and my results. In the closing section I will argue against the idea that

clustered tracks are due to natural radioactivity or cosmic rays. Paragraphs are numbered to facilitate discussion over the Internet.

2) Experimental setup and its use.

4) The electrolytic cell used in my experiments was identical to one of Oriani's cells, as schematically illustrated in Figure 2. The electrolyte was Li_2SO_4 in ordinary distilled water; the concentration was 22 grams per liter, as recommended by Oriani (5). The anode was Pt and the cathode was Ni. The cell was a glass tube containing about 10 cc of the electrolyte. The bottom of the tube was made from a replaceable 3 by 3 cm chip of CR-39 plastic material. That chip (thickness about 1 mm) was separated from the electrolyte by a layer of mylar whose thickness was 6 microns.The Ni-wire cathode, in the form of a spiral pancake, was in contact with the mylar while the Pt-wire anode, also in the form of a spiral pancake, was about 15 mm above the cathode. Potential differences applied to the cell were between about 5 and 12 volts, depending on the desired current (between 30 mA and 150 mA during preliminary experiments). At 3 V the current was close to zero. The concentration of the electrolyte was allowed to double (approximately) during experiments because water lost via electrolysis was usually not replaced till the volume of the electrolyte was reduced to approximately one half of the initial volume. The current, however, was kept constant, usually 42 mA, by an electronic stabilizer outside the power supply.

= = = = = = = = = = = = = = =

(A) -->  . (B) --> 
Figure 2
(A) The empty electrolytic cell and (B), its schematic diagram (showing the inner components). The diameter of the coin is close to 25 mm. The Ni cathode is separated from the CR-39 chip by a mylar foil whose thickness is 6 microns. Two flexible Viton O-rings are pressed against the CR-39 chip to prevent leackage of the electrolyte.

= =

5) The CR-39 chips were cut from a Fukuvi Chemical sheet purchased from Landauer Inc. (7) One of the well known properties of CR-39 material is its ability to record tracks of nuclear projectiles, such as protons or alpha particles (8), as illustrated in Figure 3. (A) shows tracks due alpha particles from an ^{241}Am source; (B) shows a cluster of tracks due to a tiny grain of radioactive material. To make tracks visible, under a microscope, CR-39 chips were etched in the 6.25 N solution of NaOH, at 72 C, for 6 hours.

= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 3 (A) Tracks of alpha particles from an americium source. Surface imperfections and dust particles can also be seen. The photographed area is 1000 by 1300 microns; magnification is X40. (B) An island of tracks around a grain containing uranium. This photo was provided by Scott Little. The magnification in (B) was higher than in (A); etching conditions were also not the same.

= =

6) According to (5), numbers of alpha-like tracks, produced in CR-39 during the electrolysis, greatly exceed the numbers of tracks on control chips. The densities of tracks in control chips fluctuated between approximately 5 and 25 tr/cm^2. The densities on electrolysis chips, on the other hand, were most often several hundred. In some cases they were "too high to count." My experiments failed to confirm these observations, except for small clusters of tracks. Oriani's paper has a table with numerical results (track densities) from about 20 consecutive experiments. The label C, which stands for "cluster" appears 14 times in his table. It indicates that clusters of tracks were often observed. By my definition a cluster is an island of many tracks surrounded by track-free areas, as illustrated in Figure 1. In this paper I will describe results from ten experiments: I, II, III, IV, V, VI, VII, VIII, IX and X. The first six of them were performed to study the (a) and (b) effects, described in Section 1. The last four experiments were performed to study the effects (c) and (d). What follows is a brief description of these experiments. Pictures of my clusters will be shown in Sections 3 and 4.

** Electrolysis in Experiment I lasted 5 days, using Oriani's seeded O-rings. The rings were received 24 hours after they were removed from Oriani's cell. The experiment started shortly after the package arrived.
** Electrolysis in Experiment II lasted 21 days, using the same O-rings as in Experiment I. The experiment started shortly after the end of Experiment I.
** Electrolysis in Experiment III lasted 5 days, using the same O-rings as in Experiment II. The experiment started shortly after the end of Experiment II.
** Electrolysis in Experiment IV lasted 5 days, using another freshly seeded O-ring from Oriani. The experiment started shortly after that O-ring was received.
** Electrolysis in Experiment V lasted 5 days, using the same O-ring as in Experiment IV. The experiment started shortly after Experiment IV.
** Electrolysis in Experiment VI lasted 5 days, using the same O-ring as in Experiment V. The experiment started shortly after the end of Experiment V.
**** Experiment VII was conducted outside the electrolytic cell. Several small CR-39 chips were applied, for two days, to O-rings used in experiment III.
**** Experiment VIII was also conducted outside the electrolytic cell. Two large CR-39 chips were applied, for two days, to another freshly seeded O-ring sent to me by Oriani.
**** Experiment IX was similar to Experiment VIII, except it started at the end of Experiment VIII.
**** Experiment X was similar to Experiment IX, except it started at the end of Experiment IX.

7) Four clusters of tracks were found on the electrolysis chip from Experiment I, zero clusters were found on the electrolysis chip from Experiment II and four clusters were found on the electrolysis chip from Experiment III. Experiments IV, V and VI failed to produce clusters. Zero clusters were found in Experiment VII. But three clusters were found in experiment VIII. Experiments IX and X also failed to produce clusters. In all ten experiments, track densities outside clusters were found to be essentially the same as on control chips. In other words, effects (b) and (d) were not produced in my experiments.

3) Clusters of tracks:
Figure 4 shows the first cluster found in Experiment I. It occupies an area larger than other clusters produced on the same CR-39 chip. That is why two fields, (A) and (B), were needed to show all of its tracks. Tracks in that cluster seem to be less dark (shallower ?) than tracks on others clusters.

= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 4
Tracks of my largest cluster. It was produced during electrolysis Experiment I. Each of the two photographed areas is a field of 1000 by 1300 microns; magnification is X40. Most of the tracks appear in the field (A); the field (B) shows the remaining tracks of the same cluster. Some tracks in the upper part of (A) can also be seen in (B). The background outside the cluster was most often less than one track per field.

= =

8) Two smaller clusters, with much darker tracks, are shown in Figures 5A and 5B. Note that tracks of the cluster of Figure 5A are mostly circular while a large fraction of tracks in the clusters of Figure 5B are conical or elliptical. Significance of non-circular tracks will be discussed later.
= = = = = = = = = = = = = = =

(A) 
(B) 
Figure 5 (first A then B)
Two clusters also produced during my electrolysis experiment I. Each photographed area is 1000 by 1300 microns; each magnification is X40. The etching time was 6 hours. Figure 8 will show the same cluster after additional 5 hours of etching.

= =

9) Not a single cluster of tracks was found on the control chip. This is significant in the context of a discussion that subsequently evolved over the Internet. Little and Little (9) also recorded clusters by using seeded O-rings. But they suspect that clusters might be due to tiny particles of radioactive material, such as uranium or radium. Figure 3A shows a cluster of tracks around a grain of uranium-containing material; they deliberately deposited it on CR-39 to illustrate the effect. My control chip had the same history as my electrolysis chip. In Section 6 I will explain why, in my opinion, the cluster shown in Figure 5B, and Oriani's cluster shown in Figure 1, cannot be due to a tiny spot of alpha-radioactive contamination. Several non-circular tracks, under ten times higher magnification, are shown in Figure 6. They belong to the cluster shown in Figure 5B.
= = = = = = = = = = = = = = =

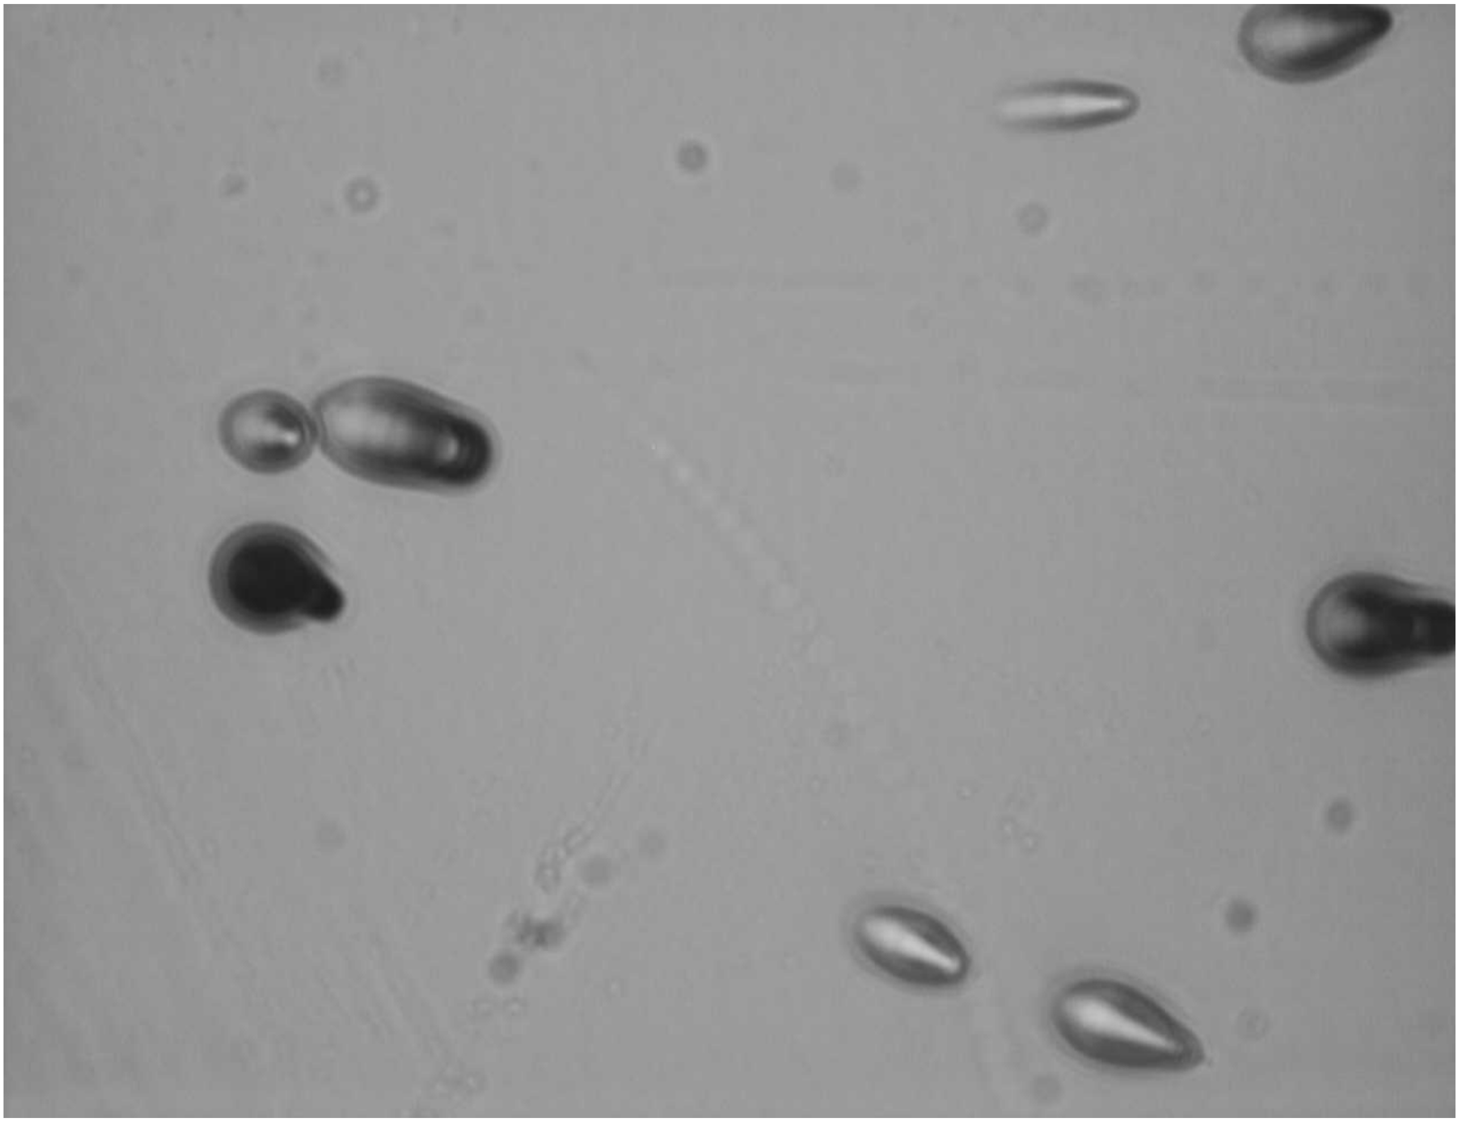

Figure 6
Some elliptical and conical tracks under the magnification of X400. The photographed area is 100 by 130 microns.

= =

10) The fourth cluster, produced during the experiment I, was not photographed when the chip was examined after 6 hours of etching. I probably misidentified it as the already-photographed island of tracks. But the fourth cluster was immediately recognized after an additional 5 hours of etching. The photograph of that cluster, with much larger tracks (due to additional etching) is shown in Figure 7.

It is remarkable that average track densities, within clusters, are very much higher than the mean 15 tr/cm^2 background. For the cluster shown in Figures 5A the local density was close to 6000 tr/cm^2; this is 400 times higher than the mean background. For the cluster shown in Figures 5B the local density was close to 25000 tr/cm^2; this is about 1700 times higher than the expected background. For the cluster shown in Figures 7 the local density was close to 20000 tr/cm^2. This is again three orders of magnitude above the background. Additional etching did not produce many more excessive tracks, as expected by Oriani. The large cluster, shown in Figures 4A and 4B also had about 90 tracks. But the area covered by these tracks was larger than for other clusters. The mean local density, for that cluster, turned out to be close to 7000 tr/cm^2.

= = = = = = = = = = = = = = =

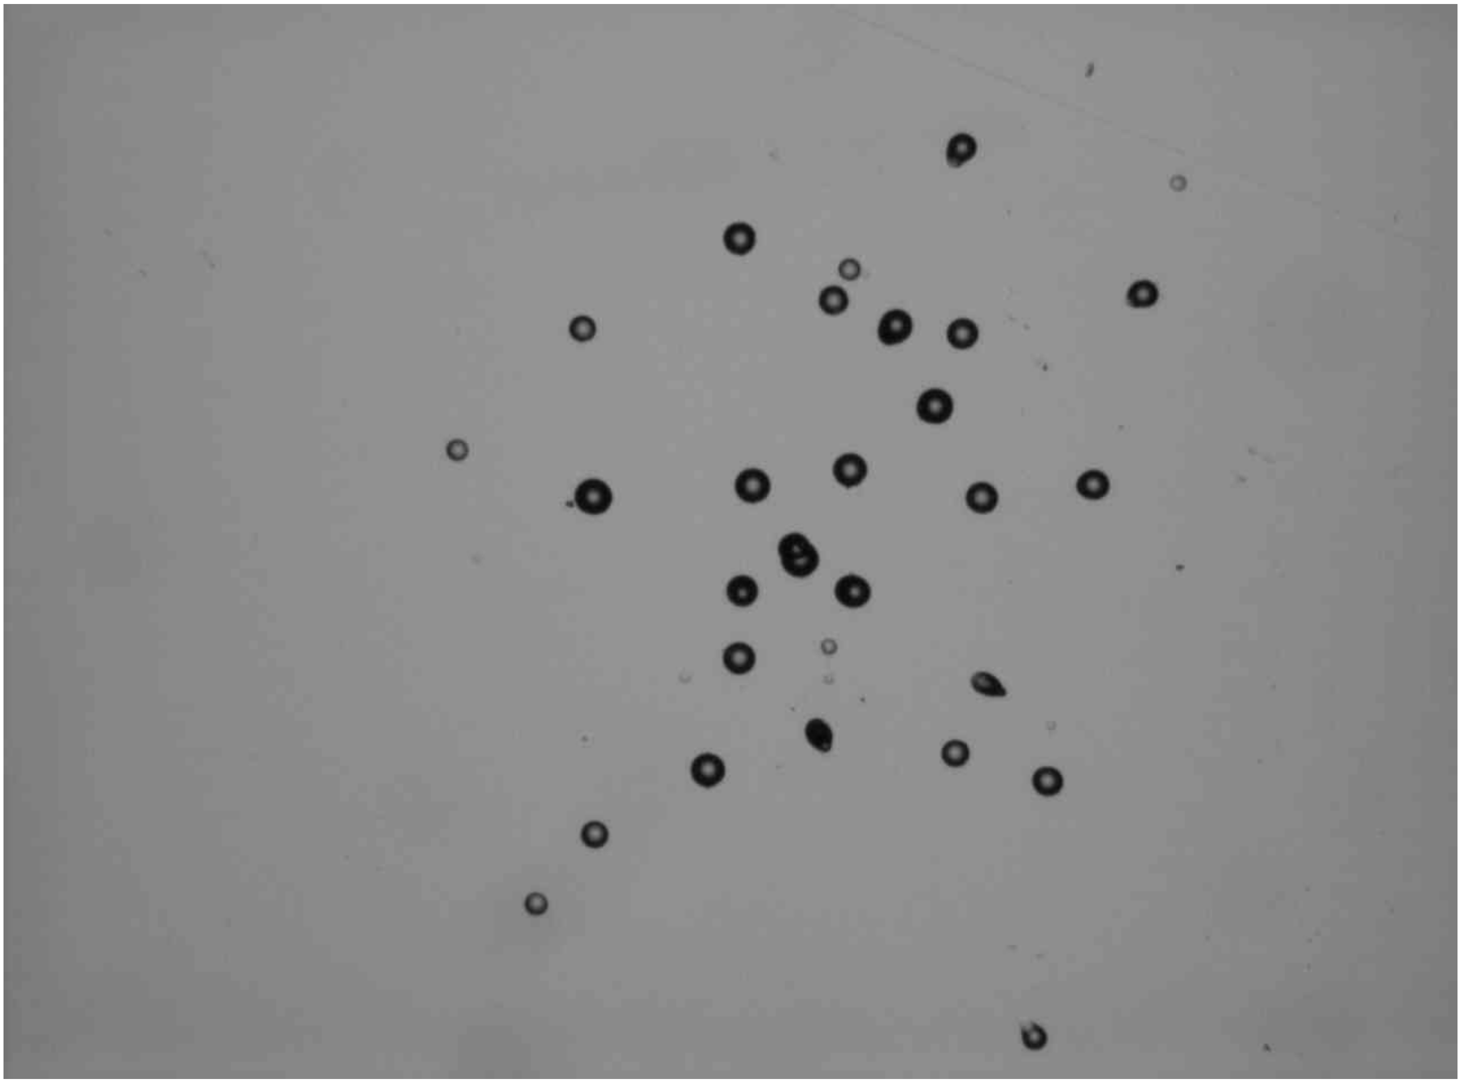

Figure 7
Another cluster from experiment I, after 11 hours of etching. The photographed areas is 1000 by 1300 microns; magnification is X40.

= =

11) One detail is worth mentioning before describing results from other electrolysis experiments. Comparing Figure 5B and Figure 8, which are photos of the same cluster, one can see that many tracks that were elliptical in Figure 5B became nearly circular in Figure 8. That was an important lesson; over-etching makes counting easier but it tends to destroy important information. In fact, etching for only 4 hours, instead of 6 hours, is likely to be more desirable, when information provided by orientation of tracks is important.

= = = = = = = = = = = = = = = =

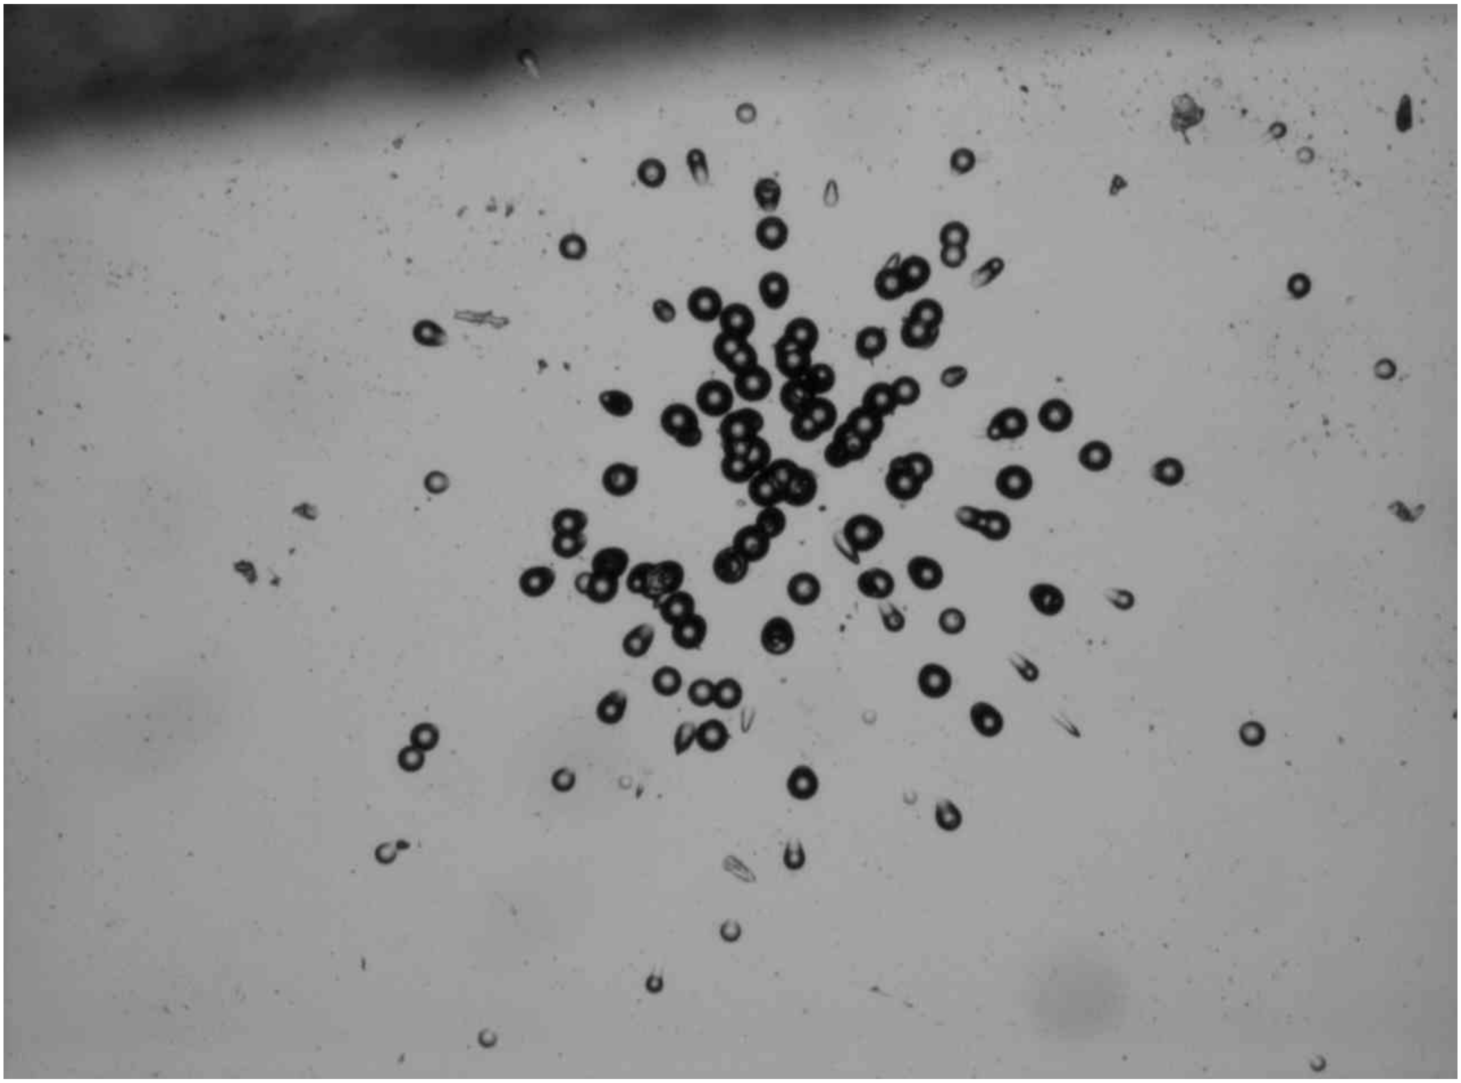

Figure 8
Same cluster as in Figure 5B but after 11 hours of etching. The photographed areas is 1000 by 1300 microns; magnification is X40.

= =

12) Not a single cluster, or excessive average track density, was found on the CR-39 chip used in Experiment II. It is easy to show that the probability of not recording a single cluster in 21 days, when four clusters were produced in 5 days, would be very low for random fluctuations. An important precondition for Oriani effect was probably not satisfied during experiment II. Clusters are not reproducible on demand. But Experiment III again produced four clusters. Three of them are shown in Figures 9A, 9B and 10A. Track densities within these clusters are 24000 tr/cm^2, 615 tr/cm^2 and 2385 tr/cm^2, respectively. Experiments IV, V and VI, however, failed to produce clusters.

= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 9
Two clusters produced during experiment III. Each photographed area is 1000 by 1300 microns; each magnification is X40.

= =

13) The cluster in Figure 10B is very peculiar. This becomes evident when it is seen under the usual magnification, as in Figure 11. The tracks are very close to each other; they can be surrounded by a circle whose diameter is comparable to ranges of alpha particles in CR-39 (10) or in the electrolyte.
= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 10
Two more clusters produced during Experiment III. The photographed area in A is 1000 by 1300 microns, under magnification X40. The photographed area in B is 200 by 260 microns, under higher magnification X200.

= =

On that basis it is reasonable to suspect that several near-by tracks might be due to alpha particles emitted from a tiny grain of radioactive material, such as radium or uranium. Similar patterns of near-by tracks, named rosettes, were reported by Oriani. He considers them to be part of unexplained background rather than clusters due to electrolysis.

= = = = = = = = = = = = = = =

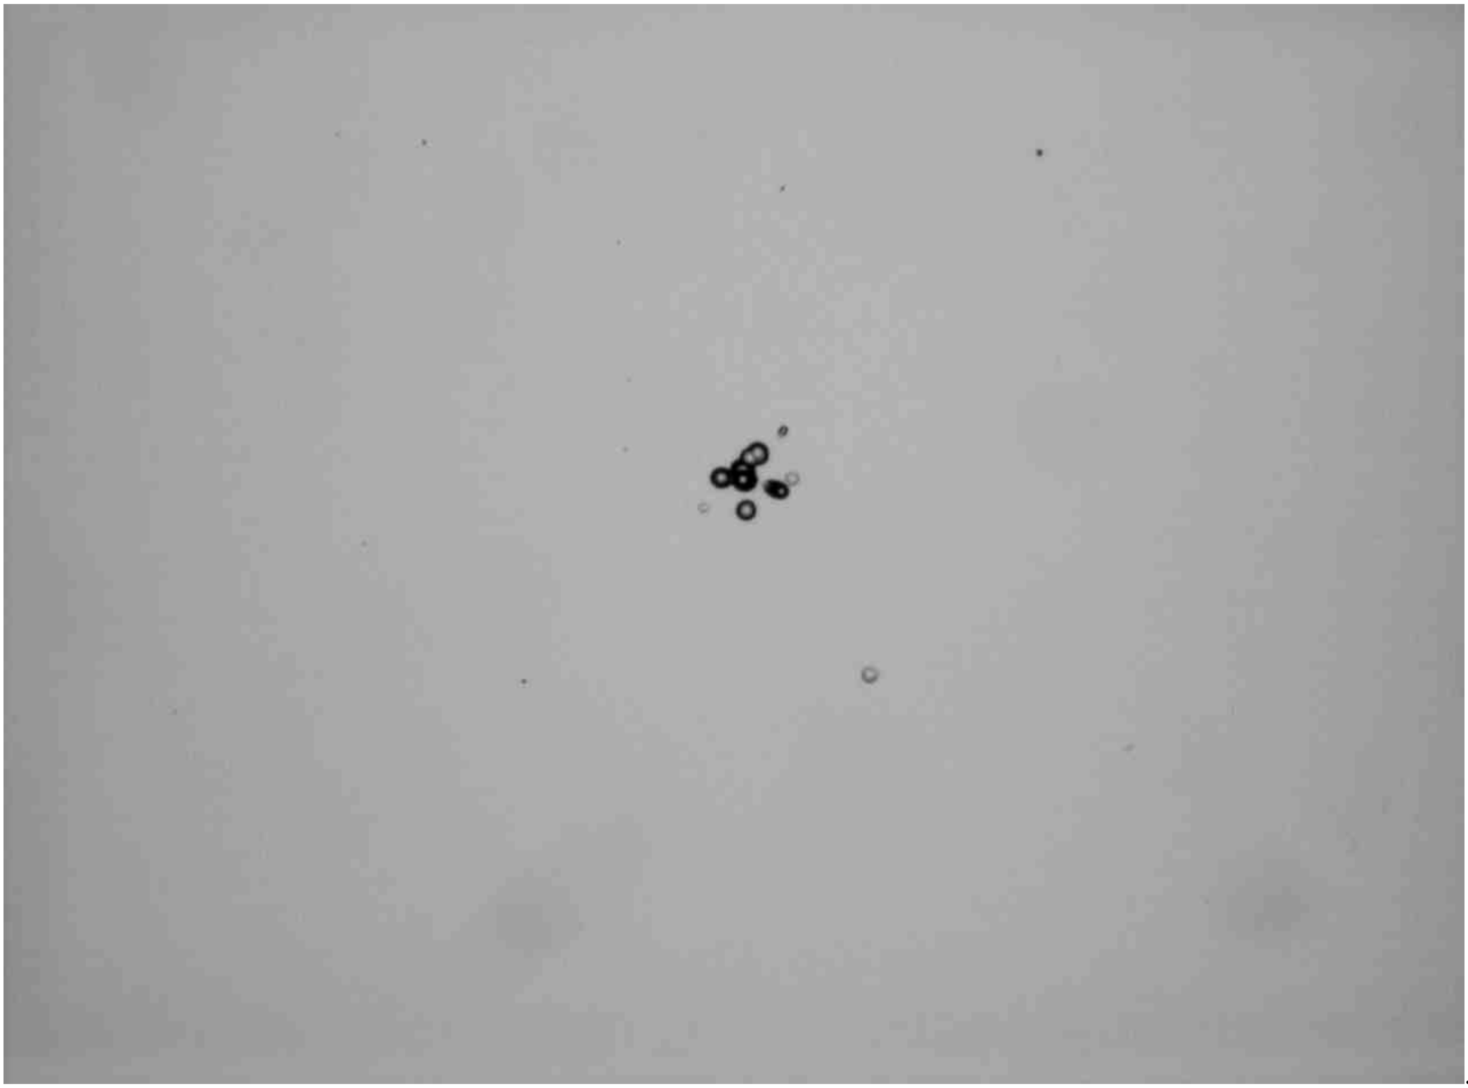

Figure 11
A rosette cluster produced during the experiment III. The photographed areas is 1000 by 1300 microns; magnification is X40. The etching time was 6 hours. Notce the usual low background, outside the rosette -- typically 0.5 tracks per field of that size.

= =

4) Clusters due to residual activity
14) Residual activity has been mentioned in Section 1 above. It is presumably induced in O-rings during electrolysis. Before using O-rings in the electrolytic cell (to induce residual activity) Oriani exposes them to CR-39 detectors, for many days, This is done to demonstrate that no alpha radioactive contamination is present on the surfaces. My own examination of new Oriani O-rings confirmed absence of measurable surface contamination. A test for residual activity begins after O-rings are removed from the electrolytic cell, usually after about four days of electrolysis. Oriani does this in his laboratory and sends the O-rings to those who desire to replicate experiments. A residual-activity test in progress is shown in Figure 12.

= = = = = = = = = = = = = = =

.

Figure 12
Residual activity setup. An O-ring is sandwiched between two CR-39 chips. The setup is supported by a test tube holder. A film of protective plastic, unpeeled from a chip, is shown on the right.

= =

15) Two large clusters (about 6000 by 6000 microns each) were produced in Experiment VIII, one on each chip. The areas are much larger than for clusters produced during the electrolysis. Unfortunately, my lowest magnification, X40, was still too high to produce single pictures of entire clusters. Only centers of these clusters are shown in Figure 13. The average densities within these clusters turned out to be close to 250 tr/cm^2. This is 17 times higher than the mean backgrund.

= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 13
Central areas of tracks from two large clusters produced in Experiment VIII. Each photographed area is 1300 microns by 1000 microns; magnification is X40.

= =

16) A very small cluster, also from experiment VIII, is shown in Figure 14A. Its tracks are nearly twice as large as tracks of alpha particles, shown in Figure 14B. Alpha particles were recorded at a corner of the chip on which the small cluster was found. That means that etching conditions were identical. What kind of projectiles can produce tracks two times larger that those due to alpha particles of 4 MeV? Note that tracks in Figure 13 are also different from tracks due to alpha particles from my source. But they are not larger. The local density of 13 large tracks in Figure 14 A is about 5000 tr/cm^2. This is 330 higher than the mean background.

= = = = = = = = = = = = = = =

(A)  . (B) 
Figure 14
(A) A small cluster of very large tracks from experiment VIII. (B) Tracks of alpha particles of approximately 4 MeV. Each photographed area is 1300 microns by 1000 microns; the magnification is X40.

= =

5) Clusters of electrolysis tracks reported by other investigators
A photo of a cluster, recorded by Oriani during electrolysis experiment, is shown in Figure 15. The mean track density, within the shown cluster area (about 1 mm^2) is close to 22000 tr/cm^2. This is at least 5000 times larger than the expected background.

= = = = = = = = = = = = = = =

(A) ---> .

Figure 15

Oriani's cluster recorded in CR-39 during electrolysis. The number of tracks in that cluster is about 220. The total photographed area of that composite photo was approximately 760 microns by 1300 microns. Orientations of elliptical tracks near the cluster periphery seem not to be random.

= =

17) Figure 16 shows two clusters recorded by John Fisher during electrolysis. The chips were sent to me and I photographed the cluster. The large fuzzy spots are tracks on the opposite side of the CR-39 chip. Their sizes are exaggerated because tracks on the other side are out of focus. The cluster was located on that part of the chip that was in air during the three day-long experiment.

= = = = = = = = = = = = = = =

(A)  . (B)  .

Figure 16
Two of Fisher clusters recorded in CR-39 during the electrolysis. The magnification was 40 and the photographed area was 1300 microns by 1000 microns.

= =

19) Figure 17 shows an electrolysis cluster reported by Marissa and Scott Little (9). In posting the picture Marissa wrote: “There is an obvious cluster of tracks on the chip! The cluster is on the side facing away from the cathode and is outside the o-ring area. There are several, much smaller clusters on the area outside the o-ring as well (containing 3-10 tracks.)” Most of the tracks are inside an area whose diameter is about 1400 microns. The mean track density, in this area, is close to 6000 tr/cm^2. This is about 1300 times higher as the average background on their new CR-39. At the time of this writing Scott and Marissa are trying to disprove their “null hypothesis.” According to that hypothesis, excess tracks are due to radioactive contamination, most likely to a radon progeny.

= = = = = = = = = = = = = = =

(A) --->  .

Figure 17
Little's cluster recorded in CR-39 during electrolysis. It was the only large cluster produced in 30 experiments. The magnification was 40 and the photographed area has the diameter of 2800 microns.

Clustering of tracks indicate that nuclear reactions are localized in space. Unfortunately, clustering tells us nothing about localization in time. Are clusters produced in sudden bursts of activity or via slow accumulation of tracks? Such questions can not be answered by those of us who use CR-39 detectors. But they are likely to be answered by users of electronic detectors. Data collected by these detectors can be recorded frequently, for example every six hours, without interrupting long experiments. Electronic detectors, providing information about energies of intercepted particles, can also be used to identify particles.

= =

6) Discussion:
20) The cluster shown in Figure 5 B has 109, plus or minus 10 tracks; the uncertainty is due to the arbitrary value of the "threshold of rejection." That is a common problem in counting tracks on CR-39 surfaces, especially when these surfaces are not clean. The most remarkable feature of that cluster is a large number of nearly-elliptical tracts. Orientations of these tracks are certainly not random. Frank DiBianca, after seeing the picture spent some time in tracing straight lines along the focal axes of non-circular tracks, as illustrated in Figure 18. Considering the angular uncertainties in drawing the lines, and possible scattering effects, the picture is consistent with the idea that all lines intersect at one point. The diameter of the small circle, 75 microns, is about ten times smaller that the diameter of the area in which most of the tracks are located. The size of the cluster is large in comparison with ranges of typical alpha particles. For 6 MeV particles, for example, the range in CR-39, or in electrolyte, is close to 50 microns (10). A similar set of lines can be drawn through numerous elliptical tracks shown in Figure 1.

= = = = = = = = = = = = = = =

(A) ->

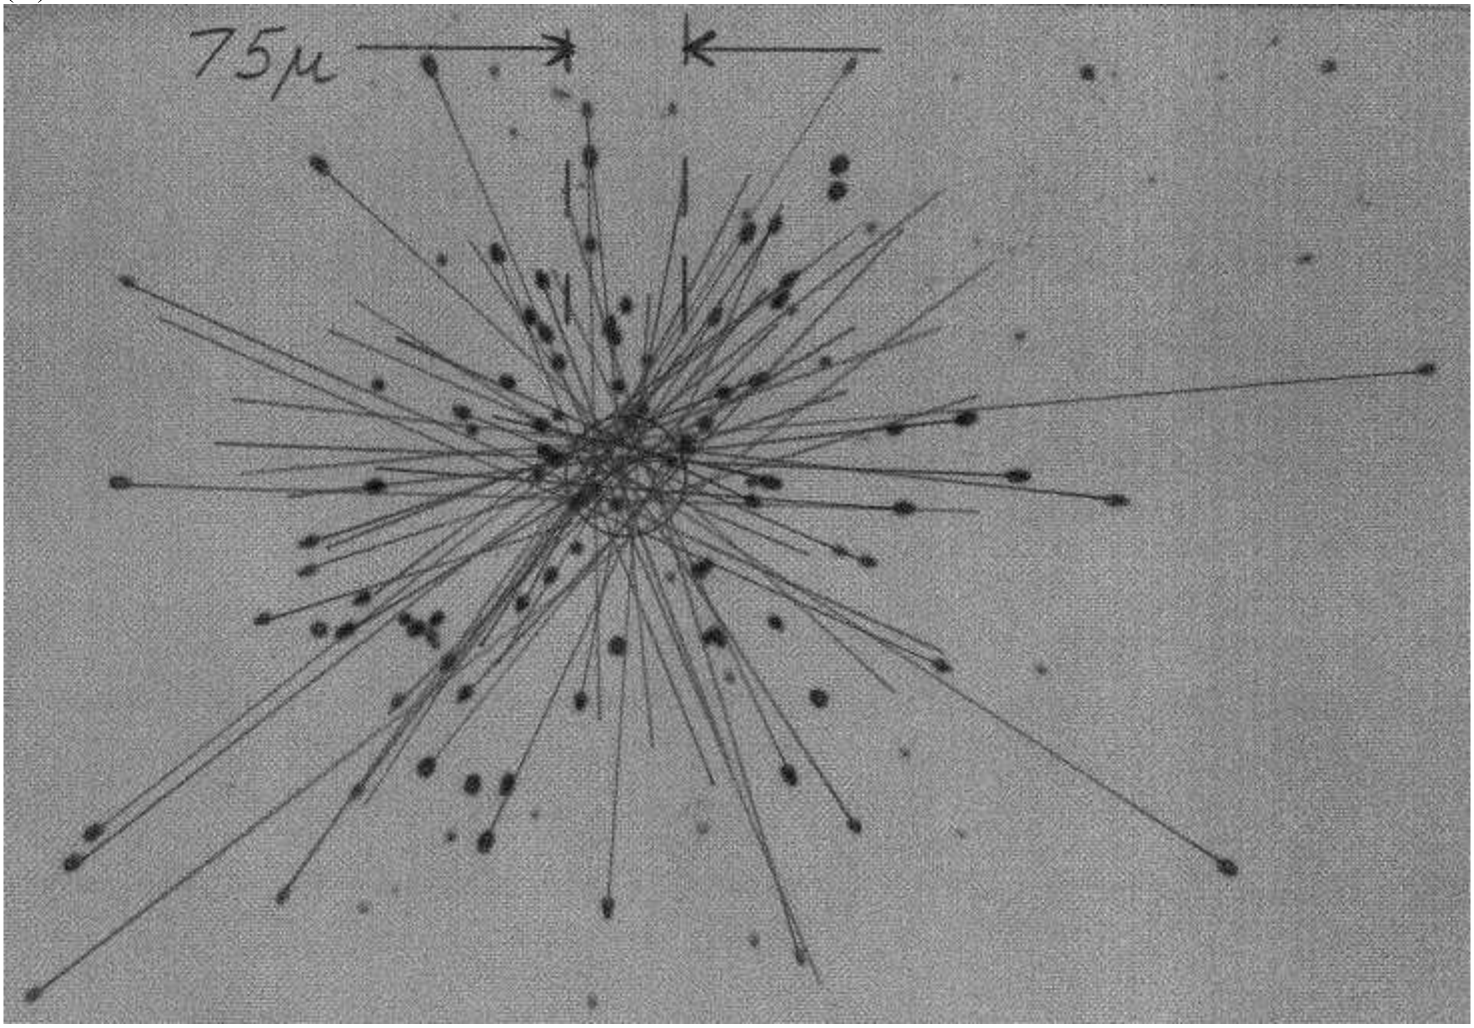

Figure 18
This picture shows tracks already seen in Figure 5 B. The photographed area is 1000 by 1300 microns; magnification was X40.

= =

21) One additional feature should be noted on Figures 5B and 1. Tracks near the centers of clusters are frequently round while tracks near peripheries of the cluster are mostly elliptical. In fact, the average ellipticity seems to increase with the distance from the central region. It is certainly too early to speculate about significance of such patterns. Also significant are locations of my clusters. Some of them, as in Figure 5A, were found on the upper CR-39 surface (facing the mylar foil and the electrolyte) while others, as in Fig 5B, were found on the lower surface (facing air below the cell). The cluster shown in Figure 1 was not produced on the CR-39 surface facing the O-ring; it was produced on the surface separated from the O-ring by about 1 mm of CR-39 plastic. The same was reported about the cluster shown in Figure 17. It is tempting to speculate that observed tracks result from collisions between protons in CR-39 ($C_{12}H_{18}O_7$) and some kind of neutral particles. Neutral particles do not ionize matter directly; that is why they can travel long distances before colliding with protons. I am not going to elaborate on this because my goal, at this stage, is to convince myself (and others) that Oriani cluster effect is real. In my opinion, theoretical considerations should wait till experiments become reproducible. It is remarkable that clusters of charged particles, reported in 2004 (3) have been observed in recent experiments of Richard Oriani, Marissa Little, John Fisher and myself. Something interesting is going on and research in this area should continue.

22) Is it possible that observed clusters are due to well known processes? One trivial explanation has already been mentioned, it is possibly the presence of tiny grains of alpha-radioactive substances, as in Figure 3B. Another has to do

with cosmic rays. Let me address them, one after another, in the context of clusters from Figure 1 and 5 B. A grain of alpha radioactive substance, such as uranium, would produce tracks whose orientations are random, except when sizes of clusters are not much larger than ranges of alpha particles. Orientations of tracks in Figure 5B (and also in Figure 1) are certainly not random. That is a sufficient argument for rejecting the idea of contamination, as far as I am concerned. Another strong argument against contamination is total absence of clusters on numerous control chips (see the Appendix).

23) Can clusters be due to cosmic rays? Collisions in which relativistic heavy ions disintegrate, producing showers of nucleons, have been studied by using high energy accelerators, for example, at Brookhaven National Laboratory. Suppose that most of the tracks identified in Figure 5 B are due to neutrons and protons resulting from total disintegration of a single ultra-relativistic ion, somewhere near the detector. What is the probability that such ion can be found at sea level? Fortunately, this question has already been answered. According to (11), the theoretically calculated flux, for ions with Z=25, at see level, is 10^{-34} particles per m^2 per second. This translates to about $3*10^{-21}$ particles per km^2 per year. For particles with much higher Z the expected flux is many orders of magnitude smaller.

24) The second cosmic ray phenomenon to consider are showers. Primary cosmic ray charged particles, mostly protons, interact with the atmosphere by producing showers of pions and muons. Can a cluster seen in Figure 5B be due to such particles? The answer is a definite no. The ionization density of pions and muons is too low to produce tracks in CR-39 detectors. I am familiar with one study (12), conducted at Brokhaven National Laboratory, in which CR-39 chips were coated with fissionable material and exposed to beams of pions with several energies between 500 MeV and 2300 MeV. The purpose was to measure cross sections of fission induced by pions. This was done by counting tracks due to fission fragments. The reported cross sections indicate that billions of pions traverse CR-39 chips for each set of fission fragments. Observation of fission fragment tracks would not be possible if individual pions could form tracks in CR-39 detectors. Cosmic ray showers, by the way, are known to be very wide, near sea level. On that basis I am inclined to conclude that small clusters observed in my experiments were not due to cosmic rays.

10) Appendix:

26) A friend who read the above asked for more information about control experiments. Here is a brief summary of facts:

a) Six electrolysis experiments were conducted but only two (I and III) produced clusters. In other words, two successes (seven clusters and one rosette) and four failures -- to replicate clusters during electrolysis.

(b) Four residual activity experiments were conducted but clusters were observed in experiment VIII only. In other words, one success (three clusters) and three failures.

(c) Not a single cluster was found on control chips. During the experiments, control chips were exposed to air (in the same room but away from the electrolytic cell and from the seeded O-rings). Two CR-39 control chips, A and B, were used in parallel with Experiment I. Chip A was covered by the original blue protective coating while the coating was removed from chip B. Chip B was exposed to air while chip A was squeezed between two O-rings and two flat plates. Four screws were used to apply pressure to the O-Orings. That pressure was higher than in the electrolytic cell. The mean track density on Chip A was ~3 tr/cm^2 ; the mean track density on chip B was ~8 tr/cm^2 . The conclusion was that mechanical pressure, applied to a CR-39 chip through O-rings, does not produce excessive track-looking defects. In a private message Oriani wrote that the mean background on his control chips was 16.6 tr/cm^2 , with, standard deviation of 9.7 tr/cm^2. My control-experiment results also fluctuated widely around ~15 tr/cm^2 . Note that even a high, 25 tr/cm^2 , translates into 0.35 tracks per my 1.3 by 1.0 mm field. Fortunately, fluctuations of background densities are inconsequential; local densities within clusters turned out to be at least 100 times higher.

(d) Absence of clusters on the chip used in the electrolysis experiment II is convincing evidence that neither electrolyte nor the O-rings were contaminated with grains of an alpha-radioactive material, such as ^{212}Pb, ^{226}Ra or ^{238}U. I am referring to the suspicion that the electrolyte, or the O-rings, might have been contaminated with such material during Experiment I. If this were true then Experiment II would also produce clusters. The electrolyte and the O-rings, used in Experiment II (21 days of electrolysis) were the same as in Experiment I (5 days of electrolysis). The number of

clusters produced in Experiment II would exceed the number produced in Experiment I. Zero clusters in experiment II versus four clusters in experiment I is not consistent with the idea of contamination. But it is consistent with the idea of irreproducibility.

(e) John Fisher suggested that additional CR-39 chips should be placed in air, very close to the cell. That was on the day 3 of Experiment II. I did this. Four small (about 1 by 2 cm) chips were placed next to the cell for the remaining 18 days of electrolysis. No clusters were recorded on these chips. This is an acceptable argument against absence of tiny alpha-radioactive aerosoles in air.

(f) Absence of clusters on chips used in residual activity experiments VII, IX and X is also acceptable evidence against the suspicion that seeded O-rings were contaminated with tiny grains of an alpha-radioactive material.

(g) The overall conclusion is that something interesting is going on, and that additional investigations are needed. Absence of reproducibility is the most disturbing thing in this episode. But this should not prevent us from further investigations. A clear yes-or-no answer, about nuclear effect due to electrolysis, will be found, sooner or later. Absence of reproducibility does not mean that a phenomenon is unreal; it means that we must learn how to control it.

336) On emission of nuclear particles caused by electrolysis

Ludwik Kowalski; 11/3/2007

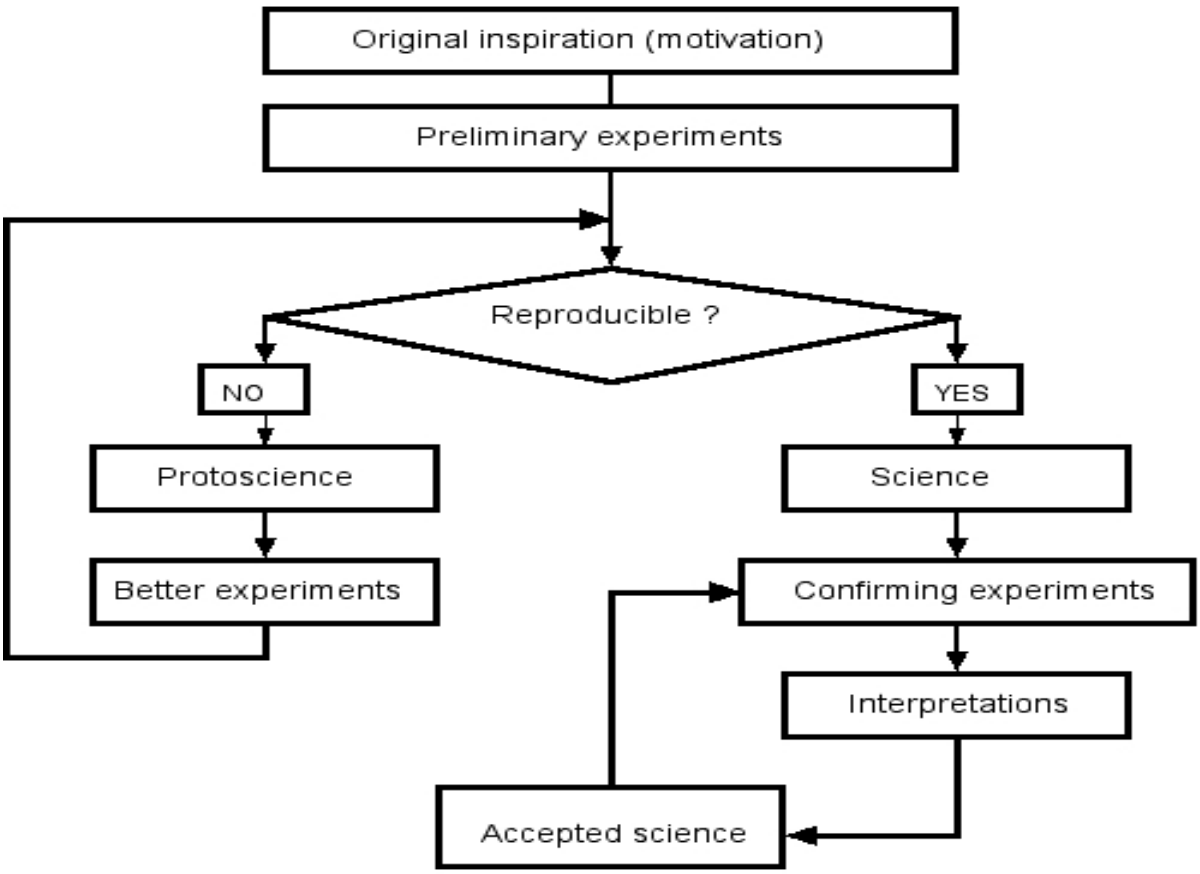
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Abstract:
Numerous tracks of charged nuclear particles, emitted during electrolysis, were discovered by Oriani and Fisher (1). More recently, emission of such particles after electrolysis was discovered by Oriani (2). This presentation is based on ten experiments conducted to replicate the reported results. Seven clusters of tracks were found in two out of six electrolysis experiments. Three clusters were also found in one of four experiments conducted to study emission of nuclear particles after electrolysis. Arguments are presented against trivial explanation of clusters, such as natural radioactivity and cosmic rays.

1) Introduction

The field of so-called “cold fusion,” also known as CANR (chemically assisted nuclear reactions), belongs to the realm of protoscience. The accepted paradigm is that chemical processes -- interactions involving outer electrons in atoms and molecules -- are too weak to produce emission of nucleons from atomic nuclei. Yet, several qualified researchers, such as A. Lipson (3), R. Oriani (1) and S. Jones (4), have for many years been reporting unexpected emission of nuclear particles. Experimental facts that conflict with existing theories should be studied rather than rejected. A flowchart illustrating evolution of protoscience toward science is shown in Figure 1.

==========



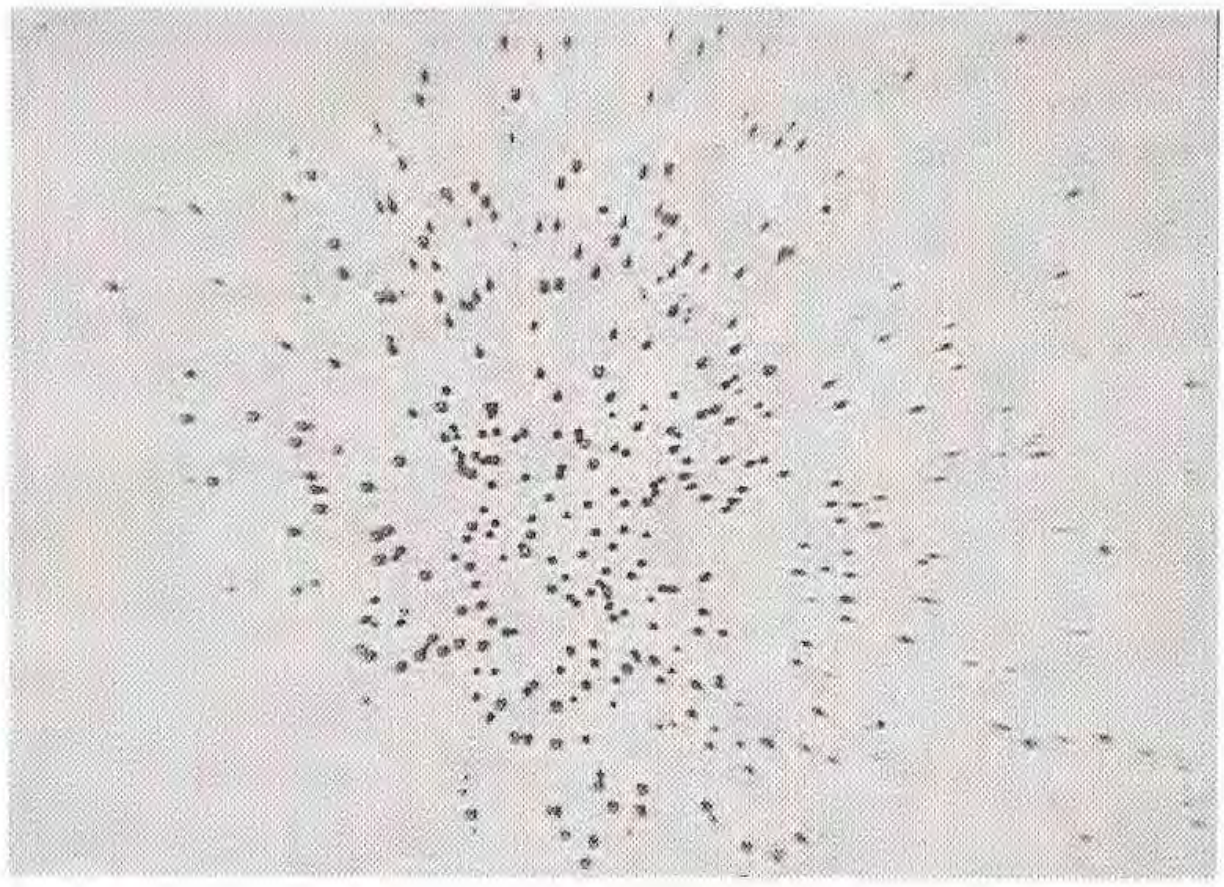
(A)

Figure 1
Schematic illustration of evolution of protoscience toward accepted science.
==========

This study, prompted by recent reports (2,5), confirms that an unexpected nuclear process seems to be occasionally triggered by a chemical process. According to Oriani (2), whose protocol was used in my investigation, nuclear particles are emitted during and after electrolysis. The high level of reproducibility, according to him, is due to residual activity. Each consecutive electrolysis experiment presumably benefits from what happens during the previous experiment. The probability of triggering a CANR effect in a new electrolytic cell is said to be very low, but it becomes very high after the first success. The probability is also said to be high in a new cell containing o-rings used in successful experiments. That is why my experiments were performed with o-rings previously used by Oriani.

According to (2), distributions of tracks left by nuclear particles on CR-39 detectors are randomly uniform. But sometimes tracks appear in the form of clusters, as illustrated in Figure 2.

==========



(A)

Figure 2
A cluster of post-electrolysis tracks discovered by Oriani (8). This cluster was produced when the CR-39 chip was exposed to an o-ring removed from the electrolytic cell. The mean density, about 30000 tr/cm^2, is 2000 times higher than outside the cluster.
==========

I was able to confirm occasional production of clusters at local densities much higher than the background. The densities of uniformly distributed tracks, however, were found to be consistent with the background. Can radioactivity acquired by these rings in Oriani's cell be responsible for clusters produced in my experiments? My answer to this question will be negative. But the issue is far from being resolved, as indicated in the appendix. What follows describes my simple apparatus and results. In the closing section I will argue against the idea that clustered tracks are due to natural radioactivity or cosmic rays.

2) Experimental setup.
The electrolytic cell used in my experiments was identical to one of Oriani's cells, as schematically illustrated in Figure 3A. The electrolyte was Li_2SO_4 in ordinary distilled water at a concentration of 22 grams per liter. The anode was Pt and the cathode was Ni. The cell consisted of a set of a glass tubes containing about 10 cc of the electrolyte. The bottom of the cell was made from a replaceable 3 by 3 cm piece of CR-39 plastic material. That piece (thickness about 1 mm) was separated from the electrolyte by a layer of mylar whose thickness was 6 microns. The Ni-wire cathode, in the form of a spiral pancake, was in contact with the mylar while the Pt-wire anode, also in the form of a spiral pancake, was about 15 mm above the cathode. The cell was designed in anticipation of experiments in which CR-39 would be removed and a silicon detector, placed below the mylar window, would be used to measure energies of charged nuclear particles.

Potential differences applied to the cell were between about 5 and 12 volts, depending on the desired current (between 30 mA and 150 mA during preliminary experiments). At 3 volts the current was close to zero. The concentration of the electrolyte was allowed to double (approximately) during experiments because water lost via electrolysis was usually not replaced until the volume of the electrolyte was reduced to approximately one half of the initial volume. The current, however, was kept constant, usually 42 mA, by an electronic stabilizer outside the power supply.

B ->

Figure 3
(A) Two flexible Viton o-rings are pressed against the CR-39 chip (by clamps applied to glass tubes) to prevent leakage of the electrolyte. The inner diameter of each tube was close to 15 mm; the wire diameters (Pt and Ni) were 0.5 mm. The Ni cathode was a “foot” supporting the rigid anode-cathode structure. (B) A CR-39 chip on top of an o-ring, as used to detect nuclear particles emitted after electrolysis.
==========

The CR-39 chips were cut from a Fukuvi Chemical sheet purchased from Landauer Inc. (6). One of the well known properties of CR-39 material is its ability to record nuclear projectiles, such as protons or alpha particles (7). Tracks of such particles become microscopically visible after etching. Sizes of observed tracks increase with time and temperature of etching. A cluster consisting of over 100 tracks is shown in Figure 4. That figure is a microphotograph of a small area of CR-39 that was removed from the electrolytic cell after five days of electrolysis and etched for six hours. Round pits are tracks of particles that were intercepted at small angles of incidence; elliptical and conical pits are tracks of particles intercepted at larger angles. After twelve hours of etching nearly all tracks become round, as illustrated in Figure 5. Nuclear activity after electrolysis was studied by placing CR-39 chips on the o-rings removed from the cell, as illustrated in Figure 3B.

==========

(A) 
Figure 4
Cluster of tracks produced during five hours of electrolysis. The area of 1000 by 1300 microns was photographed under a magnification of X40, after six hours of etching. The mean track density, over the area of 1 mm^2, is about 11000 tracks per cm^2. This is three orders of magnitude higher than in the areas outside the four clusters, on the same CR-39 chip. A section of this photo, under a higher magnification, is shown in Figure 6.
==========

All CR-39 detectors were etched for six hours in a small beaker. The average temperature was close to 72 C. But local temperatures, near individual detectors, were most probably not identical (because the etching solution was not stirred). Sizes of tracks are known to depend on the product to the etching time and temperature. It is reasonable to assume that observed difference in sizes and shapes of tracks, in different clusters, were due to differences in local temperatures. The effect of etching time on the tracks appearance can be seen by comparing Figure 4 and Figure 5.

==========

(A) 
Figure 5
The microphotograph of the same cluster as in Figure 4 but after six additional hours of etching. As before, an area of 1000 by 1300 microns was photographed under a magnification of X40.
==========

Control experiments with CR-39 chips in air showed that background track densities, after five days of exposure, fluctuated widely. The mean density was 15.5 tracks per square centimeter; the standard deviation was 9.7 tr/cm^2. Similar densities were found on CR-39 chips exposed to the electrolyte, and to other unused components of the cell (glass, o-rings, platinum and nickel). Note that even 25 tr/cm^2 density translates into 0.35 tracks per my low magnification field of 1.3 by 1.0 mm. In other words, fluctuations of background densities are inconsequential; local densities within clusters are usually much higher.

==========

(A) 
Figure 6
Elliptical and conical tracks in a small section of the area shown in Figure 4. The magnification was X400; the total photographed area was 130 by 100 microns.
==========

3) Experimental results
Six experiments were performed to observe Oriani's electrolysis effect. But only two of them were successful in terms of finding clusters of tracks. Two pictures of one post-electrolysis cluster are shown in Figures 4 and 5. Observed clusters are described in Table 1.

Table 1
Experiments to study nuclear particles emitted during electrolysis:

Electrolysis in Experiment I lasted 5 days, using Oriani's seeded o-rings. The rings were received 24 hours after they were removed from Oriani's cell. The experiment started shortly after the package arrived. Four clusters were produced. Numbers of tracks in these clusters were: 109, 75, 30, and 29. The corresponding mean track densities were: 11000, 5000, 3000, and 4800, respectively, per square centimeter.

Electrolysis in Experiment II lasted 21 days, using the same o-rings as in Experiment I. The experiment started shortly after the end of Experiment I. Zero clusters were produced.

Electrolysis in Experiment III lasted 5 days, using the same o-rings as in Experiment II. The experiment started shortly after the end of Experiment II. Three clusters were produced. Numbers of tracks in these clusters were: 85, 35, and 9. The corresponding mean track densities were 11000, 4400, and 900, respectively, per square centimeter.

Electrolysis in Experiment IV lasted 5 days, using another freshly seeded o-ring from Oriani. The experiment started shortly after that O-ring was received. Zero clusters were produced.

Electrolysis in Experiment V lasted 5 days, using the same o-ring as in Experiment IV. The experiment started shortly after Experiment IV. Zero clusters were produced.

Electrolysis in Experiment VI lasted 5 days, using the same o-ring as in Experiment V. The experiment started shortly after the end of Experiment V. Zero clusters were produced.

Experiments to study nuclear particles emitted after electrolysis:.

Experiment VII was conducted outside the electrolytic cell. Several small CR-39 chips were exposed to the o-ring used in Experiment III. The exposure time was two days; Zero clusters were produced.

Experiment VIII was also conducted outside the electrolytic cell. Two large CR-39 chips were applied to another freshly seeded o-ring sent to me by Oriani. Three clusters were produced during two days of exposure. Numbers of tracks in these clusters were: 110, 60 and 13 The corresponding mean track densities were 360, 300, and 2600, respectively, per square centimeter.

Experiment IX was similar to Experiment VIII, except that it started at the end of Experiment VIII. Zero clusters were produced during two days of exposure.

Experiment X was similar to Experiment IX, except that it started at the end of Experiment IX. Zero clusters were produced during two days of exposure.

But one cluster from Experiment III, shown in Figure 7, was very different. Similar patterns of nearby tracks, named rosettes, were reported by Oriani. He considers them to be part of background rather than clusters due to electrolysis. It is reasonable to assume that tracks in very small clusters are due to alpha particles emitted from a tiny grain of radioactive contamination, such as radium or uranium. This supposition is based on the fact that distances between radially oriented tracks are smaller than ranges of alpha particles in CR-39 or in the electrolyte (typically less than 50 microns). Peripheral tracks in Figure 4, on the other hand, are often separated by distances much larger than tracks of alpha particles. Significance of this observation will be discussed in the next section. It is remarkable that not a single cluster was found on more than twenty chips from control experiments. This is a strong indication that larger clusters are not due to background tracks.

==========

Figure 7
The microphotograph of a very small cluster of tracks produced in Experiment III. The photographed area was 1000 by 1300 microns; the magnification was X40.
==========

4) Discussion
It is clear that random fluctuations could not be responsible for zero clusters in the Experiment II (electrolysis lasting 21 days) and for four clusters in the Experiment I (electrolysis lasting five days). The same is true for clusters recorded after electrolysis. In both situations formation of clusters seems to be due to some uncontrollable factors. That is why further investigations are needed. In this section I want to show that neither contamination nor cosmic rays can be responsible for clusters shown in in Figures 1 and 4. The main argument is trivial -- ten clusters were produced on experimental chips and zero clusters were produced on all control chips.

Another argument against contamination is based on orientations of noncircular tracks. Orientations of these tracks, separated from each other by distances larger than ranges of alpha particles (in CR-39 and in water), would be random if clusters were due, for example, to large uranium particles. But orientations are certainly not random. Tracks near the centers of clusters are frequently round while tracks near peripheries are mostly elliptical. In fact, the average ellipticity seems to increase with the distance from the central region.

It is tempting to speculate that observed tracks result from collisions between protons in CR-39 ($C_{12}H_{18}O_7$) and some kind of neutral particles. Neutral particles do not ionize matter directly; that is why they can travel long distances before colliding with protons. I am not going to elaborate on this because my goal, at this stage, is to convince myself (and others) that Oriani-type clusters are due to electrolysis. In that context it is important to mention that clusters were also reported by John Fisher (9) and by Marissa Little (10). The protocols used by these researchers were essentially the same as that used by Oriani. Clusters produced during electrolysis were also observed in SPAWAR experiments

with sequential etching (11). Sequential etching was probably used to etch away myriads of chemically caused pits known to be present on the surface. Clusters with track deep inside the CR-39 material, if confirmed, would be highly significant. Note that SPAWAR experiments (5) were totally independent of Oriani's experiments, and of his protocol. Also note that in all cases local track densities, within clusters, were much higher than in the background.

Is it possible that observed clusters are due to cosmic rays? Collisions in which relativistic heavy ions disintegrate, producing showers of nucleons, have been studied using high energy accelerators, for example, at Brookhaven National Laboratory. Suppose that most of the tracks identified in Figure 4 are due to neutrons and protons resulting from the disintegration of a single ultra-relativistic ion, somewhere near the detector. What is the probability that such an ion can be found at sea level? Fortunately, this question has already been answered. According to (12), the theoretically calculated flux, for ions with Z=25, at sea level, is 10^{-34} particles per m^2 per second. This amounts to about $3*10^{-21}$ particles per km^2 per year. For particles with much higher Z the expected flux is many orders of magnitude smaller.

The second cosmic ray phenomenon to consider is showers. Primary cosmic ray charged particles, mostly protons, interact with the atmosphere by producing showers of pions and muons. Can a cluster seen in Figure 4 be due to such particles? The answer is a definite no. The ionization density of pions and muons is too low to produce tracks in CR-39 detectors. In one study (13), CR-39 chips were coated with fissionable material and exposed to beams of pions with several energies between 500 MeV and 2300 MeV. The purpose was to measure cross sections of fission induced by pions. This was done by counting tracks due to fission fragments. The reported cross sections indicate that billions of pions traverse CR-39 chips for each set of fission fragments. Observation of fission-fragment tracks would not be possible if individual pions could form tracks in CR-39 detectors.

On that basis I am inclined to conclude that clusters observed in my experiments were not due to cosmic rays, or to alpha-radioactive substances. Something interesting is going on and research in this controversial area should continue. The goal should be to identify hidden factors responsible for irreproducibility of experimental results. Unfortunately, present investigations of clusters belong to protoscience, as defined in Figure 1. Protoscience should not be confused with pseudoscience, such as astrology. Methods of validation in protoscience are not different from methods used in science.

Appendix (11/9/07):
Two important objections were made to my tentative conclusion that clusters could not be attributed to contamination with alpha-radioactive substances. The first objection was made by Lipson and Rousetski, during a recent conference in Italy (14). Discussing my presentation, they invented the following scenario. A gas bubble sits on top of CR-39. A grain of alpha-radioactive material sits on top of the bubble. Ranges of alpha particles in the gas bubble are much larger than in the electrolyte. That is why a cluster can be much larger than ranges of alpha particles in the electrolyte. Furthermore, according to this assumption, most tracks would be circular near the central region and noncircular along cluster's peripheries. Tracks along peripheries would be radially-oriented, more or less, as in our experimentally-observed clusters. Commenting on the above S. Little wrote (15) " . . . The electrolyte does not wet the CR-39. Grains of radioactive material could easily be trapped between the mylar film and the CR-39, . . . " In other words, not only bubbles can produce clusters with radially oriented tracks. I agree with these speculations.

APPENDED ON JULY 1, 2009
What I am doing now amounts to a replication of experiments described in this unit. Motivation for doing this is described in Unit 368; results will be reported in Unit 373, probably in September. The only difference is minimizing contact of chips with air. Will this eliminate "widle fluctutions" of mean densities on control chips? Will we see excessive tracks outside clusters? Will we see clusters? This remains to be seen.

337) On emission of nuclear radiation due to glow discharge

Ludwik Kowalski; 11/17/2007

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

In 2002 my renewed interest in cold fusion was triggered by research of Karabut (unit #13 at my website). That was five years ago. I was impressed by the description of spectacular nuclear effects due to the glow discharge. During a workshop in Italy (Catania, October 2007) I was equally impressed by the ongoing research of Ed Storms and Brian Scanlan. Their glow discharge apparatus is also said to produce nuclear effect -- emission of high energy electrons (0.8 MeV) and of yet to be identified heavier projectiles, perhaps protons, neutrons or alpha particles. This unit is devoted to what I learned about this recently-started investigation, and to my understanding of it. The report of S & S can be downloaded from the LENR-CANR library (1).

The glow discharge apparatus is essentially a diode filled with a gas at low pressure. The gas starts glowing when sufficiently high voltage is applied. The distance between the anode and the cathode, in the S&S setup, was about 8 mm. Their gas was D2, mixed with small amounts of oxyge. The pressure was probably close to 10 Torr. Essential components of the apparatus are identified in Figure 1. The figure is not geometrically realistic; it was made to match my simplified description.

= = = = = = = =

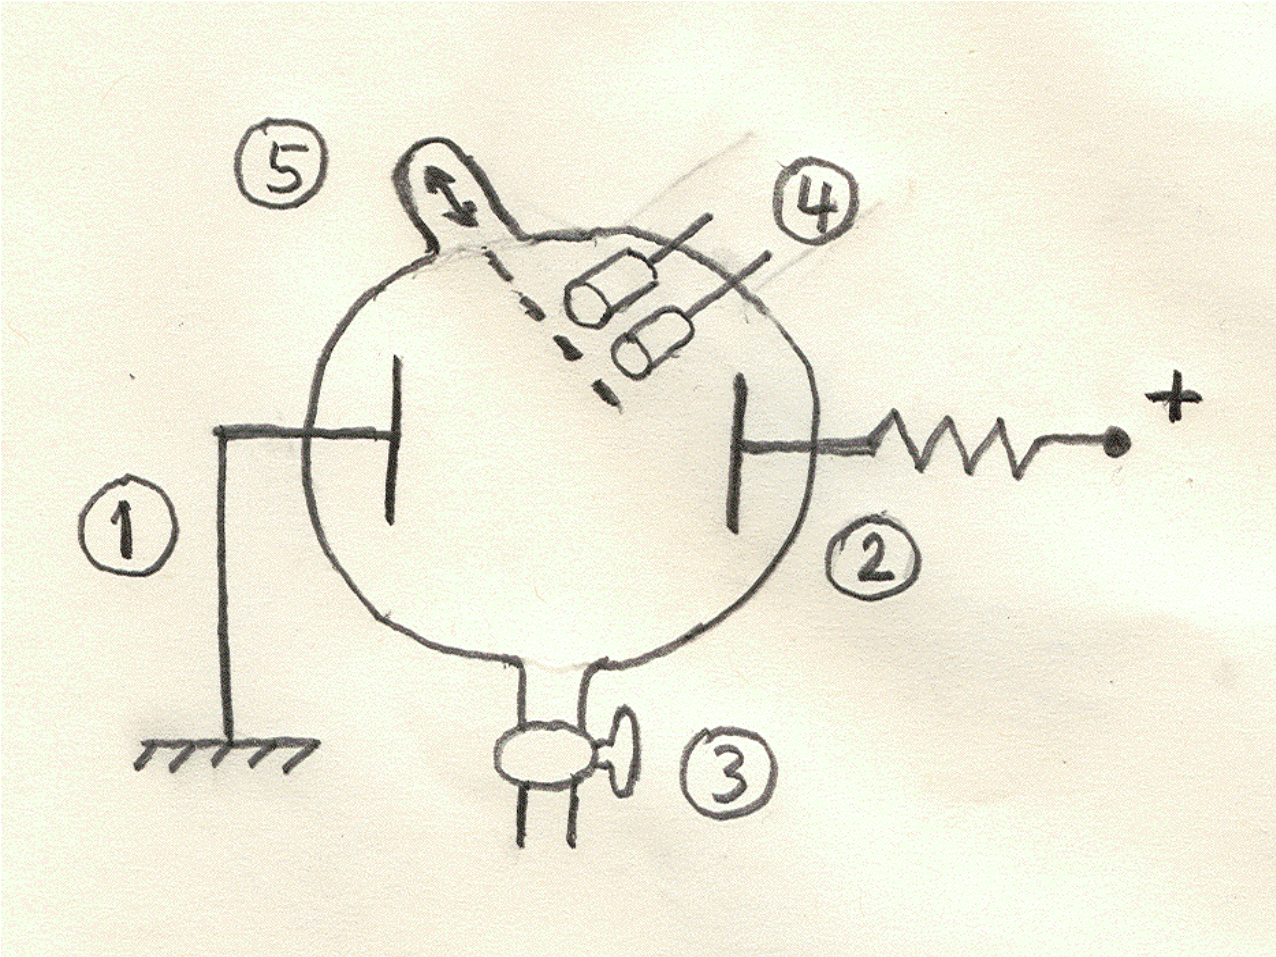

Figure 1
A schematic diagram of the apparatus used by Storms and Scanlan.

1 Grounded water-cooled cathode
2 Anode connected to the power supply via a 300 ohms resistor.
3 Valve leading to the vacuum and gas supply tubes.
4 Two detectors of nuclear radiation (GM and SBD) facing the cathode.
5 A filter of desired thickness can be inserted, as needed.
= =

According to preliminary investigation, based on the Geiger Muller counter (with and without filters), nuclear radiation is emitted when appropriate voltage is applied to sustain the glow discharge. My first reaction to this claim, after hearing Storms' presentation in Catania, was that the GM detector is probably picking up radio waves generated during the discharge. Three reasonable arguments were presented against this suspicion:

a) Placing a thin filter, of sufficient thickness (either metal or dielectric), between the cathode and the detector, reduces the counting rate to the background level.
b) The effect increases at a rate that is proportional to the D/O ratio.
c) The effect tends to disappear when hydrocarbons are added.

2) In a brief discussion I suggested an additional test, to rule out the possibility that high counting rates (exceeding million counts per second) are due to the radio-waves artifact. It consists of studying the effect of the voltage, applied to the GM tube, on the counting rate.

a) Use any radioactive source to establish the minimum voltage below which counting becomes impossible. Suppose the GM plateau region is between 700 and 900 volts and that nothing is counted below 550 volts.
b) Conduct an experiment at 800 volts to observe the claimed effect.

c) Lower the GM voltage to to 500 volts and repeat the experiment.

My level of confidence in the claimed effect would increase dramatically if the high counting rate remained essentially constant in the plateau region and dropped to zero at 500 volts. The radio waves idea (or propagation of disturbabces along wires), on the other hand, would be confirmed if the GM was still counting at 500 volts. Rick Cantwell, who conducts glow discharge investigations in Colorado, also made a presentation in Catania. My understanding was that he will try to confirm the S&S results. I hope that he and the S&S team will soon conduct the suggested test and post the results on the private Internet list for CMNS researchers. On my agenda that would be the test #1. Nothing would be investigated with a GM detector responding to electromagnetic disturbances associated with the discharge.

3) According to S&S report, two kinds of radiation are emitted: monoenergetic electrons (0.8 MeV) and heavier particles. Heavier particles have not yet been identified. Electrons are said to be emitted at the rate of billions per second. How was energy of electrons determined with a GM counter? By the use of filters, as illustrated in Figure 2. In the original report (1) this was Figure 9.
========

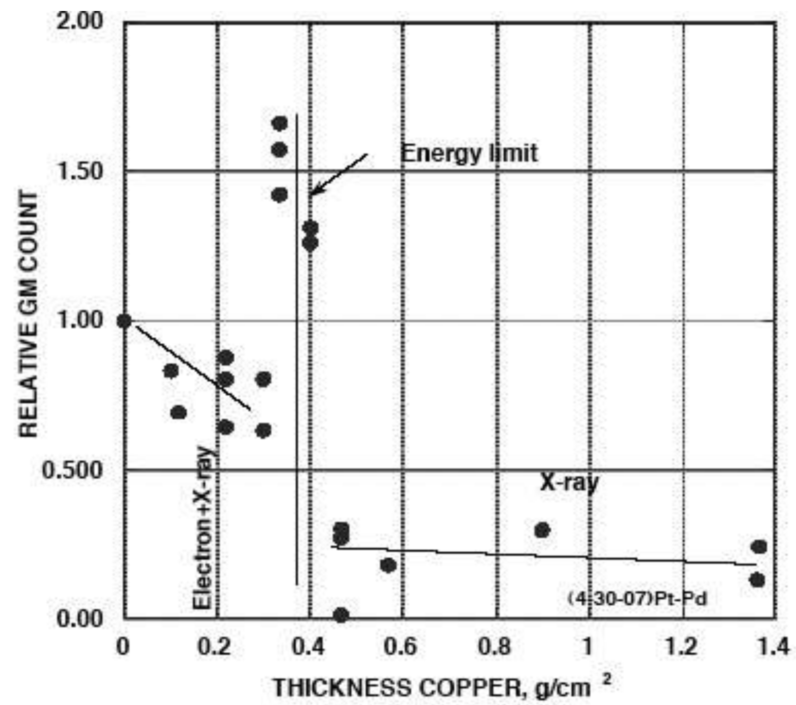

FIGURE 9. Effect of copper absorbers on the amount of radiation reaching the GM tube from a Pd+Pt cathode.

Figure 2
Counting rate verus the copper filter thickness.
============================

It shows that the counting range drops suddenly when the total thickness of filters becomes 400 mg/cm^2. That corresponds to monoenergetic electrons of 0.8 MeV. If the drop occurred at 500 mg/cm^2 then the energy attributed to electrons would 1.0 MeV, etc., according to a ranfe-energy formula for electrons. But the figure also shows a peak, at the thickness of about 350 mg/cm^2. The report states that the peak is due to bremsstrahlung radiation. Unfortunately, this is not at all convincing. My expectation would be a monotonic increase of the intensity of BR up to the maximum thickness of 400 mg/cm^2. The combined intensity (electrons plus BR) should not produce a very narrow peak at 350 mg/cm^2. I suspect that some kind of artifact is responsible for the shape of the curve in Figure 2. What can it be? To answer to this question I would like to know what absolute counting rates were. The numbers along the vertical axis are relative counts, where 1.0 is assigned to the result without a filter. The absolute values were probably close to 100. How else could wide fluctuations of data points (with respect to straight segments) be explained?

4) Referring to results obtained with the SBD (surface barrier detector), the report states that "charged particles having several energies were detected." Unfortunately, the spectrum with energy peaks is not shown. Monoenergrtic electrons of 0.8 MeV would produce their own peak in that spectrum. I will insert additional information when it becomes available, probably in another formal progress report or via our private Internet discussion list. This is an interesting line of research; I will try to follow its future developments.

Footnote:
I am composing this unit after receiving a message from a stranger. That person asked me why was nothing new posted at my CF website for many months.

Appended on 11/19/07:

= = = = = = = = = = = =

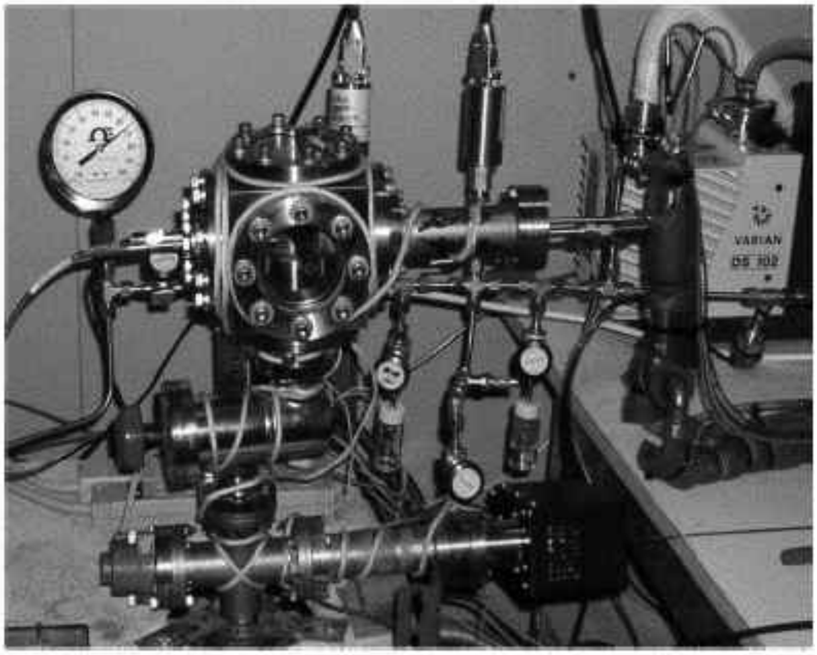

Figure 3
The overall view of the S&S apparatus.
= =

The overall view of the apparatus in Figure 3 shows its complexity, as far as practical implementation of a simple idea is concerned. The anode (see Fig 1) was made from Pd wire of 2 mm diameter. Cathodes, in the form of removable foils, were made from several materials, such as copper, palladium and silver. The observed results were more or less the same when different cathodes were used.

338) Quotes from our private list messages about theories

Ludwik Kowalski; 11/25/2007

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Introduction

On 11/2/07, Steve Krivit, the editor of New Energy Times,

http://www.newenergytimes.com/contact/contact.htm

posted the following message on a private list for CMNS researchers:

Fellow researchers,
1. Anyone who knows of any CMNS/LENR theory that is in any way correct should submit such comment to New Energy Times by Dec. 1.
2. I do not care whether the commentary is fully or only partially supportive of the theory; anything positive will do.
3. Positive commentary can be only from nonauthors of the specific theory. No self-promotion!
4. On anyone's request to me within one week, I will seek comment from Richard Garwin about any CMNS/LENR theory and report back with his response in New Energy Times. You must attach the related papers so I can forward them to Garwin.

Interesting comments about theories were subsequently made by several researchers. This morning (11/24/07) I asked Dr. Edmund Storms, the author of a new book:

"The Science of Low Energy Nuclear Reactions:
A Comprehensive Compilation of Evidence and Explanations About Cold Fusion."
(Published in 2007 by World Scientific Publishing Company)

to summarize what has been posted so far. His reply (see below) prompted me to compose, and post, this unit. It is a collage of quotes, shown with premissions. To preserve anonymity, contributors are idetifies as Researcher 1, Researcher 2, etc. (abbreviated as R1, R2, etc.). But first let me show the reply from Ed Storms (received this morning).

Reply to my message (11/24/07):
This is a good idea. However, it has two main problems. It takes time that I would rather spend finding out what is actually happening in Nature to which a theory can be applied. And, second, it is a sure way to lose friends in the CF community. Theoreticians take their ideas very personally and criticism, either implied or real, is not usually taken kindly. Criticizing theories that are either wrong or not useful gets us nowhere. The only useful activity is finding out from Nature what is actually happening, rather than making assumptions about the process. I made my previous comments only because a few people showed interest and because I object when theories are presented as real and useful when they are obviously wrong. I have no problem when people make efforts to understand the phenomenon with humility and an acknowledgment that their efforts are only a small and imperfect description of a plausible part of the process. Such an approach allows us to work together to achieve a sincere understanding, rather than an ego trip for a few people.

Selection from recent messages

R1 (11/2/07):
I think you need to focus your analysis on the assumptions, not on the math. The math is always correct as far as it goes. However, this fact means nothing if the assumptions on which the math is based are wrong. For example, Larsen-Widom assume that an electron can gain weight by accumulating energy from a low voltage field and that this stored energy allows the electron to combine with a proton to make a neutron. This assumption is in conflict with the behavior of the electron in every other situation, except the one to which they apply their model.

As another example, R2 makes the assumption that deuterons can form a cluster in the tetrahedral sites within the PdD lattice, thereby causing the ions to get close enough to fuse. Here again, no evidence is found in the large literature or suggested by R2 to support this assumption. In addition, the assumption requires the PdD lattice retain the small lattice space even though the cluster is present. All experience with this and similar materials show that this does not happen. The lattice expands as the sites are occupied.

With a little encouragement, I can note similar violations of general experience exhibited by other theories in the CF field. My question is, why don't the theoreticians note such problems and attempt to avoid them? Creating a theory that is obviously in conflict with general experience does not advance the field. Instead, we all are made to look like we accept any idea, no matter how ridiculous, as long as it "explains" CF. People doing experiments are required to justify every conclusion and demonstrate they have considered every trivial possibility. Why are theoretician exempt from this requirement?

R2 (11/2/07):
I do not understand why you referred my theory here. But, I want to point out that you are misunderstanding my model. For initiation of 4D/TSC (t=0) state (about 74 pm d-d distance), I have never assumed the steady state cluster existing in PdDx lattice, but I have been studying rather dissipative structure of dynamics (very fast transient clustering motion) with very small probability in the view of usual solid state physics. For example, deuteron density of PdDx is on the order of 1E+22 deuterons/cc. According to my latest results of Langevin equation analyses, one watt per cc 4D fusion rate with 1E+11 He-4 ash/cc/s can be generated by very small probability (1E-11) of the order of 1E+11 4D/TSC(t=0) per cc/s of PdD under D-phonon excitation.

Only 4D/TSC dynamic condensation motion under the double Platonic symmetries condensing to a very small charge neutral entity (about 20 fm d-d distance at the last moment of condensation, which is small enough and can thus exist in inter-lattice space transiently; one condensation process happens within 1.4 fs in my calculation!) can realize the super-screening of Coulomb repulsion among deuterons to get to strong interaction range (about 5 fm d-d distance) with significantly large barrier penetration probability (time-dependent) to produce 2 He-4 out-going particles without visible hard radiations (when observed from outside of cells), compared with the cases of D2 molecule, D3(+) molecule and D6(2-) molecule clusters which have converged states (ground states = steady states) with 74-80-40 pm d-d distances (thus difficult to be steadily existing in PdDx lattice inter-space without expanding lattice constants). This very small order of probability (1E-11) of dynamic motion has never been treated in orthodox solid state physics of metal-hydride lattice, or surface or interface of complex condensed matter systems. The dissipative structure looks of key. We need of course further elaboration of my model.

Dear CMNS group people; For detail, please see my papers to ICCF13, Catania07 and ACS Proceedings (LENR Source Book) to be published (some preprints with ppt slides will be uploaded soon on the iscmns-web site) together with my older papers (as recently published in Vol.1 of Electronic Journal of CMNS on http://www.iscmns.org/CMNS/publications.htm).

Apart from a debate on my own model, I hope, Steve and you and others will extend fair scientific discussions on all the proposed (or published) theoretical models. Quantification of theories with right mathematics isessential to all modeling processes, as well as proper physical insights. Self-consistency in each modeling should be self-satisfied. I remember, Peter Gluck and Steve Krivit made once a survey on available theories and reported the result on New-

Energy-Times web site. Widom and Larsen are new comers after the survey. I hope they will appear in our CMNS meetings as ICCF14 to make presentations and open discussions.

In my view, there are possibly a lot of models (due to freedom of our imagination) and we need a natural selection process to get to a final resolution someday (not now) through free discussions and random competition, to be referred to the progress of experimental results. I only prefer the truth of science.

R1, after responding to specific points in the above message **(11/2/07):**
. . . I see that we agree with the approach that needs to be applied to theory. My comments are offered to stimulate discussion and give an opportunity to address the obvious issues. I look forward to a productive debate.

R3 (11/3/07):
The controversy over theory suggests that a major deficiency in this field is a good review of all models. Without some theoretical framework, how are experimentalists supposed to refine their work? But with so many conjectures which attempt to "explain" no more than a tiny fraction of experimental observations, how is any experimentalist able to take "theory" seriously.

I commend Steve Krivit for seeking facts, but it is inevitable that response to any survey will be biased opinion. The Widom-Larsen "theory" has something to commend it, but like most theories it totally fails to explain Iwamura's observations where atomic mass apparently increases by 8 or 12. This is possibly R2's objection. In my opinion the only theory which begins to explain Iwamura's results is John Fisher's poly-neutron theory. This does not mean that I believe in such a theory. Poly-neutrons may well not exist. But the underlying multiple nucleon transfer mechanism may well be correct.

In competition with John Fisher is Akito Takahashi and his tetrahedral condensation reactions. Apart from Ed Storms' comments, there are 2 other preoblems here. Firstly, such reactions are excessively energetic and would give rise to significant lethal radiation. Secondly, they are very unselective. Anything goes. 4 deuterons will react with every known natural isotope and the results would be obvious! In contrast the poly-neutron theory is gentle and therefore very selective. In particular, it predicts that 141Pr is the inert end product from 133Cs. Any volunteers to write a review of CMNS theories? ;)

R4 (11/13/07):
My response violates [Krivit's] condition 3 for the following reason: To a first approximation every theorist believes that all theories (except his own) are wrong, and he doesn't bother to read other theories carefully if at all. It is difficult to get him to comment objectively. As an alternative I suggest that each willing theorist provide a list of clear-cut implications of his own theory, including:

A. Predictions of previously unknown and subsequently verified phenomena, and
B. Additional implications that confirm previously known phenomena.

To break the ice I list here some of the implications of polyneutron theory. They can be found in more detail in the paper "Outline of Polyneutron Theory" that I presented at the ISCMNS workshop in Catania, now available on line at

http://www.iscmns.org/catania07/program.htm

A. Predictions of previously unknown and subsequently verified phenomena include:

1. Energetic particles in an electrolyte (verified by Oriani).

2. Energetic particles in the vapor over an electrolyte (verified by Oriani; a shower of 150,000 alpha particles with energies about 2 MeV).

3. Energetic particles in the air outside an electrolysis cell (verified by Oriani).

4. Transmutation of 138Ba into 144Nd (confirmed in data of Iwamura et al.).

5. Transmutation of 137Ba into 136Xe (confirmed in data of Iwamura et al.).

6. Transmutation of 137Ba into 138Ba (confirmed in data of Iwamura et al.).

B. Implications that confirm previously known phenomena include:
1. Production of 4He.
2. Production of 3H.
3. Production of energetic protons.
4. Absence of neutrons.
5. Alpha particle showers.
6. Maximum energy production of about 21 MeV per 4He in deuterated Pd.
7. Transmutation of 133Cs into 141Pr.
8. Transmutation of 138Ba into 150Sm.
9. Role of electrolysis in sustaining nuclear reaction.
10. Role of calcium in sustaining nuclear reaction in deuterium diffusion experiments.
11. Absence of bremsstrahlung.
12. Energy of 2.1 MeV for alpha particles emitted in vapor over an electrolyte.

Although the theory is pretty good at determining which reactions are exothermic and which are endothermic, it is not so good at determining the relative rates of competing exothermic reactions. I expect that my current rate assumptions will require adjustment as additional experiments provide better guidance. Of course there is a possibility that theory and experiment will come into irreconcilable conflict, in which case the theory will have to be discarded.

R5 (11/13/07):
This point from R4 is hugely significant and has been stated explicitly and formalized by two of the most able theorists I have known. Giuliano Preparata said at ICCF5 (from memory) "At any time there is only room for one correct theory. I am right, the rest of you are wrong". Julian Schwinger refused even to look at other theories lest they contaminate his thinking. The problem I have as a non theorist is that I have neither the time nor tools to understand any of the theories well enough to know what aspects of them (if any) are right. This job really does need to be done by theorists. Steve is trying to help us hurdle this barrier to progress. We need a process or protocol. Does anyone have any ideas? (PS I did not intend to dismiss R4's suggested protocol, but rather to encourage input on it.)

R1 , addressing R4 **(11/13/07):**
I think your suggested approach is excellent. You are right, the only person who accepts any theory is the originator. In addition to listing what the theory predicts, I think it is more important to list the assumptions on which the theory is based. I get the impression that many theoreticians do not understand all of the assumptions they actually make. In addition, unless the assumptions are rational and consistent with experience, the logic that follows has no meaning, no matter what it predicts. I suggest a debate about what is a proper assumption is more useful than a debate about the theory. Once people agree upon what is a good assumption, we can then discuss the best mathematical form or logic to apply to this assumption.

R2 (11/13/07):
In JCF communications (in Japanese), N. Yabuuchi pointed out: W. Heisenberg once proposed a hypothesis that electron exchange between proton and neutron made sticking force (nuclear strong interaction) of nucleus. Later we found this was wrong assumption. However his proposal helped H. Yukawa to imagine the idea of "hypothetical-meson" (charged pion in latest understanding) exchange between neutron and proton as nuclear sticking force. H. Yukawa got Nobel Prize with the pion exchange model. But later, we found the Yukawa model was not exact to be replaced with the QCD theory. Thus even "wrong assumptions" have made significant contributions to the progress of finding true laws of physics. We may learn form the history.

R6 (11/13/07): referring to R5
The test of any theory is prediction. It is hard to determine what the best theory is until..... just wait until a theory

makes a prediction and then try it. I look for theories that how to turn a knob or do something. If it cannot do that then all you can do is wait until the theorist "connects" to the real world. If someone can say try adding He-4 or put a magnetic field on or something I can do in the lab (that I can afford) I try it. The problem is that most theories are not there yet.

R7 (11/14/07):
I think that several of the theories we know in CMNS seem "good" from the point of view a experimentalist that is NOT deep expert in theories.* BTW, most of the theories are developed by real professional Scientist and it is hard to think that they make trivial errors. We can't decided about just looking to formula. But, what we really need, is a theory that is PREDICTIVE to some (or better several) experimental set-up. I am waiting for that.

R8 referring to the above message **(11/14/07):**
Like e.g. (random example ;-) the DIESECF hypothesis, which predicts that applying different current densities to the opposite sides of a Pd membrane cathode should enhance CF. The team I belong to will keep the group tuned when we will have confirmed or infirmed this, as I hope will the other teams trying the scheme (one of which has kindly informed me they were)...

R4 addressing R1 **(11/14/07):**
I think your suggested approach is excellent. You are right, the only person who accepts any theory is the originator. In addition to listing what the theory predicts, I think it is more important to list the assumptions on which the theory is based. I get the impression that many theoreticians do not understand all of the assumptions they actually make. In addition, unless the assumptions are rational and consistent with experience, the logic that follows has no meaning, no matter what it predicts. I suggest a debate about what is a proper assumption is more useful than a debate about the theory. Once people agree upon what is a good assumption, we can then discuss the best mathematical form or logic to apply to this assumption.

R1 addressing R4 **(11/14/07):**
I agree with everything you wrote. However, I think a distinction needs to be made when the word "prediction" is used. Actually, most of the time what is called a prediction is actually a statement about which of the observations the theory has been made to fit. We all know that a theoretician works hard to make the theory consistent with what is known. The result is not a prediction, but simply a version of curve fitting. A true prediction involves a behavior that is not known in advance and was not used by the theoretician to create the theory. It must be a true extrapolation of the model.

Regardless how well the theory seems to fit the observations, if the assumption on which the theory is based predicts behaviors in other fields of science that have never been observed or violates well established understanding, such assumptions need to be viewed with caution. It is simply too easy to apply various versions of math or logic to "prove" anything. The judgment of truth is always based on the reasonableness of the assumptions, and how well the theory fits ALL the observations, not just a few that happen to fit.

I have no problem with the process of exploring all ideas no matter how novel. However, everyone needs to be very humble and acknowledge that the proposed ideas probably are very far from the truth and are presented only to encourage discussion and to suggest experiments.

R1 quoting what R2 wrote about Yukawa**, (11/14/07):**
Yes, occasionally this happens. However, I suggest the much more common result of bad assumptions are distraction, waste of time, and a lot of papers that have no meaning. The point I'm making is that the initial assumptions should be examined much more carefully than is the math and logic, i.e. that part of the paper that takes up over 90% of the space and the part that is used to demonstrate that the theory has any value. In short, I think emphasis is being applied to the wrong part of the theory in most cases.

R2 (11/14/07):
Without trials of new modeling with mathematical quantification, one can not have such good occasions as Heisenberg, Yukawa and so on have experienced. Of course there are also proposed "theories" with misunderstanding

or neglecting of well established scientific facts, or often with occult ideas. Rationalism and criticism may screen these, push the progress of theorization, and are therefore important. Experimental results being accumulated may also make cross checking of theoretical predictability. If one wants to determine which theories are based on "good assumptions" or "bad assumptions", who can do it without arrogance is however the problem.It seems for me that the natural selection by free competition may get to the resolution someday after good "effective collaboration" of people for seeking truth. Anyway I hope to see hot debate on theorization of CMNS.

R9 addressing R1 **(11/15/07):**
In my humble opinion, what you say makes a lot of sense. I fully support the approach you propose.

My own comment (posted on 11/25/07):
On 11/13/07 R2 wrote ". . . Later we found this was a wrong assumption. However his proposal helped H. Yukawa . . . " That was a good reminder that theories have their own ways to evolve. The evolutionary flowchart in

http://csam.montclair.edu/~kowalski/cf/336cat.html (see Figure 1)

has two separate boxes for theories. One box is refers to "inspiration" and another refers to "explanations." Sometimes theories are developed to extrapolate from known experimental facts (explaining and predicting) and sometimes logical predictions are made on the basis of ad hock assumptions, such as existence of neutrinos. I am thining about W. Pauli who postulated existence of neutrinos in early 1930. His prediction was confirmed about ten years later. That was a well known example of an experiment inspired by an ad hock assumption. The competitive ad hock assumption of N. Bohr (non-conservation of energy at subatomic level) was abandoned. Bending of light by gravitational fields was also discovered (during a solar eclipse) after it was predicted on the basis of an ad hock theory, by A. Einstein.

Note however, that the box called "inspiration" does not have to be limited to theories. Experimental discoveries often lead to other discoveries. Marie and Pierre Curie would not start searching for radium before radioactivity was discovered by Becquerel. If I were a historian of science I would probably be able to provide illustrations in which successful experimentalists were motivated by intuition, or other factors. I hope this thread will continue.

P.S. A Sarcastic piece at http://www.tcm.phy.cam.ac.uk/~bdj10/articles/PF_fire.html, and the recent discussion of theories, made R9 compose the following satire:

R9 (11/26/07):
Recently, Pierre and Marie Curie have reported observations of a metal permanently warmer than its surroundings. Our panel has concluded that this observation is not possible, and recommend no further research in this area. It is well established that heat cannot of itself pass from a colder to a hotter body. This basic tenet of thermodynamics have been proven again and again, and has permitted major technical advances such as the steam engine. We conclude that the metal of Pierre and Marie Curie cannot draw his heat from its surroundings. If it could, it would be possible to create a perpetual motion, an idea that is widely rejected by mainstream scientists. We therefore conclude that spending money and energy on this topic would be ill-conceived.

Steve Krivit (whose message started this thread):
As of Nov. 26, I have not received a single third-party comment about any CMNS theory besides W-L. The point of the inquiry was to find out if there were any other theories that were sufficiently developed to the point that a person besides the theory's author felt sufficiently confident to provide at least a minimal endorsement for it. The W-L theory caught my attention because Dave Nagel was, at least at one time, sufficiently confident to be enthusiastic about it, and he encouraged me to look at it.

R10 (11/27/07):
An interesting example of "a minimal endorsement" can be found in the issue 75, 2007 of Infinite Energy. I am thinking about the Rudesill's interview of Storms. Both seem to endorse Mills' theory of hydrinos. Another crazy particle? The following URL will download the file. http://www.infinite-energy.com/images/pdfs/stormsinterview.pdf

R11 (11/27/07):

I would second Storms' suggestion that the hydrino (a hydrogen atom with a sub-groundstate electron orbital) is a valid contender for LENRs. While there are problems with Mill's model(s), and I believe that he is looking in the wrong region (hot plasma instead of solid state) for hydrino production, if non-photonic (or phononic) transitions can be induced, then the "groundstate" energy is no longer sacrosanct. I am actually exploring (theoretically) the transitions into a non- 1/r potential to see if this can shift the ground-state.

R3 (11/27/07):
I'm probably just ignorant of Mills' research, but if mini-atoms and molecules existed we would expect all sorts of phenomena which we do not observe.

1) We might expect detectable gamma rays from p-d fusion at the incoherent rates calculated by Koonin in NATURE VOL 339 NO. 6227 p 690-691, 29 JUNE 1989. (I pointed this out in my 27 July 2005 posting to the CANA forum.)
2) We might expect that over the 5 billion years since the solar system formed that giant planets would convert their hydrogen to very dense mini-molecules. But all the
evidence suggests that the hydrogen / helium ratio remains 3:1 as it was at the big bang.
3) If mini-atoms are the product of exotic chemistry, how is it that they have not been isolated in large quantities in the lab?
4) How are Mills' ideas consistent with Iwamura's observations?

R12 (11/27/07):
Here I go sticking my experimental nose into theoretical business.....)

As I understand it, it is relatively easy to show according to QM that the hydrogen ground state is the lowest possible energy state for a proton and an electron. If the electron is forced to exist closer to the proton, that reduction in the uncertainty of its location produces a corresponding increase in its energy. The resulting "Schroedinger pressure" counteracts the Coulomb attraction between the electron and the proton. The ground state is simply that condition in which these two forces are balanced.

This argument is supported by the fact that a neutron...essentially a collapsed hydrogen atom. has about 780 keV MORE energy than a ground-state hydrogen atom.

QM is, without question, the most successful physics theory ever derived. If it has any shortcomings, they are well hidden and very, very subtle. The argument above is not subtle. It is based upon the very foundation of QM. Countless experiments have shown this foundation to be unassailable.

Not to put too fine a point on it, the hydrino is therefore nonsense. R13, surely your understanding of QM tops that of most/all members of this forum. Would you please comment on the above?

My own contribution, (11/29/7) prompted by the sarcastic piece of R9**:**
The English translation of the famous 1903 paper (see attached file *) shows that the reported excess heat was generated at the rate of about 100 cal per hour. This translates into 116 mW. . . .
(* Source: G. Holton , General Editor, “The Discovery of Radioactivity and Transmutation” Dover Publicatons, INC. New York, 1964)

P.S. I wander how different the history of CF would be if Fleischmann and Pons, instead of claiming nuclear origin of excess heat, used the same ending as Curie and Laborde. Here is the ending of their 1903 paper again:

"The continuing development of such a quantity of heat cannot be explained by an ordinary chemical transformation. If we seek the origin of the production of heat in internal transformation, this transformation must be of a more profound nature. . . . This development of heat may still be explained by supposing that..... [our setup] makes use of an external energy of unknown nature."

A possibility of nuclear energy would certainly be raised by some speculation-inclined people. But theoretical arguments against interpretation would be decoupled from the experimental claim. The only way to challenge reality

of excess heat would be to perform careful experiments.

339) Two simple electrical orbiting systems: possible and impossible

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055

In December of 2007 this note was submitted to American Journal of Physics. But it was rejected, after an interesting exchange of messages between me and the editor of the journal. The issue had nothing to do with Figier'h hypothesis; our discussion focused on Section II, more specifically, on the issue of stability of my macroscopic three-body system. I plan to discuss this topic (Section II only) on a forum for physics teachers. The outcome of that discussion, if any, will be appended at the end of this unit.

I. INTRODUCTION

A solar system is a well-known example of dynamic equilibrium of gravitational forces. The simplest model, a single planet (mass m) revolving around a single star (mass M>>m), along a circular orbit, is often analyzed mathematically in physics textbooks (1,2). An analogous electrical system is subsequently discussed in the context of Bohr's model of a hydrogen atom. Here we emphasize that all orbits are possible in a macroscopic system but only certain orbits are possible in the corresponding submicroscopic system. The quantization of angular momenta (Bohr's postulate, formulated nearly a century ago) is still a pedagogically sensible path to quantum mechanics (3,4).

This note describes a macroscopic orbital system in which two positively charged particles, of equal mass and equal charge, revolve around a negatively charged particle, along a circular orbit. The mass of the central particle is arbitrary but the magnitudes of the three charges are identical. This leads to a description of an analogous submicroscopic system. Such problems are likely to promote independent analytical thinking. Linking QM problems with corresponding classical problems, when possible, has numerous pedagogical advantages. Motivation for this note came from a debate about the idea of a system in which two protons orbit an electron (5).

II. CLASSICAL CONSIDERATIONS

The system to be described is illustrated in Figure 1. Gravitational forces are assumed to be negligible in comparison with electrical forces. In that context the mass of the central particle is totally irrelevant. The orbiting trajectory would remain the same if the mass of the central particle were changed. This is not true for a solar system; trajectories of planets would be different if the mass of the star were different.

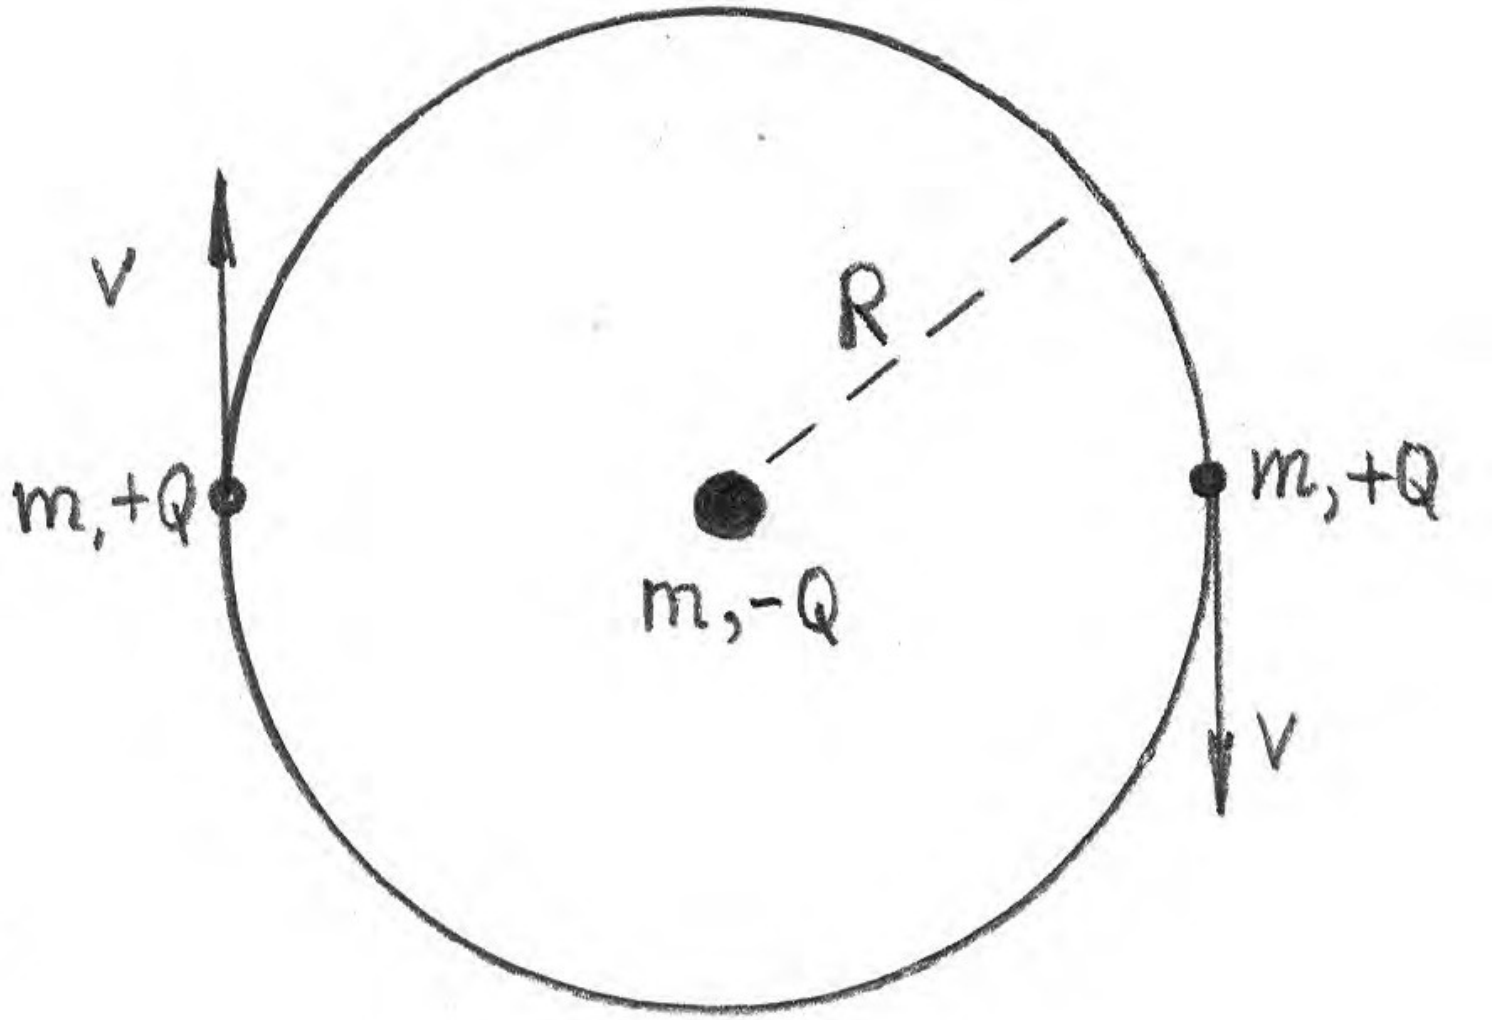

Figure 1
Caption: A three-body system to be examined in this note. Emission of electromagnetic radiation by centripetally accelerating charges will be ignored.

= =

For the set of three electric charges shown in Figure 1, the potential energy is:

$U = k*Q^2 / (2*R) - k*Q^2 / R - k*Q^2 / R = -(3/2)*k*Q^2/R$ (1)

where Q is the magnitude of each charge, k is the Coulomb law constant and R is the orbit radius. Negative terms prevail over the positive term and U is always negative. The central particle is at rest and the combined kinetic energy is

$K=m*v^2$

The net force on each positive particle, according to Coulomb's law, is $0.75*k*Q^2 / R^2$. The speed can thus be calculated by writing

$0.75*k*Q^2 / R^2 = m*v^2 / R$ (2)

This also shows that

$K = 0.75*k*Q^2/R$ (3)

The total relevant energy is

$E = U + K = - (3/4)*k*Q^2/R$ (4)

The angular momentum of our simple system is

$L = 2*m*v*R$ (5)

A numerical illustration:
Suppose that the mass of each particle is 1 kg and the magnitude of each charge is 1 C. What should the speeds of positive particles be if the desired radius of the circular orbit is 100 meters? The answer, according to Formula (2) is 8216 m/s. Our use of non-relativistic formulas is justified because v is much smaller than the speed of light. Note that the answer does not depend on the mass of the central particle. The potential and kinetic energies of the system, according to Formulas (1) and (3), are $-13.5*10^7$ and $6.75*10^7$ joules, respectively. The total relevant energy, according to Formula (4) is $-6.75*10^7$ joules. The angular momentum of the system, according to Formula (5), is $1.64*10^6$ J*s; this is about 39 orders of magnitude larger than Planck's constant.

The negative sign indicates that the system is bound in two dimensions. But is it also bound in three dimensions? The answer seems to be positive. To justify this answer, consider the configuration shown in Figure 2. The horizontal segment is the side view of the orbit shown in Figure 1. The cross represents the location of the central charge resulting from a virtual displacement. The distances between charges become d_1, d_2 and 2*R. The potential energy of the new configuration is

$U' = k*Q^2 / (2*R) - kQ^2/d_1 - k*Q^2/ d_2$

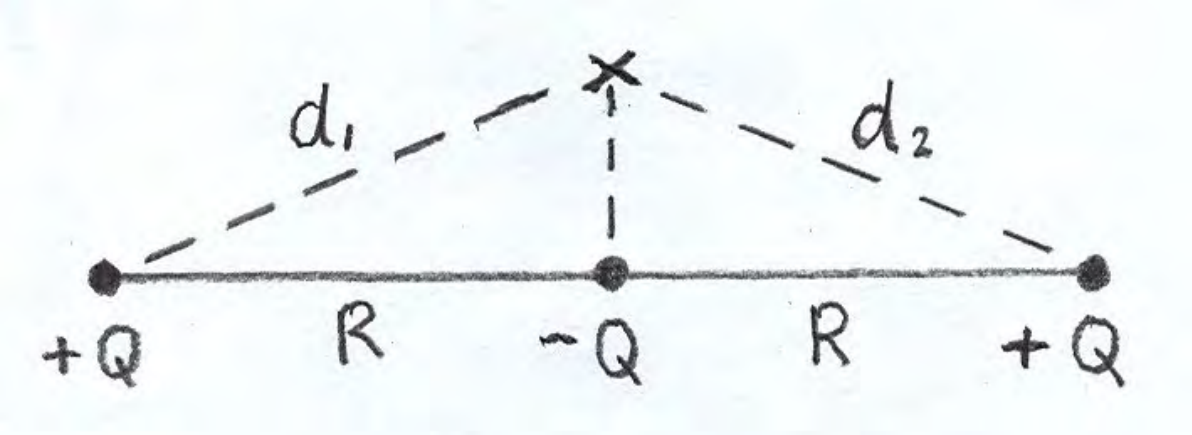

Figure 2
Caption: What happens to potential energy of the system when the central particle is virtually displaced in the the direction perpendicular to the orbit, either up or down? It becomes higher (less negative).

= =

The positive term does not change but the sum of negative terms becomes smaller. In other words, U' is higher (less negative) than our previous U. A vertical
displacement of the central charge by 10 meters, either up or down, corresponds to the increase of potential energy by $9*10^5$ joules. A diagram similar to that in Figure 2 can be sketched for a positive charge being displaced perpendicularly with respect to the horizontal orbit. The potential energy for that configuration, U", also turns out to be less negative that what one finds when the displacement is zero. For a vertical displacement of 10 meters, for example, the value of U" is by $4.5*10^5$ joules higher than U. It is a numerical problem and numerical illustrations are appropriate.

III. ELEMENTARY QUANTUM MECHANICAL CONSIDERATIONS
Some students might be familiar with elementary quantum mechanics (Bohr's angular momentum postulate and Heisenberg's Uncertainty Principle). These conceptual tools can be used to analyze a hypothetical submicroscopic system in which two protons orbit an electron. In a classroom debate, students can be guided to show that such a system could not exist. The set of formulas to be used in such activity is show below.

According to Bohr's angular momentum postulate,

$L=n * h$ (6)

where h is the Planck's constant divided by $2*\pi$, and n is a quantum number for the orbit. Find the smallest R for the p-e-p system (two protons orbiting an electron). The method introduced by Bohr can be used to discuss this hypothetical system. Equating right sides of the Equations (5) and (6) one has

$v = h*n / (2*m*R)$ . . . (7)

Substituting this into the Formula (2) gives

$R = h^2*n^2 / (3*k*e^2*m)$..... (8)

The energy for that orbit can be calculated by substituting this radius into Formula (4). The result is

$E = - 2.25*m*k^2*Q^4 / (h^2*n^2)$..... (9)

For each proton $m=1.6710^{-27}$ kg and $Q=+1.6*10^{-19}$ C. The charge of the electron is $-1.6*10^{-19}$ C. Knowing that $h=1.05*10^{-34}$ and $k=9*10^9$, both in SI units, one can
calculate R, v and E. For the ground state orbit (n=1) the result are: $R=9.55*10^{-15}$ m (9.55 fm), $v=3.29*10^6$ m/s (1.1% of the speed of light) and $E=-1.81*10^{-14}$ J (113 keV). Note that for larger n the radius becomes n^2 times larger than for the ground state while the absolute value of E, not surprisingly, becomes n^2 times smaller (E approaches zero when n becomes very large). In other words, according to the semi-classical Bohr's theory, the suggested p-e-p structure would be much smaller than the hydrogen atom. The binding energy of that system (the absolute value of E at n=1) would be much larger than for the hydrogen atom (where it is only 13.6 eV).

It is interesting that the distance between protons, on the ground state orbit, 19.1 fm, is still much larger than the range of the strong nuclear force (~2 fm). Only electrical forces are of any significance in this problem, as initially assumed. Also note that the energy at n=2 is -113/4=-28.2 keV. The difference, 84.7 keV, corresponds to the lowest energy photon in the Balmer series. For hydrogen, spectral lines of that series are in the ultraviolet region; for the p-e-p system they would be in the X-ray region. Speculations about significance of such findings can be educationally valuable.

The above considerations could naturally lead to Heisenberg's Uncertainty Principle, dp*dr ~ h. Is that principle (HUP) consistent with the existence of the conceived p-e-p structure? The answer turns out to be negative. To demonstrate this numerically one could begin with $E=-1.81*10^{-14}$ J (113 keV), as above. That represents the depth of the ground state potential energy well. According to initial consideration (see Figures 1 and 2) the electron was assumed to be at rest in the center. That implies that both location and momentum are accurately specified (r=0 and p=0). But this is impossible, according to HUP. By decreasing the uncertainty in r we are always increasing the uncertainty in p, and vice versa.

The maximum possible uncertainty (fuzziness) in p can be estimated from the depth of the well. An electron, randomly oscillating about the center, would escape from the well if its kinetic energy, K, were larger than the depth. This gives us the maximum possible $K = 1.81*10^{-14}$ J. The corresponding linear momentum, p, for an electron, is $1.81*10^{-22}$ kg*m/s. Using that value in HUP one has $dr=5.80*10^{-13}$ m. This is 61 times larger than the above-calculated radius of the p-e-p structure. The initial assumption (electron being confined to a small sphere at the center of the orbit) is in conflict with HUP. It is easy to show that, in order to be consistent with HUP, the mass of the electron would have to be at least as large as the mass of an alpha particle. Motivation for this note, by the way, was provided by such discussion among several researchers. The idea of a tiny particle in which two protons orbit an electron was actually suggested by Jean-Pierre Vigier (5), a French theoretical physicist who worked with Louis de Broglie. No one seriously claimed that such particles exist in nature. But theoretical speculations about them can be pedagogically instructive.

IV. CONCLUSION

a) Linking of similar classical and non-classical problems has obvious pedagogical advantages in undergraduate physics courses.
b) The idea of the possible existence of a stable p-e-p structure, conceived and published by Vigier (5), offers a rare case in which an interesting hypothesis can be numerically investigated by using elementary QM tools. Students familiar with such tools are likely to benefit from a properly structured discussion of Vigier's hypothesis. Note that the hypothetical p-e-p system is similar, but not identical, to the neutral p-e system, analyzed by Bohr.
c) The mass of the central particle, totally irrelevant in the macroscopic problem, becomes highly relevant in the analogous submicroscopic one. The idea of hidden parameters is interesting.

V. ACKNOWLEDGMENT

Contributions from Scott Little (USA) and Akito Takahashi (Japan) are highly appreciated. Information about Vigier was provided by Jean-Paul Biberian (France) and by Andrew Meulenberg (USA).

Should I interest comments about Bohr's model and HUP, found in (6) ?

VI. APPENDIX

I was not aware, when the above was composed, that the proposed classical system would be highly unstable. In real life, unlike in idealized world of mathematical ideas and simulations, inevitable small perturbations would quickly destroy the system. This would become visible in less than one period of one idealized (perturbation-free) revolution. The corresponding two-body system, like a star and a planet, is expected to be stable under such perturbations. But this is not true for the orbiting three-body system, like three stars, or three charged macroscopic spheres. This appendix was inspired by messages posted by several physics teachers during an interesting Internet debate about stability and chaos.

340) Can decay of radioactive substances be speeded up?

Ludwik Kowalski (1/10/08)

Montclair State University, Montclair, NJ, 07055

The issue of possible influence of chemical environment on nuclear phenomena is not new; it has been investigated by Marie Curie. The probability of a process taking place inside of an atomic nucleus, such as radioactive decay of radium, was shown to be the same in all substances containing that element. It was also shown to be independent other factors, such as high pressure, magnetic field or cooling. Factors of that kind affect atoms and molecules; they do not affect atomic nuclei. Cold fusion researchers, however, claim that this is not always true. The ongoing controversy surrounding that topic started as soon as discovery of cold fusion was announced in 1989.

In some cases, however, as reviewed in (1), the effect of chemical environment on the probability of nuclear decay has been demonstrated and understood. It happens when beta-plus radioactive substances decay via electron-capture. According to (2), for example, the nuclear decay rate of ^{7}Be implanted in palladium is about 0.8% higher than in ^{7}Be implanted in gold. According to (3) the decay rate of ^{7}Be in BeO is 54.23 days while in $Be(OH)_2$ it is 53.42 days. This amounts to the 1.5% difference. The effect of chemical surrounding on the probability of the electron-capture process has been recognized by mainstream scientists long before 1989. It is considered to be an exception from the general rule -- other forms of radioactive decay cannot be modified by making changes in chemical environment. As indicated above, the ^{7}Be effect is rather small.

Can the rate of another kind of radioactive decay be changed? The negative textbook answer to this question conflicts with observations described by at least two teams of CMNS researchers. John Dash et al., for example, reported that the decay time of the alpha-radioactive uranium was shortened by a factor of four after the material was exposed to the glow-discharge plasma for 18 hours (4). Likewise, V. Vysotskii et al., reported that the decay time of the beta-radioactive ^{137}Cs, in some biological cells, was reduced from 30 years to less than one year (5). Bacteria, as suggested by authors, are able to cause the

$^{137}Cs(p,\gamma)^{138}Ba$

transmutation process. The reaction is exothermic (5.58 MeV) but the coulomb barrier is very high (~10 MeV). I do not know why such barrier is not preventing bacteria from transmuting cesium into barium. The main question, however, has nothing to do with an explanation; it has everything to do with validity of the experimental claim. This claim is important because ^{137}Cs is a significant contributor to high radioactivity of waste produced by nuclear reactors. The suggested possibility of destroying radioactive waste with bacteria should be investigated. A confirmation would open a new era in the field of nuclear electricity. Unfortunately, as far as I know, nothing is being done to either confirm of refute the claim. Why is it so?

Excited by earlier reports on destruction of radioactive materials in a high-voltage electrolytic cell (6,7) I asked for a chance to see the replication of one experiment. The principal investigator of that study, Hal Fox, invited me and the experiment, in slightly modified form, was repeated in my presence. The modified version of the experiment was expected to demonstarte the reported effect. The observed reduction of radioactivity, however, turned out to be apparent. It was due to changes in the counting geometry occurring during the experiment. At the beginning the

radioactivity was in the electrolyte, at the end most of it was in the precipitation, at the bottom of the cell. The resulting reduction of counting efficiency produced an illusion of the loss of radioactivity, as described in (8).

341) High voltage electrolysis: neutrons and production of tritium

Ludwik Kowalski; 12/25/2007

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Introduction

1) During a recent conference in Catania Yuri Bazhutov suggested that we use CR-39 detectors to explore a possibility that track-forming nuclear particles are emitted in one of the setup he experimented with in the past. This suggestion was a natural outcome of our conference presentations, my talk about investigations of Oriani-type effect and his poster about the ongoing search for erzions, elementary particles that might be able to account for some CMNS effects. Similar suggestion for cooperation was made by Pierre Clauzon, when I visited him in Paris (on the way to Catania). Pierre demonstarted to me generation of excess heat in an improved setup for high voltage electrolysis. About a month ago I sent each of them several CR-39 chips to perform preliminary, background testing, experiments. So it is about time I write something about about Yuri's experiment in which the CR-39 will be used. Pierre's new setup, by the way, is described in a report that can be downloaded from the library at <www.lenr-canr.html>. Numerous Bazhutov reports can also be downloaded from that library.

2) The concept of an erzion, a massive hadron, was first formulated, in 1981. Existence of such stable particle was postulated to explain energy spectra of cosmic-rays muons. According to Bazhutov's Catania presentation, there are two erzions, negative, E^o and E^-. Their internal structure, in terms of quarks, is not essential in my context. The rest mass of an erzion is said to be close to 200 u (atomic mass units), the charge of the negative erzion is the same as the charge of an electron. Negative erzions are believed to form loosly-bound structures with positive atomic nuclei. These structures are called enions. The binding energy of E^- and p, for example, is said to be ~1.5 eV, while the binding energy E^- and ^{208}Pb, is ~50eV.

Electrolytic - anodic glow discharge

3) Let me begin be summarizing a Russian paper of Y. N. Bazhutov, W.G. Grishin and W.N, Nosov. The title is "Electrolytic anodic glow discharge." The date can be inferred from the most recent reference --2003. The high voltage electrolysis apparatus used by Bazhutov et al, is illustrated in Figure 1. The upper left part shows Bazhutov's cell immersed in cooling water. The electrolyte is 7M KF in a 50% mixture of light and heavy water. The stainless steel cathode, on the right side, had the area of 400 cm^2. The anode was a tungsten rod (diameters 1 to 6 mm), only partially immersed in the liquid. The cell had to be cooled (in the aquarium-like container with ordinary water) because the electric power dissipated in the cell was rather high (glow discharge at 300 v with various currents up to 2A, depending on experiments).

4) The glow discharge at ~300 V, near the anode, was said to be quazi-stable (current in the plateau region was changing monotonically from about 1.2A at 200 V to about 1.5A at 300 V). Typically an experiment lasted for about one hour, depending on the rate at which the anode was consumed. Some electrolyte had to be added to the cell during the discharge to keep the current constant, more or less. The cell was placed into an aquarium-like vessel containing cold water. The temperature of the electrolyte was rising during the experiment, typically up to 50 C.

= = = = = = = = = = = = = =

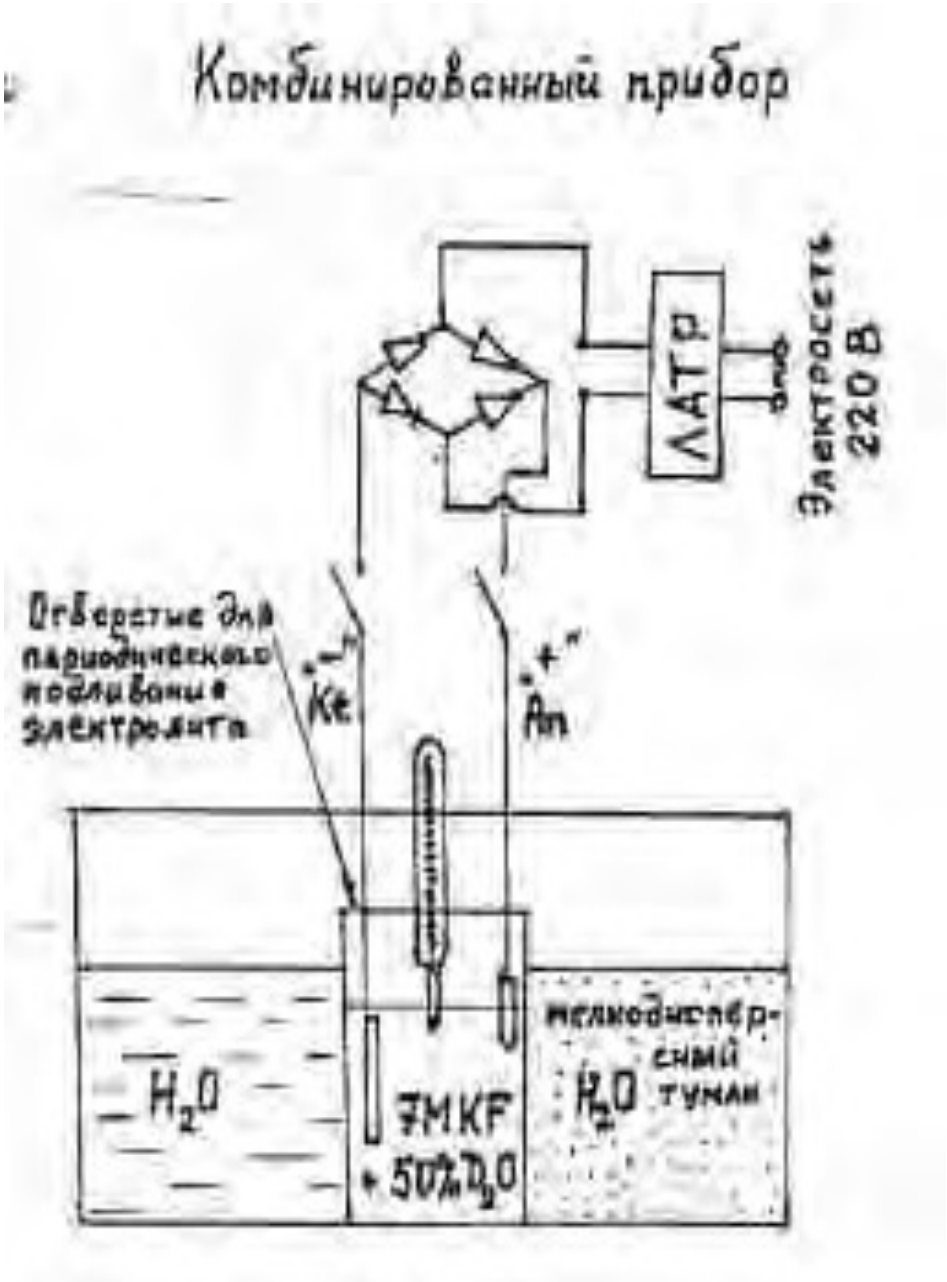

Figure 1
Bazhutov's cell. Dots in the right side of the aquarium-like vessel represent bubbles formed in cold water.

= =

5) The phenomenon discovered in these experiments consisted of unexplained changes in cooling water. After 40 minutes water on the right side of the cooling vessel started loosing its transparency. Water on the left side remained transparent, at the same 40 C temperature. A sample of bubbly water, removed from the right side, was tested for induced gamma radioactivity. No such radioactivity was found in it; the sample became transparent after 24 hours. Attempts to reproduce the long-term loss of cooling water transpaency with other electrolytes, and under different electrical discharge conditions, were not successful. But the effect was highly reproducible when experimenting with the tungsten-anode cell and the 7 M KF electrolyte containing 50% of heavy water.

Erzion interpretation of bubble formation

6) Note that cooling water at the right side (see Figure 1) is close to the anode while cooling water on the left side is

close to the cathode. The disappearance of bubbles, after the electrolysis, was very slow (half-life of about 10 hrs). Attempts to explain the phenomenon in terms of cavitation, and other ultrasonic effects, were not successful. The only satisfactory explanation was possible within the framework of the erzion model. Authors believe that bubbles are produced when neutral erzions, E^o, generated at the anode, are elastically scattered on ^{16}O. Enions are always present in water (one out of 10^{15} nuclei in ^{16}O is believed to be attached to a negative erzion).

7) Here are some calculations. At the current of 1 A, the flux of OH- ions, in the electrolyte, is ~10^{19} per second. Thus, the flux of enions bombarding the anode is $10^{19}*10^{-15} = 10^4$ per second. The following nuclear transmutation reactions, induced by enions, are believed to take place in the anode:

$^{180}W + E_N = E^- + {}^{181}W$ (equivalent to $^{180}W + n = {}^{181}W$)
$^{182}W + E_N = E^- + {}^{183}W$ (equivalent to $^{182}W + n = {}^{183}W$)
$^{183}W + E_N = E^- + {}^{184}W$ (equivalent to $^{183}W + n = {}^{184}W$)

8) Erzions produced in these reactions are expected to be isotropically distributed. In a 1 cm layer of the 50% D_2O electrolyte; their intensity is expected to be reduced by the factor of ten, due to inelastic nuclear reactions with deuterium. The glass wall of 2 mm is believed to be totally transparent to neural erzions. Thus the flux of neutral erzions arriving into the cooling water on the right side is expected to be about 10000*0.1*0.1=100 per second. The first 0.1 factor is due to absorption; the second is due to scattering in the electrolyte(the solid angle effect). This can be contrasted with the expected flux of negative erzions of 0.001 per second on the left side of the cell (because the layer of the electrolyte between the anode and the wall of the cell is 6 cm). That is why the effect described in the next paragraph is not observed on the left side.

9) Neutral erzions, entering cooling water have a range of about 1 cm. They collide with oxygen nuclei and produce recoils with energies close to ~0.1 MeV. Ranges of such recoils in water are about 1 micron. Each recoiling oxygen nucleus is thus able to produce a highly ionized region. Long-lasting bubbles of vapor (half-life of 10 hrs) are formed in regions of high ionization. Sizes of bubbles are of the order of 1 mm. Each negative erzion, entering cooling water, produces about 10 bubbles. The estimated number of long-lasting bubbles, produced in 1000 seconds is one million. In reading this I was thinking about bouble chambers containing liquid nitrogen. Such track-recording instruments were often used in high energy research.

Appended on 1/12/08

10) Let me begin be summarizing another Russian paper; it describes more recent resualts obtained by using a similar high-voltage electrolytic cell. The authors are Y. N. Bazhutov, V. Y. Velikdnyi, W.G. Grishin, A.W. Eremeev, E.W. Pletnikov, A. D. Rumiancev, Y. A. Sapozhnikov and N. I. Khokholov. The title is “Nuclear diagnostics of cold fusion transmutation at electrolysis with anodic gas discharge in water solutions.”

Experimental setup showing the detector of neutrons (on the left) and the detector of gamma rays (on the right of the cell).

= =

The paper begins by mentioning earlier publicaions that provided motivation for the new study. In the first publication the radioactive ^{183} Ta was produced during the electrolysis. It has been identified by characteristic gamma radiation peaks and by the half-life. The second publication has been described above (starting at point 3). The experimental setup in the new investigation was essentially the same as summarized above, except that four nuclear instruments were used in anticipation of nuclear radiation. These were:

a) NaI gamma ray spectrometer (6.3 by 6.3 cm) had a background of 100 c/s. Spectra, in the energy range of up to ~2MeV, were recorded on the 1024 multichannel analyzer.

b) A commercial gamma dosimeter “Sosna” (background 0.1 micro-rad per hour)

c) Two liquid scintillators to study production of tritium in the electrolyte (background ~1 Bk/mL). Samples of electrolyte (removed from the cell before and after each experiment) were injected into the liquid scintillator to detect tritium.

d) A commercial detector of thermal neutrons (RUP-1”) The available ranges (n/cm^2 per second were: 100, 1000, 10000 and 100000 sensitivity could be chosen

Twelve series of experiments, using different electrolytes and different anodes, were performed between July 20 and September 1, 2005. Cell temperature, current and voltage were recorded each minute. The readings of the dosimeter

and of the neutron flux detector were also recorded each minute.

11) The NaI detector was accumulating counts during the electrolysis and then, for the same duration, after the electrolysis. The authors wrote "unfortunately, the spectra were never seen to be not significantly different from the background." But emission of neutrons, and production of tritium, were observed in some experiments. Numerical results (minute-by-minute readings of the neutron detector), are shown in their figures 3, 4, 5, 6 and 7. The reported 2 neutron/cm^2 per second background was exceeded in all cases. But the actual counts in the 7th series, for example, fluctuated between 20 and 75 while in the 9th series they fluctuated between 2000 and 2200.

12) Production of tritium, on the other hand, took place only in the 5th series. It was at the level of about three times the background. The authors conclude "if we were really recording neutrons, then the maximum production (in the 9th series) was ~10^6. Using the data from series 5, in which production of tritium was observed, we conclude that the ratio of the total number of tritons (10^{12}) over the total number of neutrons (10^7) was close to 10^5. This is typical for cold fusion experiments but not for thermonuclear reactions, where the ratio is close 1."

13) The motivation for these experiments was to check the hypothesis that neutrons are produced by reactions induced by erzions. With this in mind, the electrolyte in series 11, was changed to make such reactions impossible (according to previously postulated mechanism). The absence on the emission of neutrons in that series confirmed the hypothesis. In all other series the choice of the electrolyte was made to maximize, not to minimize, the mechanism based on erzion theory. In that sense, one can say that experimental results are consistent with the theory.

Appended on 1/18/08

14) Here is a brief summary of some terminology. Hopefully, it will be sufficient in the context of Yuri's investigations. It is based on what I knew before the conference in Catania and what I learned from Yuri during that conference.

a) Nucleons are not elementary particles; they are composed of particles called quarks. The up quark, u, has a charge of +2e/3 while the down quark, d, has a charge of -1e/3, where e is the magnitude of the charge of one electron.

b) A neutron consists of one u and two d; that is why its electric charge is zero. A proton consists of two u and one d; that is why its charge is +1e.

$$n = \{u,d,d\} \text{ <--- charge of n is } +2/3 -1/3 - 1/3 = 0$$

$$p = \{u,u,d\} \text{ <---- charge of p is } +2/3 + 2/3 - 1/3 = 1$$

c) Yuri has good reason to postulate existence of a massive stable "mirror aniquark," U^*. That elementary particle is rare; in comparison with common u and d quarks. On the average, only one U^* exists for every 10^{15} of common quarks. Combining with one common quark (either u or d), U^* becomes part of a neutral or a negative pair, as shown below. Such pairs are called erzions.

A neutral erzion E^o consists of U^* and u; it is bag of two quarks (a meson).

$$E^o = \{U^*,u\} \text{ <----charge of } U^* \text{ is } 0 - (2/3) = -2/3, \text{ equal but opposite of the charge of u}$$

A negative erzion E^-consists of U^* and d; it is a bag of two quarks (a meson)

$$E^- = \{U^*,d\} \text{<----charge of } E^- \text{ is } -(2/3) - 1/3 = -1, \text{ equal but opposite of the charge of p}$$

d) A negative erzion, according to Yuri, can form a bound with a proton. This produces a "bag of 5 quarks." The name of that structure is enion,

$$E_N. = \{U^*,u,u,d,d\}$$

The neutral enion can dissociate into a pair of particles, a negative erzion (charge -e) and a proton $\{E^-,p\}$ or a neutral erzion and a neutron $\{E^o,n\}$. In other words,

$$E_N \text{ --> } E^- + p + \Delta_1 \ldots \text{ or } \ldots E_N \text{ --> } E^o + n + \Delta_2$$

where Δ_1 and Δ_2 represent reaction energies. They are positive for exothermic reactions and negative for endothermic reactions.

e) Enions (E_N), negative erzions (E^-) and neutral erzions (E^o) are rare (because U^* are rare). But they can interact with common atomic nuclei, (A,Z).

15) For a given atomic nucleus, (A,Z) one can consider only six possible interactions: two with an enion, two a neutral erzion and two with a negative erzion. They are:

$$(A,Z) + E_N = (A+1,Z) + E^o + Q1 \text{ neutron is going from the enion, } E_N, \text{ into } (A,Z)$$
$$(A,Z) + E_N = (A+1,Z+1) + E^- + Q2 \text{ proton is going from the enion, } E_N, \text{ into } (A,Z)$$

$$(A,Z) + E^o = (A-1,Z) + E_N + Q3 \text{ neutron is going from the neutral erzion into } (A,Z)$$
$$(A,Z) + E^o = (A,Z+1) + E^- + Q4 \text{ proton is going from the neutral erzion into } (A,Z)$$

$$(A,Z) + E^- = (A-1,Z-1) + E_N + Q5 \text{ neutron is going from the negative erzion into } (A,Z)$$
$$(A,Z) + E^- = (A,Z+1) + E^o + Q6 \text{ proton is going from the negative erzion into } (A,Z)$$

where symbols Q1, Q2, Q3, Q4, Q5 and Q6 stand for energies released in six possible reactions. In the first two reactions the enion is changed into a neutral erzion while in the second the enion is changed into a negative erzion. In either case the unusual antiquarks, U^*, remain outside the newly formed nucleus. The same is true for the next two reactions (transformation of a neutral erzions into enion or into a negative erzion) The last two reactions (transformation of a negative erzion into an enion or into a neutral erzion) also do not consume the unusual antiquarks. These elementary particles always remains available to produce numerous reactions, one after another. That is why the U^* can be said to be a catalyst. It participates in reactions but it is not consumed in them.

16) Suppose the symbol A is used to describe the target nucleus (A,Z) and the symbol B is used to describe the product nucleus. Then the above six reactions can be described in the following way. The symbol Q represents the absolute value of the released nuclear energy (+ when the reaction is exothermic and - when it is endothermic).

$$A(E_N,E^o)B + Q$$
$$A(E_N,E^-)B + Q$$
$$A(E^o,E_N)B + Q$$
$$A(E^o,E^-)B + Q$$
$$A(E^-,E_N)B + Q$$
$$A(E^-,E^o)B + Q$$

Yuri Bazhutov would replace my Latin symbol E (see above) by the Cyrillic symbol (see below). What follows is a list of possible nuclear reactions (induced by enions and erzions) in light isotopes. Column 2 shows natural abundances of target nuclei while numbers in column 3 can be used to identify reactions.

17) Yuri thinks that some of these reactions might be responsible for production of neutrons in his experiments. He also thinks that formation of tracks in CR-39, such as those I reported in Catania, can be explained in terms of the above reactions.

18) After listing six possible reactions (see items 15 and 16 above), Bazhutov writes: “Enion, due its special quantum numbers, is strongly repelled by atomic nuclei. But, due to its electric dipole moment, it is also attracted to them.” At some distances these two tendencies cancel each other and a “stable long-lived state” can be formed, provided “the exothermic exchange reactions are absent. The bounding energy is about 1.5 eV for proton (Z=1) and about 60 eV for ^{208}Pb (Z=82). Atomic nuclei able to form bound states with enions (^{1}H, ^{4}He, ^{12}C, ^{16}O, ^{64}Ni, . . .) are called ‘donors’ .”

19) A little later, after mentioning the low concentration of “captured enions” (about one out of 10^{15} nuclei), Bazhutov continues: “When enions become free they react exothermically with atomic nuclei; the cross sections of such reactions are expected to be of several mega-barns. Sequences of reactions, as described above, are very fast, approaching billion per second, under the most favorable conditions. As usual, only exothermic reactions [see Table 1 above] are expected to occur, under ordinary temperatures. The table shows that exothermic reactions induced by negative erzions are relatively rare. The eleven stable isotopes, reacting with the negative erzion, are called converters. To produce a long sequence of nuclear reactions one must have a mixture of donor nuclei and converter nuclei. Deuterium happens to be the best converter. To produce neutrons one must have a mixture of hydrogen and lithium atoms.”

Appended on 1/30/08 What follows was not seen by Yuri Bazhutov. I will add his comments after receiving them.
20) To illustrate the idea of chains Yuri pointed to reactions 9 and 10 (see the above table). That was during our

Catania conversation. Note that C represents 1.1% of carbon atoms in a plastic material, such as CR-39. It is an example of a converter. An enion being neutral, approaches the ^{13}C nucleus, deposits a neutron into it (production of ^{14}C and a neutral erzion). That is reaction 9. The neutral erzion, created in that reaction, approaches another ^{13}C converter and triggers the reaction 10. That reaction is also exothermic; it results in the pickup of a neutron, from ^{13}C (creating ^{12}C and a neutral enion). This constitutes an element of a sequence of identical pairs of reactions. The sequence ends when the enion is either captured by a donor, such as ^{12}C, or escapes from the plastic material. The net result of reactions 9 and 10 is conversion of one ^{13}C into one ^{12}C, and release of 3.2 MeV of energy.

21) Similar long sequences of repetitive nuclear events can be based on reactions 16 and 17, or on reactions 3 and 4. To calculate Q values of reactions produced by enions and erzions one must know exact masses of these projectiles. How large are these masses? How were they determined? Not knowing the answers I can work backward, taking the posted energies (2.0 MeV and 1.2 MeV) for granted. Suppose the exact mass of an enion is X while the exact mass of the neutral erzion is Y. Then

$M13 + X = M14 + Y + Q9/c^2$ <-----(Q9=2.0 MeV in reaction 9)
$M13 + Y = M12 + X + Q10/c^2$ <--- (Q10=1.2 MeV in reaction 10)

where c is the speed of light. This is a set of two equations with two unknowns. Using the known nuclear masses (in atomic mass units, u):

M12 = 12.000000 u
M13 = 13.003354 u
M14 = 14.003074 u
1 u = 931.5 MeV (1 MeV = 0.001073537u)

22) This leads me to X=1.0017677 u and Y=0.000099343 u. My calculated rest mass on the enion is only slightly smaller than the rest mass of a proton.(1.0078252 u) while the calculated mass of the negative erzion is 5.4 times smaller than the rest mass of an electron, (0.0005389 u). The mass of the negative erzion can be calculated, for example, from the 5.6 MeV of reaction 2. Yes, I know that this is not the answer to my questions. The simple algebra tells me what enion and erzion masses were actually used to compose the table. What I want to know, however, is justification for these masses. Something is missing in my understanding of Yuri's explanations. What is it? My guess is that masses of erzions were assumed to be negligible while the mass of the enion was assumed to be 1.0017677 u, perhaps on the basis of some advanced QCD considerations.

23) I will try to learn more about quarks in the furure. And I will try to summarize what I learn. One thing is already clear; most quarkologists probably never heard about the U* antiquark. The accepted standard model quarks, and antiquarks, are listed at

http://en.wikipedia.org/wiki/Quark

Mainstream theoretical physicists probably treat the idea of another quark in the same way in which the idea of thermonuclear reactions at low temperatures is treated by mainstream nuclear physicists. In the final analysis, only experiments will show who is right and who is wrong.

Appended on 4/4/08 (to be posted later):
24) This is a message I posted at the Internet discussion list for CMNS researchers. " Some time ago Juri Bazhutov sent me a message saying that the last part of what I wrote above (appended on 1/30/08) has a mistake, and that rest masses of the enion and neutral erzion, are about 200 u each. (The u stands for what used to be abbreviated as amu (atomic mass unit); it is defined as 1/12 of the mass of C12. The mass of a proton, for example, is approximately one u. Note that E=m*c^2 becomes E=m*931.5, when E is in MeV and m is in u.)

Yuri is correct, I made a mistake; the mass of C14 should have been 14.003242, and not 14.003074. The mass I used

would be OK for N14 but not for C14. The very small print in the mass table was probably responsible for the mistake. I just corrected the mistake and recalculated the masses. But this did not bring me closer to Yuri's masses of approximately 200u. In fact, my values of Y is now negative.

How can this be interpreted? Masses of particles are always positive. My interpretation is that the suggested reactions 9 and 10 (From Yuri's table), are not consistent with masses attributed by him to the enion and to the neutral erzion. Please help me to bring clarity to this. I will update my webpage accordingly.

P.S.
Here are numerical calculations, where X is the mass of an enion and Y is the mass of an erzion)

Yuri's reaction 9:
13.003354 + X = 14.003242 + Y + 2/931.5 --> X + Y = 1.002035

Yuri's Reaction 10:
13.003354 + Y = 12.000000 + X + 1.2/931.5 --> X - Y = 1.002266

Solving these two equations with two unknowns I found that

X = 1.00215 u (rather than ~200 u)
and
Y= -0.000115 u (rather than ~200 u)

X is the rest mass of an enion and Y is the rest mass of a neutral erzion."

25) I calculated the X and the Y again but from another pair of reactions (reactions 16 and 17 in the same Yuri's table). The new values of X and Y turned out to be:

X=1.004219 u (rather than ~200 u). Thus is slightly larger than before.
and
Y = -0.002146 u (rather than ~200 u) The absolute value is 18.7 times larger than before.

That is strange; the masses of the enion and the erzion should be the same no matter which pair of reactions is used to calculate them from. Either what I am doing is wrong or reactions in Yuri's table are not consistent with each other. Once again X and Y are very different from ~200 u.

26) Suppose a totally different approach is taken to 24 exothermic reactions listed in Yuri's table. Let me rewrite four of them.

Reaction 9 ---> C13 + X = C14 +Y + 2.0 MeV
Reaction 10 ---> C13 + Y = C12 + X +1.2 MeV

Reaction 16 --->O17 + X = O18 + Y + 1.9 MeV
Reaction 17 ---> O17 + Y = O16 + X + 2.0 MeV

where X stands for the enion and Y stands for the neutral erzion, as before. Each of these reactions can be used to calculate the difference between the rest masses of X and Y.

According to reaction 9, the difference is
X-Y = C14 - C13 + 2/931.5 = 14.003242 - 13.003354 + 0.002147 = 1.002035 u

According to reaction 10, the difference is
X-Y = C13 - C12 - 1.2/931.5 = 13.003354 - 12.000000 - 0.001288 = 1.002066 u

According to reaction 16, the difference is
X-Y = O18 - O17 + 1.9/931.5 = 17.999160 - 16.999133 + 0.002040 = 1.002067

According to reaction 17, the difference is
X-Y = O17 - O16 - 2/931.5 = 16.999133 -15.994915 - 0.002147 = 1.002071

The differences obtained from the four reactions are nearly identical. The mass on the enion exceeds the mass of the neutral erzion by nearly one u. The results are consistent with X-Y values calculated yesterday. But yesterday I was able to calculate masses of X and Y, not only X-Y. Each mass was much smaller that ~200u. I am making no progress in trying to understand the situation.

27) On 3/24/08 Bill Collis wrote:
Ludwik I'm not sure I follow all your discussion about Erzions and Enions. One point I would make is that no data regarding reaction energies is going to give the absolute mass of any particle. Masses are relative. In the case of conventional nuclear reactions they are relative to C12. In the case of Erzions, we may arbitrarily choose the mass (or mass defect) of one of the three Erzions.

28) On 3/24/08 Ludwik wrote:
1) I am leaning on Yuri Bazhutov's Catania presentation available from

http://www.iscmns.org/catania07/program.htm

His paper can be download by scrolling down to the "Monday 15 October" and by clicking on the corresponding "pdf" link.

2) Yuri's paper lists 24 exothermic nuclear reactions. What were the masses of three exotic particles (enion and two erzions) that were used to calculate the Q values? I simply tried to answer this question. Each of Yuri's reaction gives an equation with two unknown. The three unknown masses -- I labeled them X, Y and Z -- can be found by solving three equations with three unknowns.

3) The values of X, Y and Z should be the same, no matter which three reactions are chosen to calculate them. And each mass should be positive. Right or wrong?

P.S. (after reading Bill's message):
OK, suppose the mass of X is declared to be 1.000000 by definition. Also suppose that Y and Z, according to a theory, happen to be one thousand times smaller, or larger, than X. How would you use this information to calculate the Q values of Yuri's 24 reactions? I think that this would be possible only if masses of X, Y, and Z were accurately expressed in familiar C12 units. I took Yuri's Q values for granted and calculated X, Y, and Z from them in C12 units. What was wrong with this?

29) On 3/25/08 Bill Collis wrote:
Ludwik, reaction energies, whether chemical or nuclear, are based on the energy difference between products and reactants. For conventional nuclear physics nucleons are treated as indivisible particles (we cannot weigh quarks) and we choose a single "anchor" to specify an absolute mass of C12.

This is not sufficient for Erzions because they cannot be specified in terms of nucleons alone. They cannot be converted into "normal" nucleons. Erzion Number is always conserved so hypothetical Erzion reaction energies can only give the difference between Erzion masses.

The first such difference, as proposed by Yuri, is the Erzion / Enion mass difference required to ensure low level tritium production without simultaneous 14.1 MeV neutron production:-

2H + zN --> 3H + z0

This reaction would have to be almost endothermic otherwise fast tritons would interact with deuterium. ;)

Similarly some reaction must be found to fix the negative Erzion mass. With these 2 parameters you can calculate any number of Erzion reactions.

Last year I presented a paper on this at ICCF13 using results from ENSAP software. If anyone would like a full list of ALL hypothetical Erzion reactions with naturally occurring isotopes I'll be happy to send it to them privately. For ICCF14, I'm working on a paper revising the Erzion masses with a view to further reducing the predicted radio-activity which Erzions would otherwise induce through interaction with ordinary matter. The goal is to explain heat and transmutation without lethal radiation, without Coulomb barrier using the ordinary laws of physics. That's quite difficult of course (but software helps!). If anyone would like to collaborate on this, just let me know.

30) On 3/25/08 Ludwik wrote (addressing Bill):
OK, Let us calculate the Q value (released energy) in the following
reaction

Na23 + A = Na24 + B

where A and B are exotic particles of some kind. The answer is Q = m*c^2, where m is the mass difference between the right side and the left side. I know the difference between the masses of two sodium isotopes. What I need is the mass difference between B and A, in the same units (such as kg or u). I assume your answer is Q=0.8 MeV, when A is an enion and B is the neutral erzion. Please show your arithmetic. Why do I assume that your answer is 0.8 MeV? Because that is what was reported by Yuri; it is reaction 21 in his Catania presentation at:

http://www.iscmns.org/catania07/program.htm

31) On 3/25/08 Bill Collis wrote:

Following Yuri's logic and the reasoning given in my previous message, we can write:-

23Na + t = 24Na + d + 0.702 MeV

More precisely, in the case of Erzions being the catalytic intermediaries 2 reactions are possible:-

23Na+ EURO N -> EURO- + 24Mg +5.194 MeV
23Na+ EURO N -> EURO 0 + 24Na +0.708 MeV

The first reaction is favoured over the second by energy and spin considerations and may explain why we do not observe radio-active sodium in our experiments. Does this answer your question?

32) On 3/25/08 Ludwik wrote:
Bill wrote: "Does this answer your question? " Perhaps it does but I am still in the dark. My question was about the reaction

23Na + (enion) = 24Na + (neutral erzion) +Q

According to Yuri's table, Q for this reaction is 0.80 MeV. How was this calculated? Please describe assumptions behind Yuri's logic. Please show the arithmetic.
P.S.

I also got the Q=0.702 MeV for your first reaction. How can this number be used to calculate Q=0.80 MeV?
.
P.P.S.
In the previous message you wrote:

Similarly some reaction must be found to fix the negative Erzion mass. With these 2 parameters you can calculate any number of Erzion reactions..... "

a) What is the erzion number?
b) How much is ``almost" (in almost endothermic), and why?
c) The 23Na + t = 24Na + d + 0.702 MeV and the 23Na + (enion) = 24Na + (neutral erzion) +0.80 MeV reactions describe conversion of 23Na into 24Na (adding a neutron to 23Na). But why should the Q of the second reaction depend on the Q of the first reaction? I need a more detailed description of logic (and assumptions) used to calculate Q of reactions involving enions and erzions. Hints are not sufficient, at my zero-level familiarity with such particles.

33) On 3/27/08 Bill Collis wrote:
1) Ludwik wrote: "I am still in the dark. My question was about the reaction 23Na + (enion) = 24Na + (neutral erzion) +Q According to Yuri's table Q for this reaction is 0.80 MeV. How was this calculated?" I suggest you ask Yuri. It may be a misprint. My calculation, agrees with yours.

The assumptions [in Yuri's logic] are that endothermic nuclear reactions are impossible at room temperature and fast tritons would create unobserved 14.1 MeV neutrons in any heavily deuterated material.

2) [He also wrote] "Please show the arithmetic." See my previous posts.
3) [He also asked] "What is the erzion number? It's another way of saying that Erzions cannot be created nor destroyed.
4) [He also asked] "How much is ``almost" (in almost endothermic), and why? Almost means a few keV. The d+t reaction would be detectable if the tritons had more than about 10 keV.
5) [He also asked} "The 23Na + t = 24Na + d + 0.702 MeV and the 23Na + (enion) = 24Na + (neutral erzion) +0.80 MeV reactions describe conversion of 23Na into 24Na (adding a neutron to 23Na). But why should the Q of the second reaction depend on the Q of the first reaction?" The two Qs should be similar. As I say, this looks like an error. Or maybe Yuri is refining his model in some undocumented way. Ask him.

At this stage we can make many assumptions varying the two parameters which describe Erzion masses. When we find a pair which coherently explain CMNS observations, we may be closer to the truth. You don't have to be a nuclear expert to do this if you have the right software.

Ludwik (not posted):
At this stage I do not mind performing manual calculations. Software is useful in repetitive calculations. And I will wait for Yuri's input. I hope he is no longer sick, as he was last month. The idea that a mass cannot be associated with a particle participating in a reaction is not easy to swollaw. The answer to my question "what is the erzion mass number" does not add clarity. I wanted to know what physical quantity is represented by the erzion number EN. Suppose someone tells me that EN=3. How does this differ from EN=7, 13.5, or -2, etc. ?

34) Appended on 4/10/08 (to be posted later)
Two days ago I posted this message on the Internet list for CMNS researchers: "

Dear Bill, your slide #6, of Catania presentation, shows four reactions involving Yuri's erzions and enion. Let me use X for an enion, Y for the neutral erzion and Z for the negative erzion. With these labels your four reactions are:

Li6 + Z = X +He5 +3.48 MeV (A)
Li6 + Y = X + Li5 + 0.58 MeV (B)
Li6 + X = Y + Li7 + 0.99 MeV (C)
Li7 + X = Z + Be8 + 9.17 MeV (D)

Masses of nuclei involved in these reactions are know. They are:

5He --> 5.01222 u
5Li ---> 5.01254 u
6Li ---> 6.01512279 u
7Li ---> 7.01600455 u
8Be --> 8.00530510 u

The accuracy for the highly unstable 5He and 5Li (life-times of 10^-21 sec) are not as high as for the other three nuclei. But that is OK, I will take the Q values for granted. Suppose that x, y and z stand for masses of three exotic particles: enion, neutral erzion and negative erzion. Then, applying the energy conservation law to reactins (B) and (C) one has:

6.01512279 + y = x + 5.01254 + 0.58 / 931.5 (b)
6.01512279 + x = y + 7.01600455 + 0.99 / 931.5 (c)

1) Each of these equations tell me than the enion, X, is more massive (by about one mass unit) than the neutral erzion, Y. That is is an important conclusion. I suppose the Q values were artificially chosen to make the (x-y), calculated from (b) and (c), identical. Please confirm.

2) Let me do the same thing with equations (A) and (D).

6.01512279 + z = x + 5.01222 + 3.48 / 931.5 (a)
7.01600455 + x = z + 8.00530510 + 9.17/931.5 (d)

Each of these equations tell me than the enion, X, is more massive (by about one mass unit) than the negative erzion, Z. Once again, I suppose the Q values were artificially chosen to make the (x-y), calculated from (a) and (d), identical. The masses are knot known accurately enough for this to happen, except by accident. Please confirm.

3) In other words, erzions, neutral and negative, have about the same mass. Their masses are by about one C12 unit smaller than the mass on the enion.

4) According to one of Yuri's papers erion is a "single charged particle with mass -- M of about 200 GeV/c^2." If that number were exact then the mass of a negaitve erzion would be 200000 / 931.5 = 214.707461 u. In other words, the A would be 214 and the mass deffect would be 0.7074611 units. The value of A for the enion, according to my calculations above, would be close to 215. But the 200 GeV/c^2 seems to be only a very rough estimate based on cosmic-ray data. The bottom line is that erzions and enions are very massive particles. Enion and neutral erzion, like polyneutrons, are not repelled by atomic nuclei. That is a very important property.

5) Is my description acceptable? If not then what else should be added to introduce Yuri's particles to students and teachers?

35) **Ed Storms wrote:**
This discussion is interesting, but I don't understand how it relates to LENR. Are these erzions proposed to be everywhere and can initiate nuclear reactions under certain circumstances? Why are they not easy to detect when material is vaporized and/or ionized? What keeps them from reacting at anytime in any material?

36) Bill Collis wrote:
"Ludwik your description looks OK but please remember we do not know what the absolute or relative masses of Erzions are. Erzions are a model system of neutron transfer catalysts. Another such model is John Fisher's polyneutron theory. The question at this time should be, "What properties should these catalysts have to explain CMNS observations".

Ed, yes Erzions are supposed to be everywhere! In most materials they do not react or react but once and so are never observed. More interesting effects occur in a limited range of composite materials, an Erzion picks up a neutron from one isotope and deposits it into another.

The neutral Erzion can react with a deuterium producing a proton and a heavier Enion. But the Enion cannot normally react further (but perhaps if it has a little more energy it can create tritium).

In pure Beryllium, Erzions should set up an exothermic chain reaction producing helium and radioactive 10Be! Can you see why? (Be9 can both accept and donate a neutron). The fact that nobody has detected 10Be suggests either they weren't looking or the model is wrong! (Fisher's initial polyneutron theory did not make this prediction.)

If Erzions are everywhere why are electrolytic cells good places to find them? I haven't really thought about this problem deeply, but maybe negative erzions somehow get trapped there and so accumulate."

37) Responding to Bill, Ludwik wrote (also on the private CMNS list**):**
``Your statement about not knowing `the absolute or relative masses of erzions' still troubles me. I have three concerns

1) Consider reaction 9 from Yuri's Catania paper:

X + 13C = 14C + Y + 2.0 MeV

This implies that

(x-y) = 14Cmass - 13Cmass) +2.0 / 931.5 =1.002034 u. <------ (E)

This does give the absolute difference between the masses of two exotic particles. If the value of (x-y) is not known then the Q of the reaction is also not known. But the Q=2 MeV is given. How was that Q determined?

2) Or consider reaction 10, also from Yuri's Catania paper:

Y +13C = 12C +X +1.2 MeV

This implies that

(y-x) = 12Cmass - 13Cmass) + 1.2 / 931.5 = -1.002066 u <----- (F)

If the value of (y-x) is not known then the Q of the reaction is also not known. But the Q=1.2 MeV is given. How was that Q determined?

3) Suppose I do accept the fact that the Q of each of these reactions is given. Then what is wrong with treating the (E) and (F) as two equations with two unknown? That would give me exact values of x and y. In other words, specifying

Q of reactions, induced by exotic erzions and enions, does not seem to be consistent with the statement that "absolute masses" are not known. On what basis were the very accurate value of Q chosen? Some assumptions were probably made. Please explain these arbitrary assumptions.''

Appended on 4/12/08

38) Responding to Ed, Bill wrote:

The beauty of catalysed neutron transfer reactions is that only a tiny number of catalyst entities need be present to make measurable excess heat. Being (mostly) neutral, their reaction cross sections are measured in Mega-barns because no gamma-ray emission is necessary to conserve energy (in contrast to neutron capture). This enhancement of about 1 million is due the fact that the nuclear force is 6 or 7 orders of magnitude stronger than the electromagnetic force and correspondingly faster. In turn this means that the mean free path of such neutral catalysts is about 1 millionth of that of a neutron. Consequently a 3 dimensional CMNS reactor may be 10**18 times smaller than a fission reactor! Instead of weighing 10**12 g scales are reduced to tiny hot-spots of 10**-6 g. Indeed individual hot spots may be caused by single catalytic particles. Of course these figures are all VERY approximate.

No let's see how these particles catalyze neutron transfer. In the case
of Erzions we may have simple cycles such as:-

EURO N + 6Li-> EURO 0 + 7Li +0.99 MeV
EURO 0 + 6Li-> EURO N + 5Li +0.58 MeV
5Li -> 4He + p +1.966 MeV

As you can see Erzions are regenerated and we get lots of He4 and protons (but no X-rays or gammas). However we all know that bulk Lithium alone does not get hot! We must explain why. One possibility is:-

EURO N + 7Li-> EURO- + 4He + 4He +10.85 MeV

Once the negatively charged Erzion is formed its reactivity is dramatically reduced (but not quite eliminated). Of course the situation is much more complicated in reality because our hypothetical catalysts may react with other isotopes too. Furthermore we do not know their masses (and therefore their reactivity). We need to make reasonable assumptions, test them against reality, and refine the parameters. I am making some progress in this direction and hopefully I'll report at ICCF14.

So how many catalytic neutral particles would you need to make say 1 watt? Dozens? Hundreds? So few that they would be undetectable by density or physical properties.

39) Responding to Bill, Ed wrote:

I agree, some kind of semi-neutral catalyst is required. Apparently, we now have hydrinos, Erzions, and polyneutrons to consider. Such a catalyst must be made either by an exothermic reaction, as with hydrinos, or be supplied fully formed by nature, as is the case with the latter two possibilities. I think we agree, creation of a catalyst, such as neutrons, by a endothermic process is not possible. How do we evaluate each of these possibilities?

As an answer, I suggest we need to consider two questions. What conditions make each catalyst reactive and what are the expected products. Both questions can be answered by experimental observation. In addition, these answers have to be provided with a minimum of arbitrary assumptions that can not be verified. At the present time, we already have some of these answers.

In the case of polyneutrons and Erzions, we need to assume that they are more or less uniformly distributed in nature. Therefore, the trigger that initiates a nuclear reaction must be created by a unique chemical or physical environment. Next, we need to ask why this environment is so rare and difficult to create. Why do the few environments used by CF researchers work and most other environments do not work? This question is easier to answer about hydrinos. This nuclear catalyst requires a chemical catalyst to form. Therefore, nuclear reactions can occur only when this rare chemical catalyst is present. Nevertheless, I find one fact rather troubling. In all of nature, why are these possible nuclear reacts not being catalyzed all the time in various opportune circumstances? The result would be an isotopic

distribution in nature that would be highly distorted, favoring the reaction produces being proposed by the various proponents of the different catalysts.

I suggest we need to discuss these broader issues rather than debating hypothetical reactions that might never occur. We know that certain nuclear products are produced. I suggest we need to discover why and how these products are formed. Other products might be produced, but until they are verified, their formation is simply an assumption having no value. Meanwhile, we know that tritium and helium result from the CF reaction. How are these elements formed and what are the required conditions? Why have these conditions not converted all of the deuterium to tritium then to He3 or to He4 during the life time of the universe? This question is easier to answer for hydrinos than for the other possibilities.

40) Responding to Ludwik, Bill wrote:
I answered your questions already, but here goes again! To calculate Q values for Erzion reactions we need to assign 2 parameters for mass differences between the 3 Erzions. In the case of the 2 reactions you cite above which do not involve the negative Erzion only 1 parameter is required. It is fixed (in Yuri's view) by the non observation of 14.1 MeV neutrons in tritium producing deuterated which implies in turn the absence of fast tritons from the reaction:-

$$X + d = Y + t$$

If the above reaction has an energy close to zero, the Q for reactions 1 & 2 can be calculated. Is this clear now? John Fisher used the same reasoning, quite independently, to fix poly neutron masses. However I am not convinced that this method is appropriate. After all, tritium has been produced in light hydrogen systems too.

41) Responding to Bill, Ludwik wrote:
Thanks for being patient with my slow learning. Let me follow your hint. I will continue using X, Y and Z for neutral enions, neutral erzions and negative erzions, resperctively (and x, y, z for their unspecified masses)

1) Let me try to calculate the Q value for the

$X + {}^{13}C = {}^{14}C + Y + Q1$ ---------- (9) Yuri's reaction #9

I want to verify that the answer is 2.0 MeV, as given by Yuri. You suggested I lean on the zero Q for the

$X + {}^{2}H = Y + {}^{3}H$ ---------- (0) Bill's reaction (assuming Q=0; to impose absence of 14.1 MeV neutrons)

This gives me two equations:

$x + 13.003354 = y + 14.0032419 + Q1$ -------- (9')
$x + 2.0141022 = y + 3.0160494$ ---------- (0')

The first equation gives me

$x-y = 0.999888 + Q1$

The second equation gives me

$x - y = 1.001947$

In other words,

0.999888 + Q1 = 1.001947 or Q1 = -0.0020592 u = 1.92 MeV

That is indeed close enough to Yuri's value 2.0 MeV; I am using masses from an old table. Let me do this again for Yuri's reaction #10.

Y +13C = 12C +X +Q2 --------- (10)

x-y = 13.003354 12.000000 - Q2 = 1.003354 - Q2------- (10')
x-y = 1.001947

In other words,
1.003354 - Q2 = 1.001947
or Q2 = 0.001407 u = 1.31 MeV.

This is again close enough to Yuri's value of 1.2 MeV. He probably used more accurate masses. Things become clear in my mind. Thanks for your help, Bill.

2) But one thing remains to be clarified. What is the second independent assumption? It must known to calculate the Q values of reactions involving a negative erzion, Z.
P.S.
3) I wander why Yuri is silent. In the last private message, about three weeks ago, he wrote that he was recovering from being sick. How are you now, Yuri?

42) Bill Collis (responding to Ed) wrote (on 4/19/08):
1) The questions you pose are relevant, but in my view they may not be the primary questions to resolve the issue! The first requirement is that any theory of CMNS explains (most of) the generally accepted observations. The second is that the theory must not make predictions which are not observed. Many theorists conveniently overlook this second requirement.

2) My approach is to assume some (not too many!) parameters (1 or 2 masses in the case of Erzions) and see what happens to their interactions with ALL known natural isotopes. I refine the parameters as needs be. It seems that all interactions of the E0 Erzion produce no penetrating radiation whatsoever! That's a miracle that makes me think the theory is worth looking into in more detail. Every theory I know purporting to "explain" heavy element transmutation fails at this hurdle.

3) In the early 90s there were many reports (Notoya, Bush & Eagleton etc.) of apparent transmutations by exactly 1 nucleon. Again, that is something expected by polyneutron or Erzion catalysis. I don't pretend for a moment that these models explain everything. I merely suggest that they are very testable, and therefore worthy of study.

4) If you want to analyse an extremely complicated series of transmutations it may be well to concentrate on very simple systems first before applying ones attention the generality of all CMNS experiments. For example how many theories attempt to explain the emission of neutrons from cold deuterium gas in a magnetic field (Mizuno)? Could it not be that our hypothetical catalysts have a magnetic moment and are trapped in a magnetic field? Could this also explain the successes of Letts, Piantelli and others?

5) I am not convinced that the Nuclear Active Site is a chemical catalyst. Rather, it may be an environment where specific nuclides permit and participate in a self sustaining series of reactions. This unusual combination of nuclides does not occur in nature and so CMNS reactions are not observable in natural systems.

6) You ask "Why have these conditions not converted all of the deuterium to tritium then to He3 or to He4 during the life time of the universe?". In order to achieve a sustained chain reaction the Erzion model requires:-

a) The presence of neutron donors like deuterium, Li6, Be9, C13, O17

b) The presence of neutron acceptor nuclei such as He3, Li6, B10.
c) The absence of negative Erzion precursors such as Li7, Be9, B10, N.
d) Some Erzions!

Of course what counts as an acceptor, donor or poison depends critically on the mass differences we assign to the Erzions themselves. This is why it is so important to discuss "hypothetical reactions that ... never occur" because they help us refine the model.

7) If you look at Physics as a whole, and at Cold Fusion in particular it is littered with untestable (and therefore unscientific) conjectures and models which barely survive because although useless (they make no predictions they cannot guide experiment), they cannot be demolished either. We are left with a set of models which are wrong in detail but leave open the possibility of improving that detail, and suggesting new experiments to perform. If this is unsatisfactory, it is nevertheless common reality of most science at the frontiers of knowledge.

8) I do not believe that hydrinos or mini-molecules explain CMNS. They might explain excess heat but not the observed nuclear transmutations. They predict unobserved nuclear reactions such as p+d->3He+gamma.

9) As you mention the Universe, consider this. Venus, Mars and Earth (in that order) have a higher D/H ratio than the interstellar medium which in turn has a higher ratio than the giant planets, Jupiter, Saturn, Uranus, Neptune. These last 4 radiate more energy than they receive from the Sun. Could that excess heat be cold fusion? If so one might presume that the power was greater in the past when deuterium concentrations were higher (assuming deuterium is the fuel and is being consumed). Well the 2 inner satellites of Jupiter have no atmosphere. Were these atmosphere blown away by nuclear heat some 5 billion years ago?

43) Ed Storms wrote:
[Referring to 1] I agree totally, Bill. However, I would add several other requirements. The theory must not violate any basic law and must show why the phenomena is so rare and difficult to initiate. In addition, a theory must explain how the Coulomb barrier is overcome and how the resulting energy is communicated to the observed world. These mechanisms must have universal application and not be uniquely available to the CF environment. Therefore, any proposed mechanism must be observed to be part of other phenomena besides CF. As you say, most theories overlook these requirements as well.

[Referring to 2] I agree, this hurdle is worth exploring. If no radiation is produced, how is the energy converted to heat? Can the resulted Erzion be detected? If not, the transmutation reactions would result in no detectable heat because all energy would go off with the invisible Erzion. How does the Erzion model fit with the Russian gas discharge work where heat and radiation are claimed?

[Referring to 3] Study is always worthwhile. However, there is always a competition between the time it takes for the study to be made and its potential success. If the model is too far from reality, potential success is too low to make the study worthwhile. We see this problem in most of the suggested theories. As you argue, it may be too early to render a judgment about Erzions.

[Referring to 4] Here, we get to the issue of what needs to be explained. Personally, I see no need to explain a single, unreplicated experiment, no matter how unusual the result. I suggest the effort should be directed to explaining the well known and well documented behavior. We have a lot of such information without being distracted by what could be a wild goose chase.

[Referring to 5] I agree, the NAE could take many forms. However, we have found a few universal features to be present. For example, oxygen can always be found in the environment. The local deuterium concentration is high, but not because it is dissolved in a metal lattice. I could suggest other less well documented features, but will avoid getting into the resulting debate, which is a subject for another time.

[Referring to 6]
The model, as I understand it, exploits the energy gain that results when neutrons are added to certain atoms resulting

in an unstable isotope. In addition, the Erzion also has to change mass for this process to be exothermic. My question is, What features about the environment must be unique to permit such reactions to occur? Why would a Erzion not immediately react with, say 6Li, just as soon as it has made contact? Some additional condition must be present to make such a reaction very rare. This condition is the "secret" that would make such a reaction reproducible once it is known and can be created at will.

[Referring to 7] True, but some theories are easier than others to improve. Some are so far from meeting the conditions we both agree are necessary that they are worth very little time. I suggest it is worthwhile to weed out such theories early in the discussion to avoid wasting a lot of time.

[Referring to 8]Yes, this reaction would be expected. However, the gamma may be eliminated by the same process that operates during the d + d = He4 reaction. To fit the hydrino model, we have to make an assumption about why this reaction does not occur. Making similar assumptions is not an uncommon requirement even in the Erzion model.:-)

[Referring to 9] I agree, cold fusion probably operates in such environments. Too bad we can't create a Jupiter atmosphere here on earth.

44) Bill Collis wrote:
{Bill, earlier] The questions you pose are relevant, but in my view they may not be the primary questions to resolve the issue! The first requirement is that any theory of CMNS explains (most of) the generally accepted observations. The second is that the theory must not make predictions which are not observed. Many theorists conveniently overlook this second requirement.

[Ed] I agree totally, Bill. However, I would add several other requirements. The theory must not violate any basic law and must show why the phenomena is so rare and difficult to initiate. In addition, a theory must explain how the Coulomb barrier is overcome and how the resulting energy is communicated to the observed world. These mechanisms must have universal application and not be uniquely available to the CF environment. Therefore, any proposed mechanism must be observed to be part of other phenomena besides CF. As you say, most theories overlook these requirements as well.

[Bill] We agree completely!

[Bill, earlier] My approach is to assume some (not too many!) parameters (1 or 2 masses in the case of Erzions) and see what happens to their interactions with ALL known natural isotopes. I refine the parameters as needs be. It seems that all interactions of the E0 Erzion produce no penetrating radiation whatsoever! That's a miracle that makes me think the theory is worth looking into in more detail. Every theory I know purporting to "explain" heavy element transmutation fails at this hurdle.

[Ed] I agree, this hurdle is worth exploring. If no radiation is produced, how is the energy converted to heat?

[Bill] When heavy charged fragments such as alpha particles or fission fragments pass through condensed matter, they lose energy principally by interaction with electrons. Because electrons weigh so much less (say 8000 times less in the case of alphas) they can only take a tiny proportion of the energy away. So we would expect heat to be removed by energetic electrons in the 100s-1000s eV range. There would be corresponding soft X-rays too with very little penetrative power.

[Ed] Can the resulted Erzion be detected?

It would be wise to determine its properties before attempting detection. He3 neutron counters might work.

[Ed] If not, the transmutation reactions would result in no detectable heat because all energy would go off with the invisible Erzion.

No. The Erzion is not so light and may be charged itself. Its mean free path in dense matter is of the order of microns

as I have already discussed. We expect "hot spots".

[Ed] How does the Erzion model fit with the Russian gas discharge work where heat and radiation are claimed?

See above.

[Bill, earlier] In the early 90s there were many reports (Notoya, Bush & Eagleton etc.) of apparent transmutations by exactly 1 nucleon. Again, that is something expected by polyneutron or Erzion catalysis. I don't pretend for a moment that these models explain everything. I merely suggest that they are very testable, and therefore worthy of study.

[Ed] Study is always worthwhile. However, there is always a competition between the time it takes for the study to be made and its potential success. If the model is too far from reality, potential success is too low to make the study worthwhile. We see this problem in most of the suggested theories. As you argue, it may be too early to render a judgment about Erzions.

[Bill, earlier] If you want to analyse an extremely complicated series of transmutations it may be well to concentrate on very simple systems first before applying ones attention the generality of all CMNS experiments. For example how many theories attempt to explain the emission of neutrons from cold deuterium gas in a magnetic field (Mizuno)? [Ed] Here, we get to the issue of what needs to be explained. Personally, I see no need to explain a single, unreplicated experiment, no matter how unusual the result.

Agreed.

[Ed] I suggest the effort should be directed to explaining the well known and well documented behavior. We have a lot of such information without being distracted by what could be a wild goose chase.

True.

[Bill, earlier] I am not convinced that the Nuclear Active Site is a chemical catalyst. Rather, it may be an environment where specific nuclides permit and participate in a self sustaining series of reactions. This unusual combination of nuclides does not occur in nature and so CMNS reactions are not observable in natural systems.

[Ed] I agree, the NAE could take many forms. However, we have found a few universal features to be present. For example, oxygen can always be found in the environment. The local deuterium concentration is high, but not because it is dissolved in a metal lattice. I could suggest other less well documented features, but will avoid getting into the resulting debate, which is a subject for another time.

[Bill, earlier] You ask "Why have these conditions not converted all of the deuterium to tritium then to He3 or to He4 during the life time of the universe?". In order to achieve a sustained chain reaction the Erzion model requires:-
1) The presence of neutron donors like deuterium, Li6, Be9, C13, O17
2) The presence of neutron acceptor nuclei such as He3, Li6, B10.
3) The absence of negative Erzion precursors such as Li7, Be9, B10, N.
4) Some Erzions!

Of course what counts as an acceptor, donor or poison depends critically on the mass differences we assign to the Erzions themselves. This is why it is so important to discuss "hypothetical reactions that ... never occur" because they help us refine the model.

[Ed] The model, as I understand it, exploits the energy gain that results when neutrons are added to certain atoms resulting in an unstable isotope.

No. If the products were unstable, we would have penetrating radiation in most cases - Bremstrahlung in the case of beta decay. Such radiation would be fatal (and not just to the theory!). We need to show, without any magic, that stable products are the only ones possible from stable precursors.

[Ed] In addition, the Erzion also has to change mass for this process to be exothermic. My question is, What features about the environment must be unique to permit such reactions to occur? Why would a Erzion not immediately react with, say 6Li, just as soon as it has made contact?

It is expected to.

[Ed] Some additional condition must be present to make such a reaction very rare.

Why? The trouble with pure lithium is that it generates negative Erzions which being charged cannot move in condensed matter. They have a half life of at least seconds so nuclear catalysis is slowed by at least 9 orders of magnitude. However if the layer of lithium were very thin, as it may well be on the surface of an active cathode, the energy of the reaction might be sufficient to send it somewhere else (such as the electrolyte)

[Ed] This condition is the "secret" that would make such a reaction reproducible once it is known and can be created at will.

When you find it, I'll come to Stockholm!

[Bill, earlier] If you look at Physics as a whole, and at Cold Fusion in particular it is littered with untestable (and therefore unscientific) conjectures and models which barely survive because although useless (they make no predictions they cannot guide experiment), they cannot be demolished either. We are left with a set of models which are wrong in detail but leave open the possibility of improving that detail, and suggesting new experiments to perform. If this is unsatisfactory, it is nevertheless common reality of most science at the frontiers of knowledge.

[Ed] True, but some theories are easier than others to improve. Some are so far from meeting the conditions we both agree are necessary that they are worth very little time. I suggest it is worthwhile to weed out such theories early in the discussion to avoid wasting a lot of time.

It would be nice if someone would write a critical review paper for JCMNS. A good starting point would be Preparata's review published in Fusion Technology.

[Bill earlier] I do not believe that hydrinos or mini-molecules explain CMNS. They might explain excess heat but not the observed nuclear transmutations. They predict unobserved nuclear reactions such as p+d->3He+gamma.

[Ed] Yes, this reaction would be expected. However, the gamma may be eliminated by the same process that operates during the d + d = He4 reaction. To fit the hydrino model, we have to make an assumption about why this reaction does not occur. Making similar assumptions is not an uncommon requirement even in the Erzion model.:-)

Not really. Assuming mass or energies is quite different from assuming new physics. What assumption do you make with the hydrino model? Is there a paper anywhere which discusses CMNS in terms of hydrinos? I ask because Mills himself is said not to believe in "Cold Fusion". Dufour has abandoned his hydrex / deutex model.

Ludwik:
It is evening of 4/21/2008. I just stoped appending messages to this unit. The last two messages (from Ed and Bill) were even more convoluted than the last one. I decided not to record them here. I have to stop somewhere; this unit is already too long. Then I uploaded the expended unit 341 to my website. That should not prevent me from being interested in what is going on. I might decide to compose another unit abou erzions at some later time.

This website contains other cold fusion items.

342) Speculations or truth?

Montclair State University, Montclair, NJ, 07055
1/16/08

1) The private Internet discussion list for CMNS researchers has been quiet in recent weeks. Then, on 1/12/08 an interesting message was posted by Ivan Ragland. Two days later another speculative message was sent to me in private. This shows that people are thinking about the ongoing CMNS controversy. These contributions are worth posting here. Perhaps someone will conceive and perform experiments to test the ideas. **Evan wrote:**

2) "Dear CMNS group, While things are quiet on the CMNS circuit it seems opportune to suggest an alternative structure of matter which might lead to new insight of cold fusion phenomena. I hesitate to make such introduction as no cold fusion theory is clearly established. However, it was cold fusion which caused me, *in the spirit of empirical equivalence*, to originally present an Alternate Model to Standard Model interpretation of the nuclear strong force. I have written extensively on the structure of matter and have two published papers on the subject. Recently, a third paper is accepted for presentation at the March Meeting of the American Physical Society. The abstract is appended herewith. In preparing for this meeting I solicit and welcome advice, interest, and questions of the CMNS group.

I am elderly, 81, a retired engineer, not a physicist, mathematician, or theorist. After a long career in computer design my interest is nuclear fusion. I bring to technology, success in things that, "*cannot be done*," and strong technical opinion. The Standard Model is a tragic wrong theory which for decades has failed the most prestigious of all sciences, high energy physics; string theory, nuclear fusion, M theory, super symmetry, TOE, ITER, NIF, and so on fail, while *all* sciences, solid state physics biology, medicine, communications, chemistry, computers, space, etc. flourish. Your advice, interest, and questions are appreciated." What follows was attached to the message:

3) "Alternate atomic model posits concentric electron and nucleon fields spinning together about an empty center. It is alternative to the generally accepted planetary system in which electron point particles orbit about a center clump of nucleon point particles. Introduced in 1992 as an alternative to the standard model of the nucleus it applies scientific space-time knowledge unknown when the standard model was conceived. Originally advanced in the spirit of alternative equivalence it evolved to model the entire atomic structure plus many features of space-time. Structural definitions assume space-time properties of: unidirectional expansion, special relativity, electrical field, magnetic field, spin field, gravity field, and space-time surface effect. Field effects are associated with Faraday lines of field force. Model properties feature symmetry and complementarily. Mass structures of the electron, proton,neutron, and protium atom plus the atomic and nuclear constituencies of all elements are developed. In addition the nuclear strong force is defined, the magnetic anomaly explained, etc. Model logic constructs the neutron as the complement of the hydrogen (protium) atom."

4) **My reply was**: "OK. I will tell you what I think.
a) I suspect that many people on this list, myself included, know the name "standard model" but never studied it, or used it as a tool to solve problems. In other words, most of us are not qualified to discuss this topic. If you want to criticize standard model, and offer a better alternative, then you should find a list with people prepared to deal with your ideas.

b) On the other hand, if you want to propose a new theory of atomic structure, starting from scratch, then this list is OK; it has a lot of people able to face your ideas. I would certainly try to follow you, at least as long as arguments are

scientific, and match my personal background. The rules of the game -- how to justify new statements in terms of what is already accepted -- are well known. In that way the CMNS field is not different from other fields of physical science.

c) Is your theory based on experimental facts or is it based on ad hoc assumptions? Please describe it briefly. In other words, you have to make the first move. Then wait for questions and comments about your theory. By the way, you will not be the first one to do this here.

5) **Two days later Evan wrote:**
"Thanks for your response. It is very helpful to me to know your thoughts. [a] I suspect you are right, many may know the name but have not studied or used the "standard model." It is my experience most scientists avoid 'standard model' complexity because they feel lack of expertise. Dr. Johnathan Allday writes, 'SM calculations are beyond us; [thus].simplifying assumptions have to be made." The AM is simple classical physics. I append descriptive material for both SM and AM with this reply.

[b] I do want to propose a new theory. I am sure you follow my reasoning and do value your expertise and comments. Also, I have confidence and respect for others on this list. Fortunately, young scientists are joining, plus, I hold highest professional regard for other scientists I know and have worked with since 1992. The rules are clear and, while my AM proposal may be controversial, it 's correctness can rescue physical agendas.

[c] It is based on facts, experiment, and assumption. The appended list of these is basis for evaluation of my written paper for the March meeting. My presentation is directed to the "*now"* of space-time. A description of the AM follows. Also, the paragraph entitled the crucial issue in the attached PDF is worth review. CMNS commentary and critique would be of value to me but I would not want to reflect any embarrassment upon the group. On the other hand CMNS participation might be worthy of consideration. I hope all this helps. Regards, Evan Ragland."

6) What follows is the attached piece:
"The logic of the Alternate Model constructs the neutron as the complement of the hydrogen (protium) atom;i.e., an electron captured inside a proton. The neutron's resultant internal field is the nuclear strong force. According to this model the nucleus is a concentricity of individual proton and neutron fields, each confined to a distinct shell location by wave length and angular and spin momenta. The structure conforms to the Pauli exclusion principle, the principles of quantum mechanics, and with the exception of the protium nucleus is bound together by neutron(s) internal field(s). The Alternate Model is plausible and easily visualized.

Nuclear Notes on March paper
01. electrons don't orbit; they ***nest***
02. nuclei don't clump; they ***nest***
03. electron & proton are fundamental; (soliton field energy packets)
04. protons ***don't*** decay; (probability 10^30 doesn't happen).
05. space is expanding: (in time)
06; space is a surface function; (as we know it)
07. ***spin*** is a property of space; (spin up, spin down)

7) My reply, on 1/14/2008:
You wrote that "the electron in spinning inside a proton." How can this be reconciled with HUP (Heizenbeg Uncertainty Principle, dx*dp~h). For a proton the dx is ~ 1 F. Introductory nuclear physics textbooks often use sizes of a nuclei (several F), and HUP, to explain why an electron cannot exist inside an atomic nucleus. Hydrogen is a small neutral atom and its electron is known to be outside the central nucleus.

8) Next day a carbon copy of another speculative message was sent to me by an old acquaintance (see item 268).
Dean Sinclair wrote: “ I've been out of contact for some time; but, thought you-all might find the following little essay which, I submitted to Helium.com as a "Debate" subject today, a little bit interesting. Can molecules be changed to atoms?

Yes. Under the right circumstances there is no reason why simple molecules cannot be transformed into atoms. Atoms combine into molecules and when one figures out the energetics, it can be shown that in many cases the atom version should be more stable than the molecule. Let us look at one case which is best explained by a molecule to atom transformation.

In 1998, two scientists, Stanley Fleischmann and Marvin Pons, announced that when they had carried out an electrolysis with a Palladium electrode and "Heavy Water," there was energy produced within the Palladium electrode, to the point, in one case of melting the electrode down. They ascribed this energy production to the fusion of Deuterium atoms to Helium 4 atoms, and called the process, "Cold Fusion."

The scientific community "went ballistic" at the term, "fusion." It is an item of faith in the scientific community that "fusion" can only take place at extremely high temperatures and pressures such as are found in the center of the Sun. In the almost twenty years that have passed since then a number of other workers have shown that the phenomenon reported by Fleischmann and Pons is real and have also reported other results of similar types. However, most of the establishment considers the area as "Kook science," rather than as a frontier between molecular and nuclear science where it probably should be considered. Unfortunately, explanations given for the phenomenon range from the fanciful to the bizarre.

The problems with this whole area stem from the separation of nuclear chemistry from molecular chemistry which started with Chadwick's discovery of the neutron in the 1930's. and the "romance" that enshrined as a fundamental particle of nature, an essential unit of every nucleus except of that of Hydrogen 1, This choice of the neutron as a basic building block of nature was in spite of the fact that it is energetically unstable to both the electron and proton as free entities and the Hydrogen 1 atom which can be considered as isomeric to it. The neutron was not given its proper place as an alternate state of matter which can come into existence under certain high-energy conditions. As a consequence of the neutrons "mis-placement" there began the high energy particle physics field searching for other "fundamental particles," which could be found by "atom-smashing." For some seventy years these scientists have discovered more and more "fundamental particles," which. like the neutron, should be properly classified as "alternate, high-energy states of matter.

All of this has led to such inanities as the Standard Model based upon these sets of "fundamental particles. " and the ideas of "Strong and Weak Nuclear Forces." The latter are ideas that arise directly from the ascribing to neutrons their existence as such in the nuclei of atoms. If. instead of adopting the neutron as a "fundamental particle," which had to be accounted for as such in nuclei, the neutron had been given its proper place and nuclei had been considered in the same way as molecules are, that is, as centers bonded by electrons moving in paths within and among them, perhaps we would have had a much more productive 70 years.

The point of all this is that. for the Fleischmann-Pons observations, there is a very simple probable explanation if one notes that both the Deuterium molecule, D:D, and the Helium 4 atom, He4, can be properly considered as being composed of four protons bonded by four electrons. Even the shapes are somewhat similar. The D:D unit can be

visualized as a "stretched tetrahedron," and the He4 nucleus as compact, perfect tetrahedron. The latter could be an instantaneous shape of a vibrational mode of the former. If there is a "receptor" available to drain off the excess vibrational energy of the "D:D form," the more stable "atom" structure can be taken on. Palladium with its plethora of energy levels is an ideal receptor for the excess energy of vibration.

What Fleischman and Pons almost surely observed was what could be called an "Iso-set isomerization" between the molecular and atomic forms of a set of protons and electrons. There are many such possibilities, some of which have apparently been observed in other "Cold Fusion" type experiments. Surely molecules can be transformed to atoms under the proper conditions. It's an area that should be wide open to open-minded scientists."

9) From Evan to Ludwik (1/16/08):
"I do not think it can be reconciled with the Uncertainty Principle as there is no action between the proton and electron constituents of the AM neutron. They spin together in a common wave packet about a common center.

Nuclear Physics by Irving Kaplan (pages 149-152) uses the UP to show a *free* electron in the neutron would approach velocity near 0.999 C which is contrary to experimental observations of emitted electron kinetic energies. Kaplan also suggests other reasons questioning the electron/proton hypothesis. The E/P hypothesis posited the electron constituent was *free* to *orbit* or actively relate to the proton constituent in the neutron. The AM holds the electron and proton are fundamental, electrostatic wave packets which spin as one in electron spin attitude.

The AM was conceived as a nuclear structure to keep protons from flying apart and neutrons from wandering away. It evolved from fundamental electron and proton structural definitions and their constituencies, the complementary protium (hydrogen) atom and neutron. It was never intended to revive the E/P hypothesis. Included herewith is additional information which may help explain the AM."

10) I do not want to argue about theoretical topics. But I must reply to Evan; his message was sent to me only. Both sets of ideas might be valid. Unfortunately, neither Dean nor Evan suggest experiments that could be performed to test the ideas. I am not prepared to speculate about their ideas.

11) Ludwik to Evan (1/17/08):
My theoretical background is too elementary to venture in that direction. It is safe to stick to what I learned from textbooks. Textbooks say that the Uncertainty Principle should be used to distinguish between what is possible from what is not. And "possible" does not mean "real." That is why the last word belongs to reproducible experimental data. It would be natural to abandon that principle, or to restrict its universality, to account for new experimental data.

Can beta radioactivity of neutrons (T~10 min) be used as experimental evidence that electrons live in them? Can beta radioactivity of tritium (T~12 y) be used as evidence that electrons exist in it? Can beta radioactivity of U-239 (T~23 min) be used as evidence that electrons exist in these nuclei? The answers are negative, according to most textbooks. Why should I reject these answers? In any case, I am not a good sounding board for speculating about standard model.

12) Closing message from Evan to Ludwik (1/21/2008):
I appreciate your offer to pose the question of, "Speculation or truth?" apropos the concepts of Dean Sinklair and myself. Sinklair's memo is impressive. It is *thinking outside the box,* representative of questions troubling physics today. And, I am honored by association with the two of you. However, I do not believe a URL has potential to answer the question. I agree most people are unfamiliar with the Standard Model and thus see no virtue in upsetting it. This whole matter is a hot potato. No one wants to become involved even to argue that concepts are wrong. One might lose the argument which would be worse than ignoring the issue. *No response* is symptomatic of science when the ground begins to change under prevailing dogma. Unsaid is:

"We know what we were taught, we are professional at what we do, there is much needed work in our specialties, just like everybody else we have mortgages, vacations, kids to put through college and we don't intend to, and won't become involved with challenge to prevailing theory."

That surely is understandable. Ludwik, if High Energy Physics continues to fail, as I expect, stagnation of *energy*

independence will trigger public demand for new high science. That may happen within this year. Many who work with nuclear are near disillusion with the Standard Model. Now is a time for patience. Thank you again for your interest, efforts, and proffer of help.
P.S.
Inasmuch as the new unit is already posted, herewith is copy of review items used in my estimate of URL potential to generate questions of Alternate Model validity. I am certain the nested AM [alternative model] a physically more accurate nuclear structure than the contrived point particle SM [standard model]. And, of course, it does so without imaginary particles (quarks, gluons) and force fields (colors). I am confident to answer all questions regarding my posited model. Although no harm is done, I will be surprised if the CMNS list generates much interest in different nuclear structure. . .

344) What is going on in our CMNS field?

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
February, 19, 2008

The CMNS field continue to be active. What follows are pieces of information and comments which do not form a coherent pattern. Why are they are worth recording here? Because these pieces caught my attention; I found them interesting. The first item is a review of of a recently published book about cold fusion. It appeared in the *Journal of Scientific Exploration*, volume 21, no. 4, pp. 801-805. The author is Dieter Britz, he is from Denmark.

= =

1) The Science of Low Energy Nuclear Reaction: A Comprehensive Compilation of Evidence and Explanations about Cold Fusion by Edmund Storms. Singapore: World Scientific Publishing Co. Pte. Ltd., 2007. 312 pp. $71.OO (hardcover) ISBN-13978-981-270-620-1.

"Cold fusion" refers here to the claim that by simple electrolysis of heavy water with some electrolyte, the deuterium ions (deuterons) that accumulate inside palladium or some other metal can be made to fuse. This surprising claim was made by Fleischmann, Pons, and Hawkins (1989) and, almost concurrently, by Jones et al. (1989). Much has been said about this subject, which has become a scientific "affair" of sorts, with most mainstream scientists refusing to accept the reality of cold fusion, and a smallish band of researchers continuing work and indeed publishing their findings. The present author began to collect a bibliography (hereafter, the Bibliography) of the literature in 1989 (see http://www.chem.au.dk/~db/fusion), including only papers in refereed journals, and the present count is 1367. As many as 30 books have been published on the subject. Of these, not all are notable, some being hasty productions or having clear weaknesses, but some stand out. Some of these were written by proponents of the phenomenon, and some by skeptics. Most of the books were written by people who have not themselves worked on the phenomenon, some being science journalists or enthusiasts without a scientific background.

Two books written by adherents of cold fusion stand out in that they were written by people active in "normal" science, with solid research records, and who have themselves done research on cold fusion. One of them was by T. Mizuno (1997), an electrochemist, and the other by radiochemist Edmund Storms, whose book is the subject of this review. It must be recalled that the claim of cold fusion is astonishing to anyone with a smattering of knowledge of physics. The fusion of deuterons is resisted strongly by electrostatic forces keeping these positively charged particles apart. Fusion can be achieved by heating a plasma (hot fusion), and theoretical studies of the expected rate of fusion at low temperatures, as obtains in an electrochemical cell, predict rates so low that nothing will be detected. There are, then, good reasons for being skeptical of cold fusion claims. A book such as this one, however, makes a strong case for cold fusion, not only by the results presented, but also by the impression the reader gets of the writer. Storms is a working scientist, and this shows clearly in the book. He begins with a clear statement that he is convinced of the reality of cold fusion (preferring to call it low energy nuclear reaction or LENR). He is not-like some proponents of the phenomenon-oblivious to the weaknesses of many claims, that is, he shows the proper critical attitude of a normal scientist and will (mostly) not accept unsound evidence. Much shoddy work has been done in the field, but after eliminating this, some evidence remains that leaves the skeptic in a quandary; the phenomenon is unlikely to be real for many reasons, but there is much evidence nevertheless that it may be. Storms does his best to point out such

evidence based on his own work. The book contains an interesting account of his own work, and to a practicing scientist, he conveys a true picture of science as it is done: it rings true to someone who is a working scientist.

The book is divided into ten chapters and six appendices. It begins with an overview, a brief history of the field and (Chapter 3) a description of Storms's own work. The book's strength lies here, and the scientific reader will feel at home. Chapter 4 outlines what is known or believed; Chapters 5 and 6 focus on where cold fusion might occur and how perhaps to affect or even initiate it by means of experimental parameters. Chapter 7 considers fusion products and their detection, and, in the last chapters, Storms looks at some theories, the future of the field, and, in Chapter 10, provides a brief summary. Each chapter has its own bibliography, with Chapter 4 having a massive 646 citations.

The claims by Fleischmann, Pons, and Hawkins and of Jones et al. immediately engendered an embittered controversy between the "believers" and the "skeptics", with arguments and evidence not always strong on either side. In general, one should be wary of blank pronouncements by scientists that something is impossible, and as Storms points out, although there is as yet no good theory of cold fusion, the experimental evidence is not easy to dismiss (in his view, it proves the phenomenon real beyond doubt). As mentioned above, the Bibliography has over 1300 entries. Compared with other fields that appeared around the same time, such as high temperature superconductivity, however, this is not a large number. The Bibliography also shows that the publishing rate rose sharply initially, but fell roughly exponentially thereafter, similar to the polywater affair (Franks, 1981), a curve that has been likened to the course of an epidemic (Bennion & Neuton, 1976). Many journal editors flatly refused papers on cold fusion, and some referees probably rejected papers not so much on the basis of the evidence presented, but on the basis that cold fusion simply must be an error. It must also be said that many cold fusion papers submitted (and published) have been of poor quality and deserved to be rejected. Storms agrees with this. The result has been that in recent years, although some work is still appearing in mainstream serious journals, most work now appears in enthusiast journals, where refereeing probably is not very strict. If these articles were counted (which they are not in the Bibliography), then several thousand papers have been published. Storms himself has published some of his work in these journals, no doubt tired of unfair rejections by the normal journals.

When two deuterons fuse (against a strong electrostatic barrier), there are three branches along which the reaction can proceed, two of them the most probable. One branch leads to tritium and a proton, the other to helium-3 and a neutron, and the third branch, normally occurring with a frequency of only 10^-7 that of the other two, to helium-4 and highly energetic gamma emission. In all cases, the end result is particles carrying extra energy corresponding to lost mass to be dissipated in various ways. This all happens in "normal", that is, hot, fusion. Skeptics argue that all emissions must be present, while proponents point to one or two of them as proof, or they say that the process may not be the fusion of deuterons, but some "hitherto unknown nuclear process" (Fleischmann Pons, & Hawkins, 1989). They insist that experimental observations are paramount, and the lack of theory will be made up later. Storms takes this view, hence his use of "LENR".

Storms' own work concentrates on tritium production and "excess heat". Storms was ideally placed at the Los Alamos National Laboratory (LANL) to detect tritium. When a solution of an electrolyte in heavy water is electrolysed at length, deuterium gas is given off but also some tritium, contained as an impurity in the heavy water (and perhaps also in the palladium). Storms is careful to account for these sources. His findings are interesting: excess tritium appears first in the electrolyte, not in the effluent gas, indicating that it is produced at the palladium electrode. Storms was careful to perform control experiments aimed at eliminating environmental effects (at LANL, there might occasionally be tritium in the air) and convincingly shows that they were indeed accounted for. Similar results were obtained by Will, Cedzynska, & Linton (1993), equally competently obtained, and the skeptic is hard put to reject these results.

Excess heat is measured with a calorimeter. There is current passing through an electrochemical cell, with a voltage across it, producing an input power, and the electrolysis reaction absorbs some of this power at a well-known rate. Effluent deuterium and oxygen might carry off some heat, and heat is both radiated and conducted away from the cell. To keep track of all this is not trivial, and Storms became expert in calorimetry over the course of years, as problems were found, some of them by skeptics and addressed by him, carefully doing control experiments to assess the magnitude of interference effects. One of them is the way the temperature inside the cell is measured. There may be temperature gradients inside the cell, and this problem can be overcome by a better calorimeter design, as was done by Storms. If in the accounting of the known input and the measured output powers there is an excess, this indicates the

presence of some phenomenon producing heat. One problem is the irreproducibility of the effect; only some electrodes show it and not all the time. This is one of the strong points that skeptics make. A new effect must be reproduced by others, and this has not been done to the skeptics' satisfaction, even after almost 20 years. Reproducibility can only be achieved, however, when we understand all the factors at work, which is not the case here, so irreproducibility itself does not invalidate cold fusion. Needless to say, Storms tried many different variables: various sources of the palladium, how best to vary current with time, how best to load the palladium with deuterium, what loading degrees are needed, and surface treatment of the metal before the experiment. The results do not yet give a very clear picture.

So the book makes a good case for cold fusion. There are some weaknesses. Some of the figures are poorly done, and the text is often awkward. Some expert criticism of Storms' calorimetry (Shanahan, 2006) is not mentioned, and there is some imbalance in attribution: to some extent, The work by Jones's team is reemphasized in favor of that of Fleischmann and Pons's team. Storms is not good especially with foreign names, mangling some of them, and Kirk Shanahan, one of his staunch critics, appears as "Kurt Shanahan" in the Index. Storms suggests the fusion of up to six neutrons with some nuclei, which will surprise many. The term "enthusiast" applies to Storms. The word "amazing" is seen six times in the book, and his critical attitude does seem to lapse at times. For example, he appears to accept what has been called "biological fusion" (Kervran, 1972), which is even less likely to be real than cold fusion, and even suggests that it might be behind spontaneous human combustion; and he also accepts claims by Mills & Kneizys (1991) of electron orbitals of the hydrogen (or deuterium) atom below the ground level, although here Storms appears to be a little skeptical, admitting that there is a lack of theory (which can equally well be said of cold fusion). In Chapter 9, he writes "... the skeptics went to war- a war they have now lost". In the Preface, he writes that cold fusion has now been proved. Many would disagree and remain unconvinced. So, the book is not n neutral on the subject. Nevertheless, these weaknesses are comparatively minor and do not detract from the major message of the book, the rather solid experimental evidence of some exotic process taking place, from a careful and self-critical researcher.

What then is the bottom line? This writer is still agnostic with respect to cold fusion because even a thorough worker like Storms has not succeeded in demonstrating the effect at will. This is not to say that we can dismiss cold fusion but simply that we must wait for evidence so convincing that even skeptics must accept it as real. If it indeed is real, then it is subject to parameters that as yet elude most workers in the field. Other newly discovered phenomena have been irreproducible for some time (albeit rarely for 18 years as here) and this alone does not prove it to be false. We shall have to wait and see. The Storms book certainly is recommended reading, for both skeptics and proponents.

2) Faradic efficiency thread on CMNS list for researchers (Inserted on 3/5/08)
I am neither chemist nor electrochemist. But two messages under this thread are worth recording. One was from our electrochemistry and calorimetry expert, Mike McKubre and one from the author of the above review, Dieter Britz.

3) On 3/4/08 Mike wrote: This debate is diverging. I suggest we propose a new rule to encourage convergence. Let's call it: QUANTIFICATION.

A lot of the more subtle condemnation of cold fusion is disguised - as in politics - behind unspecified doubts concealed in the implication that electrochemistry is "too complicated", contains "unknown or mysterious" variables, somehow an "art not a science" --- you know, sort of like witchcraft. IT IS NOT! Let us role back this deception, I suspect unsuspectingly practiced by some on this list. The way forward is NUMBERS!

Under this rule new material can be entered into the discussion if it is clear the the proponent has made numerical estimates of the effect he proposes. I am not picking on Dean, Dieter or Scott but am going to use their recent input as examples of how things might change (I argue for the better) with the influence of such a rule.

Lithium forms several substitutional alloys with palladium. The reaction enthalpies can easily be found by anyone with access to a library or internet. Let's take (for example) the most famous experiments of F&P and calculate how much enthalpy could be released (you need the volume of electrolyte times the Li concentration, the putative phase formed and the Li heat of solution times the volume of Pd). If that number is small compared with the excess energy observed then we can stop. If not then we need to dig a little deeper and quantify the extent to which Li can deposit in aqueous electrolysis and how far it can diffuse into the Pd*. I am not going to do it for you - but I recommend the exercise.

Scott asked about electrolysis current below the formal breakdown potential. We have gone round this loop before and I took some trouble to answer it in terms of electrochemical kinetics and thermodynamics. I don't want to discourage debate but I do want to encourage learning. To make the question and answer quantitative one needs to look at the solubility and diffusion of molecular D2 and O2 in the solution (water) and recognize that - if the solution contains no dissolved D2 or O2 then the breakdown of water can occur at an (unspecified) low voltage. Ficks first law, the diffusion coefficient and the diffusion layer thickness will get you near-quantitative answers. The answer to this question will also help with the answer to the next.

I was surprised to see Dieter as a proxy for Shanahan's straw man make a Hillary-like** statement that he "I don't know whether this happens or not, but that is his argument." Why don't you know? If you don't know, why introduce the unsupported argument of another? You have all the expertise to do the experiment and access to a good library. Information on the catalyzing power of Pt and Pd under a monolayer or more of water is readily available as this is very important in fuel cells and heterogeneous catalysis. I am cheating a little bit here as my electrochemistry group in 1989 was studying fuel cell electrode kinetics, and happened to have been situated in the middle of a world famous group studying all sorts of heterogeneous catalysis. With a simple walk across the hall I was able to learn that the catalyzing power of wet Pt or Pd was about the same as pyrex (*i.e.* nil). Even so we still measured and studied the effect and ran closed cells to avoid it.

But the information is out there for all. If you don't know how to frame the calculation then you are probably not going

to understand (or therefore accept) the answer. We need to commit to work to make progress, not endlessly answer 1989 questions. As proponent and so far sole supporter of the QUANTIFICATION rule I pledge to not introduce new matter except with quantification and not respond to new matter on this topic unless it is quantitatively bounded. . . .

4) On 3/5/08 Dieter wrote:

IT IS NOT! Let us role back."

I hope you are not suggesting that I have some sort of agenda, other than providing information where I can. I do not. I am neutral on the subject, and would indeed be pleased if CNF turned out to be a real effect. But it has to be proven, not just assumed because it's nice thought.

He also wrote "Lithium forms several substitutional alloys with palladium. The reaction enthalpies can easily be found by anyone with access to a library or internet. Let's take (for example) the most famous experiments of F&P and calculate how much enthalpy could be released (you need the volume of electrolyte times the Li concentration, the putative phase formed and the Li heat of solution times the volume of Pd). If that number is small compared with the excess energy."

That is not necessary, because we know that very little of that Li is deposited; this has been measured to be at most 1 atomic% in a very thin layer near the Pd surface. No sausage there. There have been suggestions that the redissolution of the Li might cause heat bursts, but this will not happen during electrolysis, so that is not on either.

He also wrote "I was surprised to see Dieter as a proxy for Shanahan's straw man
make a Hillary-like** statement that he "I don't know whether this "

I am not a straw man for anybody, mate. I was just thinking of all possible side reactions that might take place, in the framework of faradaic efficiency, and this was one of the suggestions. You are echoing somebody else here, who insists that I have this anti-CNF agenda. I repeat, I do not.

I like people to get their facts straight. I don't have them all myself, but when I have some, or some ideas, I point them out. That makes me unpopular on both sides of this debate. I got into Morrisons's bad books by demolishing his "cigarette lighter effect" which he thought at one time would explain excess heat. My agenda is for people to believe what they believe, for the right reasons. I do think I have made it clear the last week or so, that I do not believe that faradaic efficiency less than 100% is the cause of excess heat.

5) On Mar 5, 2008, Mike McKubre wrote:

I am not sure I qualify as your mate, but hopefully no hard feelings. I am happy to consider all plausible reactions. What distinguishes plausible from possible is quantification. Actually I was not echoing any other comment that you have an anti-CNF bias. I have never heard that and have seen no evidence of it. In fact I believe the opposite and am trying to extract maximum benefit for the community.

He also wrote "My agenda is for people to believe what they believe, for the right reasons. I do think I have made it clear the last week or so, that I do not believe that faradaic efficiency less than 100% is the cause of excess heat."

That last clause was not clear - at least to me. From someone with your background and credentials that conclusion is significant. What I objected to was you raising Shanahan's dead horse - without doing the experimental or theoretical walk through - apparently (now) when you did not believe it was relevant to our experiments. Of course you are free to

contribute whatever you want - it will all be good. My point is that divergence promotes confusion.

6) On March 6 Dieter wrote:
In this case, somebody asked, in effect, what is faradaic efficiency, and I was trying to think of all possible effects that might reduce that. Then someone mentioned oxygen being reduced at the cathode, and hydrogen oxidized at the anode. Some appear to believe that this is what Kirk Shanahan proposes, and to counter this I added what he actually does propose. Even had I been aware that this has been experimentally tested and discounted (which I was not), I would have felt bound to mention it, to avoid this misunderstanding of what Kirk is saying. I like this forum because it seems to me that we can have rational arguments here, without excess heat. I hope it stays like that.

7) My comment (3/6/08)
Messages keep popping up under this thread. That is not my field. But I am happy to see disagreements among subscribers to the CMNS list. That is a sign of health. How different is it from what I often hear from people who say that they already know (since early 1990's) that “cold fusion” is pseudoscience. These people do not want to “waste time” on reading reports from ongoing experiments.

8) CR-39 work
My numerous attempts to get information about recent CR-39 findings (of SPAWAR team and of those who cooperate with SPAWAR) were not successful. The seem to prefer not to share preliminary results on this list (or with me via private messages), as they did so generously before Catania conference. Why is it so? But I am corresponding privately with Richard Oriani. He is making progress in trying to publish a paper on his most recent results (tracks originating deep inside CR-39). I am affraid that sharing what I know here might interfere with the process. But I do plan to write about this (with Richard's permission) later.

9) ICCF14 The next CMNS conference will take place this summer in Washington DC. The exact date will probably be announced shortly. I expect the ICCF14 to be dominated by experimental reports from Iwamura et al. (evidence for transmutation) and from Storms et al. (evidence for nuclear activity during glow discharge). Also by the report from Boss and from Oriani (evidence for nuclear particles resulting from a process induced by electrolysis).

345) My comments on Storms' new book

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 4, 2008

A published review of Ed Storms' book can be seen in unit 344. This unit consists of my own observations. I agree with Dieter Britz, the author of the review, that the book is recommended reading, for both skeptics and proponents of so-called "cold fusion." Storms also uses this term "for the sake of consistency and habit." Most scientists are not familiar with more recent terms, CMNS and CANR. For that reason the term cold fusion seems to be appropriate.

The list of references alone has a tremendous historical value; no one but a scientist who participated in cold fusion research from the very beginning could compile such list of publications, and to categorize them logically. The publications belong to two categories: those which demonstrate excess heat and those which demonstrate other manifestations of nuclear processes due to chemical (atomic and molecular) activities. Both kinds of research are important, according to Storms. But investigations of excess heat are more urgent because nuclear reactions producing excess heat are numerous, and because they might lead to practical applications. Referring to excess heat Storms writes (on page 50) "More important, the Fleischmann and Pons observation was unique because the high rate might allow their process to become a competing source of energy and a thread to conventional theory, rather than being simply a scientific curiosity. A mere scientific curiosity can be accepted without a battle; an economic and intellectual thread cannot."

Chapter 4, entitled "What is Known or Believed" is a very good summary of all kinds of cold fusion research, first excess heat, then production of tritium, production of helium, transmutations and emission of nuclear particles. I was familiar with many publications mentioned in that chapter. But reading the summaries and comments made by Storms was very useful and eye opening, especially when common features were emphasized. What follows is a paragraph from a message I posted on the Internet list for CMNS researchers. Unfortunately, this was done in the form of a side comment, under a different thread. That is probably why only one person responded to my message.

On 3/28/08 I wrote: "Why do we say that excess heat discovered in 1989, and confirmed in hundreds of replications, is due to a nuclear activity? Perhaps it is due to an unknown gravitational phenomenon, to an unknown magnetic phenomenon, to an unknown electric phenomenon, to an unknown chemical phenomenon, etc. ? I am familiar with only one answer -- production of ^{4}He. Production of each atom of ^{4}He is associated with production of about 23 MeV of excess heat. Uncertainties about the 23 MeV could be reduced in better experiments. In my opinion, experiments in which generation of ^{4}He and generation of excess heat take place are worth performing. Hopefully they will show that in at least one kind of experiment excess heat seems to be nuclear. Am I wrong that production of ^{4}He is the only case in which nuclear ashes mach excess heat? " The person who responded wrote: "The Fleischmann-Pons effect clearly involves a nuclear reaction. Of course, other sources of heat might be produced at the same time, but the main heat is clearly from a nuclear reaction."

That was certainly not clear in 1989. The only reason for nuclear interpretation, as far as I recall, was a theory according to which the pressure of deuterium ions, loaded into palladium, as calculated by Fleischmann, was high enough to allow fusion of individual deuterons. He did not write anything, at that time, about cold fusion being totally different from hot fusion. He and Pons performed an experiment whose purpose was to justify nuclear origin of excess heat by neutrons, presumably emitted from their electrolytic cell. The results of that experiment, by the way, were later shown to be in error. Neutron emission, according to Storms (page 78 of his book) is seldom found even though over

500 papers have described efforts to detect them." In section 4.4.2 Storms describes several experiments in which amounts ^{4}He was measured. These experiments continue to be the only evidence of nuclear origin of excess heat in cold fusion.

Let me now focus on topics of general interest; as described at the end of Chapter 4. Two common aspects of many electrolytic excess heat experiments are emphasized by Storms -- the dependence of the rate, at which thermal energy is generated, on the mean density of deuterium in palladium and its dependence on the current density. But experiments are not reproducible on demand. Why is it so? Because no one knows what other conditions must be satisfied. Thermal energy is released "when a lucky combination of conditions has been created." A special term, NAE (nuclear active environment) is used to identify a material in which such conditions are satisfied.

On page 13 Storms writes: " Some people are simply unable to evaluate observations with an open-mind because, to them, truth is only defined by theory. If theory and observations are in conflict, theory wins." That attitude is called faith-based science; it is not reality-based science, "the kind of science we are taught to respect." The relation between experimental facts and explanatory theories is profound and worth discussing. Absence of a theory linking NAE with what has already been learned about nuclear phenomena is deplorable but it does not mean that a rational explanation of NAE will not be found. In Section 4.2 Storms writes: "Indeed absence of conventional nuclear products of any kind [in 1990], except perhaps tritium, made the high rate claimed for heat production suspicious in many people's eyes. While this was a legitimate concern, rejection did not wait until the proper measurements were made. Only now, 18 years later have the nuclear products been detected on a sufficient number of occasions and with sufficient care to be credible."

In my opinion, cold fusion would not be rejected prematurely if the initial announcement of the discovery of excess heat were not accompanied by then-unjustified claim of its nuclear origin. The architect of rejection, John Huizenga, is described (on page 15) as "a competent scientist and teacher. ..... He was not about to change his mind, especially while so many questions remained unanswered." I had a chance of discussing nuclear topics with Huizenga -- at least two decades before the discovery of cold fusion -- and I agree that he was an extremely competent nuclear scientist. People like him feel that defending science from unreasonable claims is one of their moral obligations. The claim of nuclear origin of excess heat became reasonable only when production of helium, at the rate of approximately $2.65*10^{11}$ atoms per joule of thermal energy, was discovered and confirmed by qualified electrochemists. The inverse of this number, 23.5 MeV per atom, happens to be $E=m*c^2$, where c is the speed of light and m is the difference in mass between one ^{4}He atom and two ^{2}H atoms. This seems to support the original idea that ^{4}He results from fusion of two deuterons. But, as explained in Section 8.3.1, other nuclear mechanism to produce helium are also possible. The history of cold fusion would certainly be different if generation of excess heat and production of helium were announced at the same time.

It is interesting that Ed Storms is well aware that "In this business, too much willingness to be open-minded can be a danger." This observation, made on page 28, refers to his refusal to cooperate with an alchemist Joe Champion. I do not think that the pyrotechnical method of turning other elements into gold, suggested by Joe, can be qualified as cold fusion. The idea of associating one mystery with another mystery, especially when connections are not clear, can indeed be counterproductive.

The following hypothetical situation can be considered after reading section 4.8. Suppose that a team A makes a claim that excess heat has been observed and that it is due to accumulation of deuterium (from the D_2O in the electrolyte) in a palladium cathode. This is not very different from the claim made in 1989 by Fleischmann and Pons. But their situation was complicated by secondary factors, such as competition with Steve Jones, pressure from university administrators, and involvement of lawyers. That is why I prefer to deal with hypothetical situations. Note that the A team makes two claims, one is generation of excess heat and another is a mechanism by which this happens.

Suppose that B, who is not an experimentalist, makes the following comment. "If your explanation is correct then generation of excess heat should not take place when the D_2O is replaced by the H_2O. Perform the experiment and report the result." The team A returns to the laboratory performs an experiment and find that excess heat is also produced when the H_2O electrolyte is used. After learning about this B proclaims: "Aha, your theory is not good."

That would be a reasonable kind of thinking, considering what was known at that time. Another possible proclamation, made by B, could be: “Your claim about excess heat must be rejected because it conflicts with your own explanation. Not too many deuterons are present in the new electrolyte and excess heat due to deuterons is impossible.” That would be a totally unreasonable conclusion; the only way to refute generation of excess heat would be to perform an experiment and to show that excess heat is not generated.

This, however, as pointed out by Storms, is not simple because preconditions for success, in obtaining excess heat, are not known. The control experiment performed by B is likely to different from the experiment performed by A? That is indeed a very important point. It means that replications cannot be trusted, even when all researchers are highly qualified. In my opinion, that fact alone is sufficient to say that cold fusion is still protoscience. A field in which something occurs only “when nature is in a good mood” should not be called science. Absence of a generally accepted theory can be tolerated in a new field of science. But absence of reproducibility, when experiments are performed by qualified researchers, is not acceptable. Science has too much to loose from not insisting on “reproducibility on demand.” To be admitted to the prestigious club called science, cold fusion must offer at least one reproducible on demand experiment in which a nuclear process results from a chemical process.

Protoscience, like science, should be financially supported. The amount of money allocated to any field of research should be based on its potential benefits, both scientific and practical. I agree with Ed that “For a theory to be useful, the logical consequences of the model must be consistent with observations, including what is not observed, and with well established physical laws.” The issue of an acceptable theory and the issue of reproducibility on demand are intimately linked. Theoreticians need reliable experimental data, to validate predictions, and experimentalists need reasonable predictions to guide them. That is why I think that an acceptable theory is likely to emerge once experimental data become reproducible on demand.

In Chapter 8, Ed wrote that “incorrect assumptions in theories are equivalent to experimental errors in observations. Both lead to false conclusions and distract from general acceptance.” I like this comment. What he probably had in mind are systematic, rather than random, experimental errors. Random errors in experiments are unavoidable and fluctuation of results by a small percentage is usually acceptable in a new investigation. In other words, differences of up to about 10%, between results reported by several teams, would not interfere with the idea of reproducibility on demand, at least in some kinds of investigations.

Appended on 4/5/08 (some speculations):
According to section 7.9, most helium is produced when alpha particles slow down. If this is true then a lot of alpha particles must be emitted. SPAWAR people did say that the track density in CR-39 was very high in their experiments. But no convincing evidence was presented that tracks were due to alpha particles, or to other nuclear projectiles. Let me assume that heat is generated at the rate of 0.5 W. This translates into 0.5 J/s or to $3.12*10^{12}$ MeV/s. The energy cost of producing one helium atom was reported as 23.5 MeV. The corresponding rate of helium production, as indicated earlier, would be $3.12*10^{12} / 23.5 = 1.33*10^{11}$ atoms per second.

Note that fusion of two deuterons, originally believed to be the mechanism by which nuclear energy is released, does not call for emission of alpha particles. Recall that the name “cold fusion” was chosen to describe such mechanism, at common temperatures. In section 8.3.1 Storms reminds us that the “d-p fusion should be more common than d-d fusion.” But no evidence of d-p fusion was found. On that basis one must conclude that the d-d fusion is not a dominant mechanism by which nuclear energy is released.

What are other possibilities? That question is also answered in section 8.3.1. One of the possibilities is fusion of a deuteron with ^{6}Li. This produces a highly unstable ^{8}Be nucleus which is known to instantly decay into two alpha particles. The kinetic energies of each of these particles is 5.6 MeV energy. Note that the coulomb barrier for the d-Li fusion is much higher than for the d-d fusion. How many alpha particles would be emitted per second via the d-Li mechanism at 0.5 W? The answer is $3.12*10^{12} / 5.6 = 5.57*10^{11}$. Four other mechanisms, for producing alpha particles are described in the same section. In section 8.3.2 Storms describes mechanisms that can possibly be responsible for production of much heavier elements. One of them is fusion of deuterons (for example, one after another) with an atomic nucleus of palladium. This would produce an excited compound nucleus undergoing fission. Is it conceivable

that Cu and Fe are fission products?

My doctoral dissertation (1963) was to study fission resulting from bombardment of uranium, bismuth and gold with protons of 156 MeV. Later I participated in several projects in which fission of lighter nuclei, induced by heavy ions (after they fused with targets at various energies), was studied. On the basis of what I know, I would say that the probability of fission would be negligible in comparison with other mechanisms of de-excitation, such as emission of neutrons and protons. Note that the coulomb barrier for the d-Pd fusion, as mentioned by Storms, is very much higher than for the d-d fusion. That is another obstacle. Trying to explain presence of transmutation products by ideas taken from familiar nuclear physics does not promise to be successful. Something totally different is needed to explain experimental results. Polyneutrons? Erzions? Hydrinos? Crazions? Sanions? Smartions? Whatelsions? I predict that the answer will be found not later than one or two decades after a reproducible on demand protocol is offered to generate transmutation products. Yes, many of us will not be around to verify this prediction.

346) Information for users of CR-39

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 6, 2008

0) Chemical composition and some proprties of CR-39 are shown at:
http://tinyurl.com/yp6ld5
Last page shows that density is 1.31, refractive index is 1.498, and that 89-91% of light is transmitted.

1) CR39 detectors are likely to play an important role in CMNS research. With this in mind, all researchers should use the same etching conditions, and the same calibration curves. Otherwise it would be difficult to directly compare our experimental results. A calibration curve is a relation between the track diameter and the particle energy (for perpendicular exposures and for a chosen etching protocol). Calibrations experiments were performed by Russian scientists: Andrei Lipson, Alexei Rusetski and Eugeny Saunin, as reported at the 8th International Workshop on Anomalies in Hydrogen/Deuterium Loaded Metals (Catania, October 13-18, 2007).

Their standard etching times (in 6N NaOH at 70 C) are 7hrs, 14 hrs, 21 hrs and 28 hrs. The layers of the CR-39, etched away during these times, can be calculated from the known bulk etching rate of 1.32 microns per hour. Thus etching for 28 hours will make the CR-39 chip about 2*37=74 microns thinner. Note that the range of a 5 MeV alpha particle in CR-39 is approximately 30 microns. Longer etching can be used to reveal tracks due to alpha particles produced inside the CR-39 material.

2) The experimental data for the calibration curves are available for protons between 1 and 2.5 MeV, and for alpha particles between 5 MeV and 13 MeV. What follows are equations which fit experimental data points. Note that x is the energy in MeV while y is the corresponding diameter in microns. Also note that diameters might depend on some difficult-to-control parameters, such as additives added during manufacturing, time of storage, conditions of storage (air versus vacuum), etc. etc. For that reason, relative diameters might be more informative than absolute diameters.

Alpha Particles (5 to 13 MeV)
Etching for 7 hours: $y=12.364*x^{-0.2169}$
Etching for 14 hours: $y=30.556*x^{-0.3733}$
Etching for 18 hours: $y=81.763*x^{-0.6785}$
Etching for 21 hours: $y=145.04*x^{-0.8321}$

Protons (1 to 2.5 MeV)
Etching for 7 hours: $y=7.1395*x^{-0.3363}$
Etching for 14 hours: $y=9.6093*x^{-0.5057}$
Etching for 18 hours: $y=12.354*x^{-0.6143}$
Etching for 21 hours: $y=15.611*x^{-0.7608}$

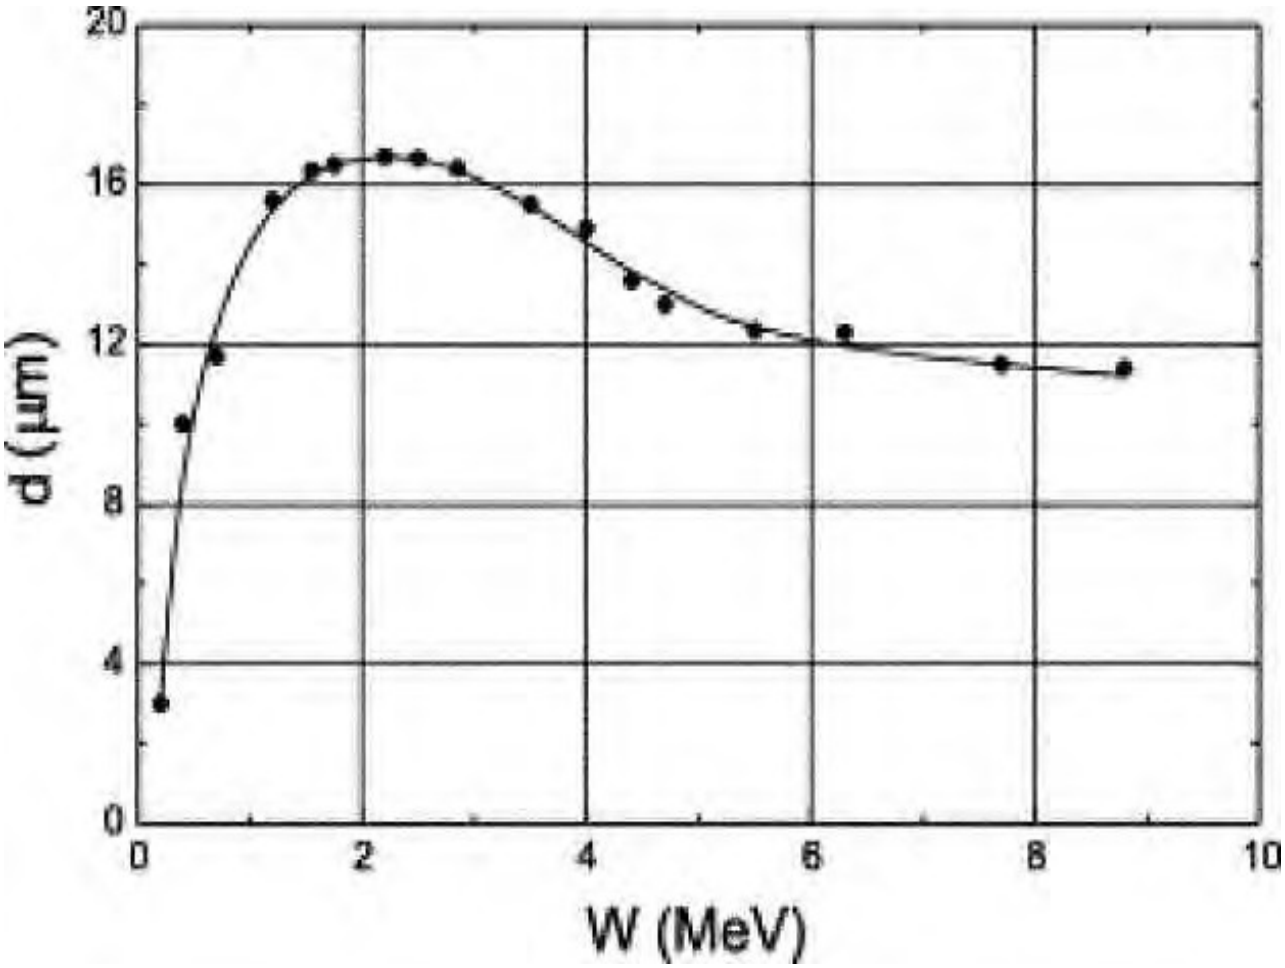
The plots of these eight functions, together with actual data points, can be seen at

http://www.iscmns.org/catania07/RussetskiAanalysisof.pdf

3) It is well known that most alpha-radioactive substances emit particles with energies between about 5 MeV and 8

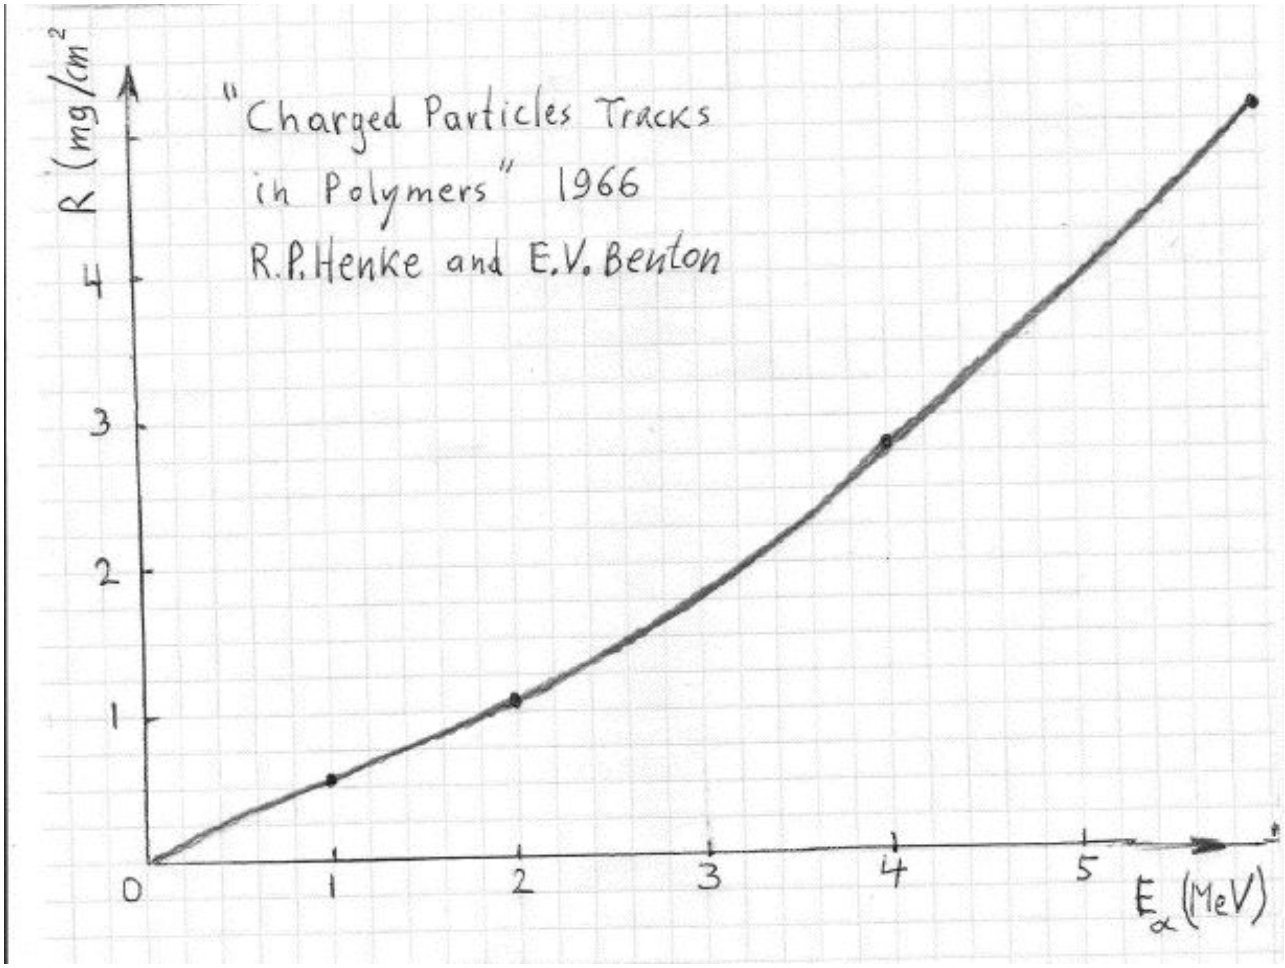
MeV. For these particles, the diameters, after 7 hrs of etching (in 6 N NaOH at 70 C), should be between about 8.7 and 7.9 microns, for nearly perpendicular incidences. For oblique incidences, tracks are expected to be more or less elliptical and the y would refer to the width of an elongated track. A track whose diameter, or width, is significantly smaller than 7.9 microns could not be attributed to an alpha particle from a natural contaminant. But it can be due to a triton, or to a neutron colliding with a proton. Likewise, a track whose diameter, under the same etching conditions, is larger than 15 microns cannot be attributed to an alpha particle from a natural contaminant. But it can be attributed to a fission fragment, for example, from spontaneous fission of uranium.

4) It is important to keep in mind that these equations should not be used outside the energy ranges specified above. Diameters do not continue to increase with decreasing energies. At some points diameters are known to decrease, rather than to increase, as illustrated in the figure below. That figure, due to Dorschel (1995?), is a calibration curve for alpha particles with data points for energies smaller than 5 MeV. The etching conditions were probably different from those used by Russian scientists. Perhaps the concentration of the NaOH, or etching temperature, or etching time, were higher than those chosen by Lipson et al. I am saiying this because Dorschel's diameters at 5 MeV and 8 MeV are 13 microns and 11.5 microns, respectively. These values are nearly 50% higher than those calculated from the first equation above. Extrapolations of the equations toward lower energies are likely to result in large systematic errors.



This curve was posted by a researcher on our Internet discussion list. But I also found it (in a slightly different form) in C. Brun, M. Fromm, M. Jouffroy, P. Meyer, J.E. Groetz, F. Abel, A. Chambaudet, B. Dorschel, D. Hersmdorf, R. Bretschneider, K. Kander, and H. Kuhne; "INTERCOMPARATIVE STUDY OF THE DETECTION CHARACTERISTICS OF THE CR-39 SSNTD FOR LIGHT IONS: PRESENT STATUS OF THE BESANCON DRESDEN APPROACHES," Radiation Measurements, vol 31, (1999), pp 89-99.

5) The next figure shows the range-energy relation for alpha particles in polymers (plotted by me a long time ago) is shown below.



6) To convert ranges from mg/cm^2 to microns one must know the density of a particular material. The density of CR-39 is 1.3 g/cm^3. That is why the range of 5 MeV alpha particles is close to 30 microns. For a material of density 1.0 the number of microns would be ten times larger than the number of mg/cm ^{2}. That is a good rule of thumb for crude estimates, even when densities are slightly different from unity.

7) Ranges of alpaha particles in air (at 20 C and 1 atm) are shown in the table below.

Here is a table showing how energies depend on distances between the CR-39 and the source of 5.5 MeV alphas, in air at 1 atm and 20 C. This table was constructed on the basis of 1966 data. I am certain that these data are reliable, but I will try to produce a similar table on the basis of more recent data.

Energy (MeV) ..... Range(cm)
1.0 . . . . . 0.50
2.0 . . . . . 1.00
3.0 . . . . . 1.68
4.0 . . . . . 2.60
5.0 . . . . . 3.63
6.0 . . . . . 4.78
7.0 . . . . . 6.02
8.0 . . . . . 7.35
9.0 . . . . . 8.77

Suppose an 241Am source (initial energy is 5.5 MeV) is used to calibrate a detector. How does the energy of alpha

particles depend on the thickness of air between the source and the detector. The answer is shown in the next table. It was produced on the basis the above data.

distance .....energy

0.5 cm..... MeV
1 cm..... MeV
2 cm..... MeV
3.5 cm..... MeV
3.75 cm..... MeV
3.9 cm..... MeV

Here are two usedul equations to calculate energy from distance, or vice versa.

E =5.416 - 0.5646 * d - 0.1790 * d^2

d = 4.092 - 0.31705 * E - 0.07847* E^2

Each of them is a reasonable fit for the data in the above table.

Appended on 4/28/08
8) Looking for something else I found an interesting paper. The title is "Variation of alpha-particle track diameters in CR-39 as a function of residual energy and etching conditions." The authors are A.H. Khayrat and S.D. Durrani. The paper was published in February 1999 (Radiation Measurements, vol. 30, Issue 1, pages 15-18). Can the track diameter be used for [rough] energy spectrometry [in the energy region between ~1 MeV and ~ 5 MeV]? The authors explore conditions under which this should be possible. They used a source of alpha particles whose initial energies were 5.5 MeV. Energies of particles entering the detector, E, were controlled by the amount of air between the source and the detector. These energies were actually measured by using a calibrated surface barrier detector, connected to a multichannel analyzer. Collimating tubes were used to make sure that angles of incidence were small. In other words alpha particles were entering detectors nearly perpendicularly. The etching solution was 6 M NaOH at 70 C.

9) The bulk etching speed, Vb, in CR-39, was measured by using a 252Cf source of fission fragments. Presumably, it is well known, that for fission fragments the track diameter, D, is directly proportional to the etching time (D=2*Vb*t). In other words Vb was determined by measuring D and t for several tracks. The track etching rate, Vt, was determined by authors by measuring the etch-cone length, Le, after the etching tile t. The used relation was Le= (Vt-Vb)*t . The Le seems to be the depth of the track. But the method for measuring it is not specified. Ranges of alpha particles of different energies in CR39, were calculated using a computer program based on old Henke and Benton's data. How do ranges plotted in their Figure 2, differ from those I plotted above? The answer is in the following table (numbers read from their Figure 2):

Alpha energy . . . Range in CR-39

5.5 MeV .....33 microns
4.0 MeV .....20 microns
2.4 MeV .....10 microns
1.6 MeV .....7 microns
0.8 MeV .....3 microns
0.0 MeV .....0 microns

10) Figure 3, in their paper, shows how the values of dE/dx (in MeV per g/cm^2) depend on energies of alpha particles.

Alpha energy..... dE/dX

5.5 MeV 800
4.0 MeV 1000
2.4 MeV 1400
1.6 MeV 1780
0.8 MeV 2000
0.4 MeV 2200
0.1 MeV 1900
0.0 MeV 0

11) It is convenient to think about dE/dx as an indicator density of ionization, or as degree of damage created by the particle in the CR-39 material. Note that dE/dx reaches a maximum when the particle is nearly stopped. The fact that dE/dx decreases rapidly when particles slow down can easily be explained. At the end of their ranges alpha particles catch two electrons (one after another), and turn into neutral atoms of helium. The dependence of dE/dx on E is after called Bragg's curve.

Note that If diameters of tracks were proportional to dE/dx, at corresponding energies, then diameters of tracks due to alpha particles of ~ 1 MeV would be two times larger that diameters of tracks due to alpha particles of 5.5 MeV. The authors did measure diameters of alpha particles at different energies and results are shown in their Figure 5. According to that figure, the diameter for 5.5 MeV particles was found to be close to 4.5 microns while diameter of 1 MeV particles was found to be close to 7 microns. For 3 MeV particles diameters are close to 6 microns while diameters below 1 MeV quickly decrease to zero, just like the values of dE/dx. It is important to emphasize that these results were obtained with etching times of 2 hours. The ratios of diameters at longer etching, for example, at 5.5 MeV versus 1 MeV, are usually much smaller, as illustrated by Dorschel's calibration curve (see my Figure at point 4 above).

12) The main point of this study is to show that it is possible to estimate energies of alpha particles on the basis of track diameters, provided etching times are very short. The slope of their curve in Figure 5 (track diameter versus the energy above 1 MeV) is approximately 0.6 microns par MeV. Suppose a CR-39 chip is exposed to alpha particles of 1.5 and 5.5 MeV. Then diameters of tracks due to low energy particles will exceed diameters of tracks due to high energy particles by 4*0.6 = 2.4 microns. This is measurable, under high magnification. Yes, the energy resolution offered by CR-39 detectors is not as high as that offered by silicon detectors. But ability to distinguish low energy alpha particles whose energies differ by two ot three MeV might be appreciated in applications in which only CR-39 can be used.

13) Why did I not say anything about Figure 4, and text describing it? Because this part is not clear to me, except for they way of etching. Instead of etching for only two hours, the chips were etched for times t=R/Vt, where R is the range of alpha particles. In other words chips exposed to alpha particles of higher energies were etched longer than chips exposed to alpha particles of lower energy. The dependence of diameters on energies of alpha particles is plotted as curve (a) in Figure 4. The rate at which diameters increase with energy is high, about 10 microns per MeV, for E>4 MeV. But how much of the slope is due to longer etching times (at higher energies) and how much (if anything) is due to other factors? The authors are trying to answer this question but I cannot understand them.

Appended on 4/29/08

14) According to my Unit #347, SPAWAR team works under the hypothesis that nuclear tracks, produced during their electrolysis experiments, are due to alpha particles of ~1 MeV. Referring to this I posted the following message on the Internet discussion list for CMNS researchers.

" Here is an idea based on that paper of Khayrat and Durrani. What would I do to confirm Pam's hypothesis -- that tracks produced during electrolysis are due to alpha particles of about one MeV?

a) First I would try to replicate the experiment of Khayrat and Durrani (using alpha particles of at least three energies: 5.5, 3 and 1 MeV and etching for two hours only). Suppose my results also showed that tracks due to alpha particles of ~1 MeV are nearly two times larger than those due 5.5 MeV.

b) In that case I would start testing the hypothesis. First one corner of a CR-39 chip would be irradiated by alpha particles from 241Am. Then I would conduct a codeposition experiment, using that chip, as described in SPAWAR last paper (*). But instead of etching the chip for 9 hours, I would etch it for 2 hours.

(*) Mosier-Boss, P., Szpak, S., Gordon, F., Forsley, L, "Use of CR-39 in Pd/D Co-deposition Experiments," European Physical Journal, Applied Physics , Vol. 40, p. 293–303, (Dec. 13, 2007)

c) After that I would compare sizes of tracks due to 241Am with sizes of tracks created during electrolysis. Suppose sizes of tracks created during electrolysis were nearly twice as large as those due to 241Am. That would be a confirmation of their hypothesis.

Does this make sense? I am assuming that tracks, attributed to nuclear particles, are nearly always produced in at least one kind of SPAWAR experiment. That seems to be the case, according to their publications."

15) In subsequent message, on the same forum, I wrote: "Suppose the following question is asked. Why are tracks due to ~ 1MeV alpha particles nearly twice as large as tracks due to 5.5 MeV particles, after 2 hours of etching, while at much longer etching (for example, ~7 hrs) sizes of tracks are nearly the same (according to Dorschel)?

I already tried to answer this question.But here is a simpler answer. It is well known that the degree of damage created by an alpha particle in CR-39, is higher near the end of the latent track. The range of alpha particles of ~ 1 MeV is close to 4 microns while the range of 5.5 MeV particle is close to 30 microns. Two hours of etching is enough to reach the bottom of a latent track of a 1 MeV particle but not enough to reach the bottom of the latent track of a 5.5 MeV particle. The highly damaged region, of the 5.5 latent track, is not etched and that is why the track is not as large as it would be after etching for 6 or 9 hours.

This probably captures the essence of the explanation without addressing many details. I would very much like to know if simulated tracks, after 2 hours virtual etching, agree with experimental data of Khayrat and Durrani."

18) About etching rates, Vb (often assumed to be 1.2 microns per hour) and Vt
Also from: C. Brun, M. Fromm, M. Jouffroy, P. Meyer, J.E. Groetz, F. Abel, A. Chambaudet, B. Dorschel, D. Hersmdorf, R. Bretschneider, K. Kander, and H. Kuhne; "INTERCOMPARATIVE STUDY OF THE DETECTION CHARACTERISTICS OF THE CR-39 SSNTD FOR LIGHT IONS: PRESENT STATUS OF THE BESANCON DRESDEN APPROACHES," Radiation Measurements, vol 31, (1999), pp 89-99. According to authors, Vt, the etching rate along the track, can be calculated from the easily measurable Vb, the bulk etching rate (both in microns per hour).

Vt = [1 +0.00155 * (LET-100)] * Vb <----- for 7 M NaOH at 60 C

and

Vt = [1 +0.00267 * (LET-100)] * Vb <----- for 8 M NaOH at 70 C

And what if LET (Linear Energy Transfer) is less than 100? In such cases Vt = Vb. The LET, in these formulas, is in MeV/cm. The coefficients 0.00155 and 0.00267 would have to be changed if LET were expressed different units, such as MeV per micron or MeV per (mg/cm^2). This is obvious because the term between square brackets must be dimensionless, like the Vt / Vb ratio.

LET is a parameter describing ionization density, dE/dx , in a given material. The general rule is that LET increases when the particle energy decreases, except when the kinetic energy becomes smaller than about 1 MeV/amu. For very low energies LET decreases when energies become smaller. In principle, the value of LET, in any given material, and for any given particle, such proton, deuteron, triton or alpha, can be calculated when its kinetic energy is given. The LET for alpha particles of 6 MeV, in CR-39, is said to be 3000 MeV/cm (in the caption of Figure 5, of the above reference). Note that LET=3000 MeV/cm is the same as 3000 / 1300 = 2.31 MeV per (mg/cm^2); 1300 is density of CR-39 is mg/cm^3. LET can also be expressed in terms of number of primary ions per unit length. It is well know, for

example, that it takes about 30 eV of energy to create a pair of primary ions in air. Thus 3000 MeV/cm = 300 MeV/mm, implies that 10^7 ions are formed along the path segment of 1 mm. Some references provide LET in terms of MeV*cm^2/mg, instead of MeV/cm.

Approximate LET values can be calculated from the range-energy data. Let me illustrate this by using the already shown data for air, at 20 C.

Energy (MeV).....Range(cm)
1.0 . . . . . 0.50
2.0 . . . . . 1.00
3.0 . . . . . 1.68
4.0 . . . . . 2.60
5.0 . . . . . 3.63
6.0 . . . . . 4.78
7.0 . . . . . 6.02
8.0 . . . . . 7.35
9.0 . . . . . 8.77

Looking at the last two rows, we see that a layer of air of 8.77-7.35 = 1.42 cm reduces the energy of alpha particles by 9 - 8 = 1 MeV. In other words the average rate at which energy is lost is 1/1.42 = 0.70 MeV/cm. I can assign this value of LET to alpha particles of 8.5 MeV. Likewise, the first two lines allow me to estimate LET of alpha particles of 1.5 MeV. The value is 1/0.5 = 2 MeV. In the same way LET = 1.09 MeV/cm at 3.5 MeV, etc. The LET versus E curve, with 8 data points, can be plotted on the basis of the above table. Note that density of air is about 1.3 mg/cm*3, Thus LET = 2 MeV/cm is the same thing as LET = 1.54 MeV*cm^2/mg. The values of LET for CR-39 can also be estimated (in MeV/micron and then in MeV*cm^2/mg) on the basis of the range-energy data for CR-39 (shown earlier in this unit).

Appended on 5/11/08
a) I found an interesting paper in Review of Scientific Instruments (78, 013304, 2007, pages 1-14). The title is “Study of saturation of CR39 nuclear track detectors at high ion fluence and of associated artifact patterns.” The authors are: by S. Gaillarda, J. Fuchs, N. Renard-Le Galloudec and T. E. Cowan.

b) Is it possible that our so-called "chopped meat" structures (in SPAWAR type experiments) results from extremely high fluence of nuclear particles? Below is a brief summary of what is new and interesting to me.

c) A CR-39 chip is exposed to an Am-241 source (activity 4 micro-curies) for 20 seconds, from a distance of 2 mm. Then the chip is etched for 30 minutes only. The source diameter was 4 mm and the track density was found to be essentially gaussian, along the diameter of the irradiated spot . Tracks were tiny and their overlappings were rare. The track density, in the center, turned out to be 0.010 tracks per square micron. Most tracks were confined to a circle whose diameter was about 9 mm, as shown in their Figure 2.

d) The purpose of this preliminary step was to learn how to control fluence (particles/cm^2) in the central region by changing the exposure time. Note that track density of 0.010 per square micron translates into 10^6 tr/cm^2. For ten times shorter exposure the fluence would be 10^5; for ten time longer exposure, it would be 10^7 particles/cm^2.

e) Experiments with a mylar filter were performed to show that CR-39 is not at all sensitive to X-ray photons, or to photoelectrons they produce. This was done by using a mylar filter that was thick enough to stop all alphas but negligibly thin for ~60 keV photons emitted by Am-241).

f) Saturation is defined as a situation in which overlapping of tracks is common, as illustrated in Figure 3c and 3c.’ Saturation can be caused by excessive fluence (particles/cm^2). For short etching times (when the layer of the etched away CR-39 is thinner than the range of particles) saturation starts to play a role when fluence exceeds ~10^6 particles per cm^2. The range, R, for alpha particles of 5.5 MeV, is 30 microns. Thus, assuming Vt=3 microns/hr, one can say that the etching time is short when it does not exceed R/Vt=30/3=10 hrs. I think that the term “saturation” is

appropriate for some regions of SPAWAR data. During the 2007 Catania conference, two scientists referred to these regions as “chopped meat.”

g) Figure 5 (pit diameters along the y axis and fluence along the x axis) is presented to show when tracks are saturated and when they are directly countable. Commenting on gray and white regions (on that figure), the authors write: “The valid region, shown in gray [lower left corner], can supply quantitative information (in terms of fluence), since the track diameter is below the track saturation diameter and the particle fluence remains low. In the zone left in white, the detector is saturated, since the tracks are too big and/or the fluence is too high. CR39 cannot be relied upon anymore to extract any quantitative information, but if carefully processed and analyzed, qualitative information (in terms of angular distribution of the ion beam) may still be extracted. Figure 5 is valid for any type of particle, since it represents the track diameter as a function of fluence. . . .

On the other hand, in the region limited by the dotted counter, which represents a zone for which the detectors are saturated, qualitative information can only be obtained in terms of beam distribution. Outside of these two zones, the detectors are in saturation and therefore do not provide trustworthy data anymore. At this point, optical ring structures start forming. The region with the dashed contour corresponds to a highly saturated zone, in which bull’s eye structures appear. The region limited by a dot-dash contour corresponds to a region for which a clumping pattern (see below) forms in the central region of the detector (including the white ring region).”

h) Figure 6 shows about 100 small pictures obtained when etched CR-39 chips were placed on the flatbed scanner whose resolution was 1200 dpi (21 microns between pits). That seems to be an appropriate way of examining saturated regions. Each picture is identified in terms of two known parameters, the fluence (between 5*10^6 and 5*10^10) and the etching time (between 18 min and 78 min). It would be desirable to see that, for a given etching time, an optical parameter, such as mean grayness, were proportional to the fluence. Unfortunately, this is not the case. The dependence of the mean grayness on the fluence is not even monotonic. This is illustrated in Figure 8.

i) Another technique used to study saturation regions was Atomic Force Microscopy. Such instruments are described, for example, at

http://en.wikipedia.org/wiki/Atomic_force_microscope

j) The second half of the paper reports on what was observed via microscopic examination of saturated regions. Some of the figures resemble what I observed in the examination of etched CR-39 detector from our The Galileo Project experiment. But my etching time was 6 hours while this paper is based on experiments in which etching times were less than 1.5 hours. This, however, does not exclude a possibility that fluences in SPAWAR-type experiments are much higher than what one measures by counting tracks in the non-saturated regions? Perhaps fluences were high enough to be compatible with reported amounts of helium produced diring excess heat experiments.

P.S.

k) According to http://en.wikipedia.org/wiki/Fluence,

“In physics, fluence [F1] or integrated flux is defined as the number of particles that intersect a unit area.” But the authors seem to use this term differently. Perhaps their fluence, F2, should be multiplied by a large factor, M, to obtain F1. Suppose they identify F2 with the number of tracks per cm^2, in the preliminary experiment (when tracks do not overlap). If this is so, then particles whose angle of incidence are larger than 22 degrees are ignored. This would make F2 considerably smaller than F1. To estimate the order of magnitude of M, defined as F1/F2, let me assume that the source diameter is large (much larger than 4 mm). In that case the source area could be treated as a set of point sources. For each point source, the factor M is nothing else but 4*Pi (total solid angle) divided by the solid angle A, within the half-angle of 22 degrees. In this case:

A=2*pi*[1-cos(22 degr)] = 6.28*0.0728 = 0.45 stereoradian.

Within my approximation, M =12.56 / 0.45 = 27.5. Thus if F2 is specified as 10^8 p/cm^2, then F1= 2.7*10^9 p/cm^2. This is for an ideal situation (well defined geometry, etc.)

l) What we are interested in is the total number of particles emitted during an experiment. Some of these particles are emitted in the direction of the cathode. They are not intercepted by the CR-39 detector. The source itself is not thin and a very large fraction of particles, emitted toward the detector, is absorbed in the source. Likewise, a very large fraction of particles, emitted toward the CR-39, is absorbed in the electrolyte. For that reason, an estimation of the total number of particles, emitted during an experiment, is not going to be easy. Only Monte Carlo simulations can help us in this task, even if F2 could be accurately determined, for example, on the basis of the mean grayness. But reliability of such simulations cannot be higher then reliability of assumptions one must make. One think is clear; the estimated number of tracks produced during electrolysis is likely to be a tiny fraction of one percent of all particles emitted during a SPAWAR-type experiment.

347) Interesting New SPAWAR Results

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 8, 2008

1) Introduction
A report presented by PA. Mosier-Boss, S. Szpak and F.E. Gordon, entitled "Pd/D Co-Deposition: Excess power Generation and its Origin," can be downloaded from http://www.lenr-canr.org/acrobat/MosierBosspddcodepos.pdf It was presented at the meeting of American Chemical Society. In this unit I want to share my own notes and comments based on this interesting report, and on a subsequently published paper. First the authors describe the electrolytic method for fast loading of deuterium into palladium. They have been using this method for many years. What evidence do we have that excess heat, measured by authors, has nuclear origin? They say that "amounts hundreds of times greater than can be delivered by any known chemical reaction/process, constituted proof of its nuclear origin. To verify that the heat generation is indeed nuclear in origin, nuclear ash needs to be detected."

The term "nuclear ash" stands for production of nuclear products in the amount matching excess heat. As I wrote in Unit 345, only helium can be considered a "nuclear ash." Production of tritium, at the rate of about 5000 atoms per second, studied by the authors, is a convincing indication that a nuclear process was going on. But, even that rate was not sufficiently high to produce measurable excess heat.

Another indicator of a nuclear process due to electrolysis was production of elements, such as Al and Mg in some spots on their cathode. These elements were identified on the basis of characteristic X-rays emitted under the bombarded by electrons. Such elements, the authors wrote, "could not be extracted from cell components and deposited at discrete sites. Furthermore it is thermodynamically impossible to electrochemically plate out metals such as Al and Mg from aqueous solutions."

2) Why am I mostly interested in what the SPAWAR team wrote about data gathered with CR-39 detectors? Because I already used their CR-39 protocol, as described in units 319 and 337. That protocol consisted of wrapping the cathode wire around a CR-39 chip, etching the chip after the experiment, and observing tracks that were produced during the electrolysis. My results were nearly identical to theirs. But my conclusion was that most of the observed tracks were too large to be due to alpha particles. The SPAWAR team did not agree with that conclusion. See item #10 in

http://newenergytimes.com/news/2007/NET21.htm#apsreport

3) In a discussion on the Internet list for CMNS researchers Ludwik wrote:
The ACS report does not allow one to compare tracks produced during electrolysis with tracks due to alpha particles from a radioactive source, under identical etching conditions. Fortunately, such comparison became possible on the basis of information they published in European Physical Journal, Applied Physics (Vol. 40, p. 293–303, December 2007). The title of that paper is: "Use of CR-39 in Pd/D Co-deposition Experiments" and the authors are Pamela Mosier-Boss, Stanislaw Szpak, Frank Gordon and Larry Forsley. Let me also mention that some pictures to which the paper refers are in the online supplement downloadable from:

http://www.epjap.org/index.php?option=article&access=standard&Itemid=129&url=/articles/epjap/olm/2007/12/ap07222/ap07222.html

Figures S1 and S2, shown below, were copied from that supplement.

===============

Figure S1
Picture of CR-39 tracks (after 9 hours of etching) due alpha particles from 241Am. Macroscopic magnification was reported as 1000.
================================

===============

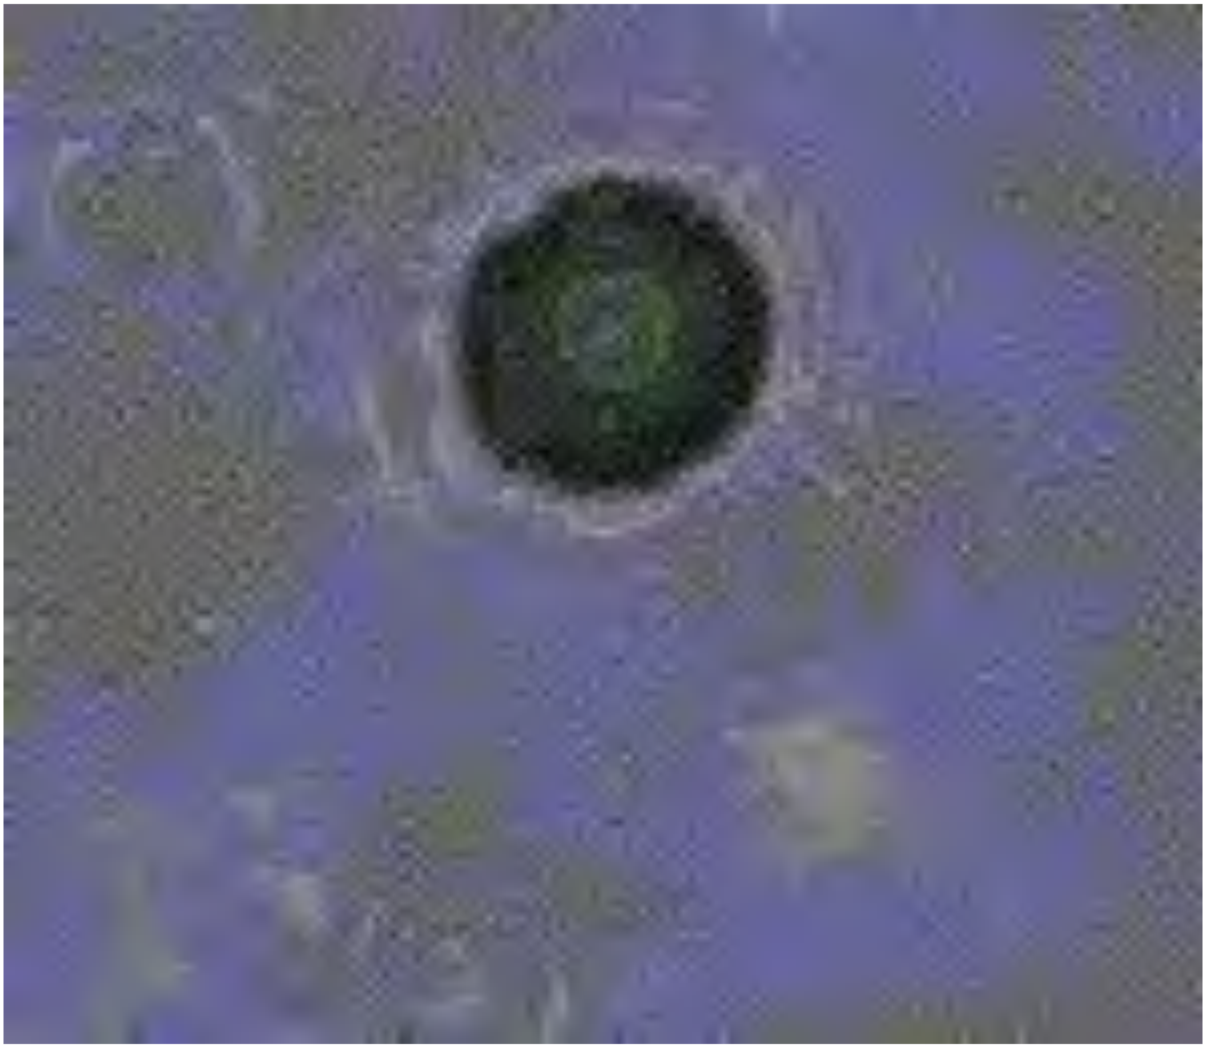

Figure S2
Picture of a CR-39 track (after 9 hours of etching) due an particle emitted during electrolysis. Macroscopic magnification was reported as 1000.

= =

Macroscopic magnifications under which these pictures were taken was 1000. On that basis I assumed that scaling factors were identical. The photographs shown in the supplement also showed the same tracks after 12, 16 and 20 hours of etching. Figure 3 shows how the widths of tracks changed with time of etching. The size of a track is defined as its diameter, when the track is circular, or as its width when the track is more or less elliptical. The length of the major axis depends on the angle of incidence, its width does not depend on that angle.

= = = = = = = = = = = = = = =

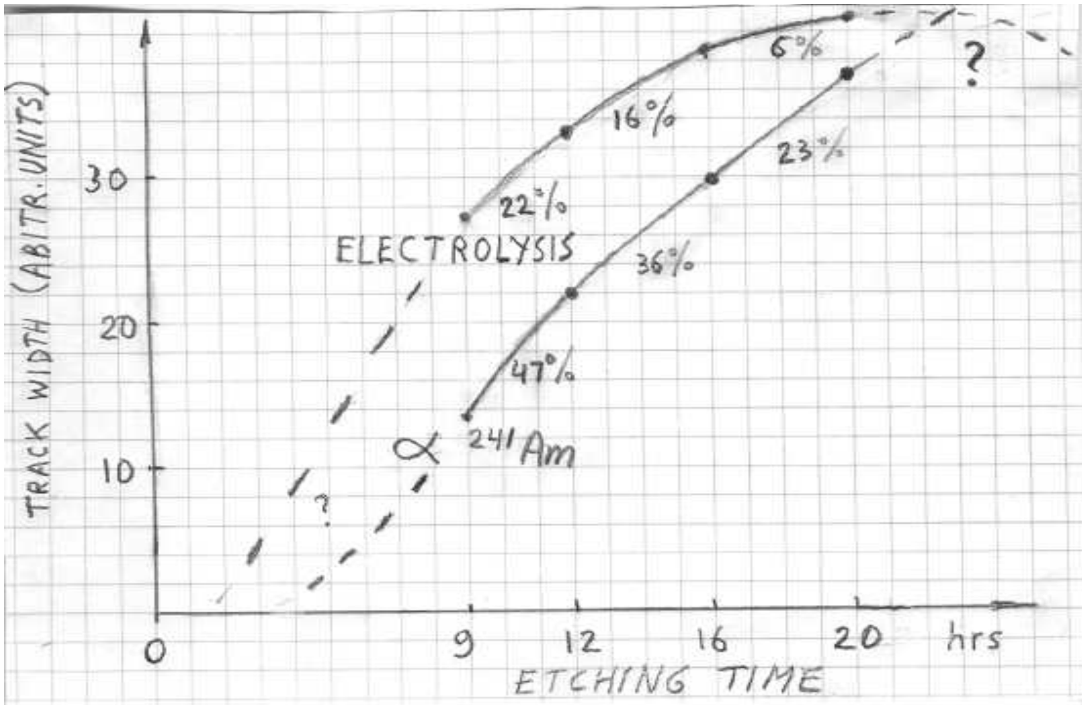

Figure 3

Depenedence of the track sizes on time of etching. For example, what does the 23% represent? The total width of an alpha track, was 30 units after 16 hours of etching and 37 units after 20 hours of etching. The ratio, 37/30=1.23, shows that the increment was equal to 23% of the final size.

= =

In what follows I will explain why, in my opinion, the large track shown in Figure S2 should not be attributed to an alpha particle of ~1 MeV, as tentatively assumed by SPAWAR team. Figure 3 and Figure 4 will be used to justify my position.

= = = = = = = = = = = = = = =

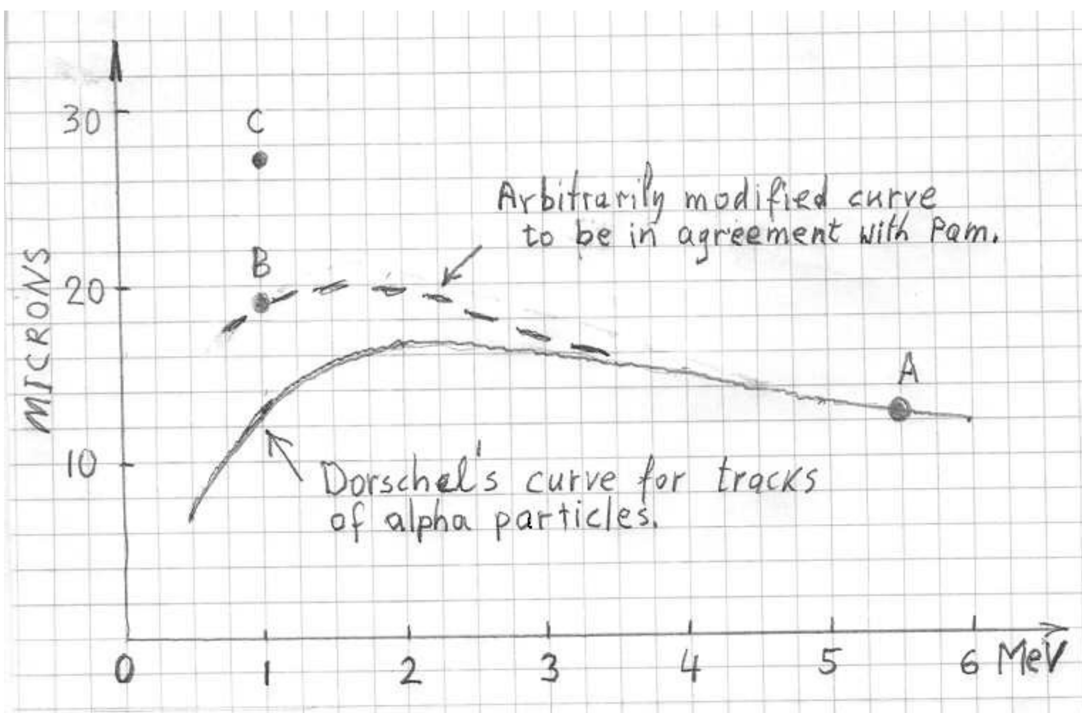

Figure 4

Dorschel's calibration curve for alpha particles (smooth line) versus a hypothetical calibration curve (dashed line). (See, for example, C. Brun, M. Fromm, M. Jouffroy, P. Meyer, J.E. Groetz, F. Abel, A. Chambaudet, B. Dorschel, D. Hersmdorf, R. Bretschneider, K. Kander, and H. Kuhne; "INTERCOMPARATIVE STUDY OF THE DETECTION

4) I am glad that SPAWAR people [Pamela Mossier-Boss et al.] showed exactly the same pits after different etching times. This is not always easy when the pit density is very high. Comparing widths of pits in Figure S1 with the diameter of the top circular pit in Figure S2, I see that pits due to alpha particles are smaller that pits due to particles emitted during the electrolysis. That is roughly consistent with my report at the APS meeting. The conclusion was that particles emitted during electrolysis must be different from alpha particles. Figure S1 and S2 (and Dorschel's calibration curve in Figure 3) seem to confirm this conclusion. . . .

5) Let me be more quantitative. (*) Tracks in Figure S1 are due to alpha particles of 5.5 MeV (241Am). (**) According to Dorschel, the maximum width of tracks due to an alpha particle can be no more than 25% larger than the width due to alpha particles of 5.5 MeV. (***) Zooming on Figures S1 and S2 I found that the width of the top track in Figure S2 is ~2.2 times larger than the mean width from seven tracks in Figure S1 (due to 5.5 MeV alphas). That is why I am claiming that the top track in Figure 2 cannot possibly be attributed to an alpha particle. (****) I will assume that the size of the top track in Figure S2 is typical; sizes of tracks produced during my electrolysis also excedded sizes of tracks due to alpha particles by a factor larger than two.

SPAWAR photos in Figures S1 and S2 also show that the top track in Figure S2 seems to be shallower than tracks due to alpha particles. I discovered this when I plotted the dependence of the track's widths on etching time (see the two curves in Figure 3). The upper curve is for the top track from Figure S2 while the lower curve is for the alpha particle track from Figure S1. The percentages indicate increments in widths between consecutive data points, as explained in the caption below the figure. The arbitrary units, along the vertical axes were millimeters, on my screen (plus or minus one), after zooming.

6) In general the width of a track (or the diameter when the track is circular) is known to increase with the time of etching. But what should one expect after very long etching? My expectation was that tracks should start disappearing; less deep tracks should disappear before more deep tracks. Consider, for example, alpha particles of 2 MeV (range ~8 microns in CR-29). Their tracks should disappear after about 7 hours. But tracks due to 5 MeV alpha particles (range ~30 microns in CR-39) should disappears after about 25 hours. These etching times were calculated from the known bulk etching rate of CR-39, about 1.2 microns per hour.

7) Ludwik wrote (not posted):
How can long etching times (deep pits) be reconciled with the idea that tracks created during electrolysis are due to alpha particles of ~ 1MeV? SPAWAR team, as far as I know, is currently working under such assumption (hypothesis).

8) Ludwik wrote:
a) According to Dorschel's calibration curve, the track widths for 1 MeV alphas should be smaller than the tracks of 5.5 MeV alphas. But the width of the top track in Figure S2, is twice as large as for a track of an alpha particle of 5.5 MeV in Figure S1. Something is not right somewhere. Do you agree?

b) I think that the top track in Figure S2 might be due to something much heavier, and more energetic, than an alpha particle. It might be a track of a fission fragment. I know, from literature, that CR-39 tracks due to FF are about two times larger that for alphas of several MeV. But that is not the only reason for suspecting fission fragments. Another part of my consideration has to do with the depth of tracks, rather than with their sizes seen from above the chips. The top track in Figure 2 keeps growing after after 20 hours. This indicates that its depth is at least 1.2*20=24 microns. How can such depth be attributed to an alpha particle whose range in CR-39 is known to be about 4 microns? Alpha particles of ~1 MeV are probably dissolved in hot NaOH after about four hours of etching.

c) Let me share another observation. According to Figure 7 (also from the online supplement, but not shown here),

widths of tracks due to particles created during electrolysis are significantly smaller than the widths of tracks due to alpha particles. Doesn't this conflict with conclusions reached from the photos in Figure S1 and S2?"

9) Pamela discovered one of my mistakes.
I assumed, in comparing sizes of tracks in Figures S1 and S2, that identical magnifications imply identical scales. She remesured diameters and informed us that the diameter of the top track in Figure S2 was 7.5 microns while the diameter of an alpha particle track, in Figure S1, was typically 5 microns. Responding to this I wrote: "OK, the ratio of track widths, after remeasuring, becomes 1.5 instead of 2.2. That is a big difference. With the ratio of 1.5, one can no longer ignore the question of how the widths of tracks were determined by Pamela and by Dorschel. Systematic errors, or differences in how the widths were defined by Pamela and Dorschel, become significant. Such things can indeed be responsible for the interpretational disagreement between Pam and myself."

10) So let me accept Pamela's interpretation -- the top track on the Figure S2 is due to an alpha particle of ~ 1 MeV. This is still not consistent with the Dorschel's curve. Figure 4 shows how Dorschel's curve (smooth line) was arbitrarily modified (dashed line) to be in agreement with Pam's hypothesis. Note that differences between the two curves are more pronounced in the very low energy region, that is in the region in which tracks become more and more shallow. Point A shows Dorschel's diameter for alpha particles of 5.5 MeV. Point B corresponds to the diameter which is 1.5 times larger than the diameter of an alpha particle of 5.5 MeV The dashed curve would have to pass through the point B to justify Pam's hypothesis. Why am I saying this? Because the diameter of her top track in Figure S2 is said to be 1.5 time larger than the width of a track due to an alpha particle of 5.5 MeV. Point C corresponds to the diameter which is 2.2 times larger than the diameter of an alpha particle of 5.5 MeV If the scale correction was not made by Pamela, then the dashed curve would have to pass through the point C, in order to accept her interpretation.

11) I am not going to argue about whether or not my arbitrary correction of Dorschel's curve (the dashed line) makes sense. Why? Because I have no information about the accuracy of his data. Neither do I know what curve is built into the simulation program used by Pam. The region of very low energies is difficult to explore. Is the error mostly on Dorschel's side or on SPAWAR's side? I do not know. The whole point of this exercise is to show what I have to do in order to accept Pamela's interpretation. Point B is much closer to the reported curve than the point C. That is why I am now willing to give Pam all the benefit of the doubt, as far as my first argument is concerned.

12) Ludwik wrote:
But my second argument, against her tentative hypothesis, seems to remain valid. Why was it ignored so far? That argument was based on the fact that the diameter of the top track in Figure S2 was still growing after 20 hours of etching. How can this experimental fact be reconciled with Pam's interpretation? The range of alpha particles of 1 MeV in CR-39 is only about 4 microns. This, as I already indicated, is much less than the layer of CR-39 that is expected to be dissolved in hot NaOH after 20 hours of etching.

13) Michel Jullian wrote:
. . . I may have the answer to your second objection to Pamela BTW. When I read your sensible suggestion that experimenting would resolve the dilemma it occurred to me that such experimenting might have been done, so I did this quick Google search:

http://www.google.com/search?num=50&hl=en&safe=off&q=alpha+0.5..1-mev+depth+etch+time+cr-39&btnG=Search

and found this 2007 paper, authored by Nikezic and Yu among others:

http://www.cityu.edu.hk/ap/nru/pub_j167.pdf

If I am not mistaken, it says that 1MeV alpha tracks are indeed visible after 15h (cf table 1) etching in a 6.25 N aqueous solution of NaOH at 70 C (cf abstract), in the form of 3 to 4 μm diameter hemispherical pits (cf table 2 and fig.3)

14) Ludwik wrote:

I printed this paper, after reading it with great interest, about two weeks ago. But the snip of information to which you refer did not catch my attention. I was mostly intereseted in the method by which profiles of tracks were deterined. Looking at what is shown on page 267, I agree with you that Pamaela's hypothesis is much more defendable than I thought. I am happy to withdraw my second objection. What is good for SPAWAR team is good for all of us. We are not competitors. My suggestion is that they replicate the experiment of Nikezic et al., if this has not already been done. Thanks for sharing; together we are stronger than each of us, individually.

15) Ludwik wrote (4/24/08):
a) I already suspected that Dorschel's calibration curve, on which my first objection was based, had a systematic error in the low energy region, as shown by the dashed line in Figure 4. But now I am even more inclined to accept this. Either something is wrong with his data or something is wrong the the SPAWAR hypothesis that alpha particles of ~ 1MeV are emitted from cathodes during electrolysis. Do you agree?

b) Unfortunately, I cannot find the reference from which Figure 4 was taken. It was posted on this list by Haiko, about one year ago. Perhaps he will share the reference in which the calibration method is described. Were his alpha particles from an accelerator or were they from a radioactive source? If he used a source then energy was probably controlled by absorbers. Was he the only one to calibrate CR-39 for alpha particles below 2 MeV? If not then how did his results compare with results of others? I wish my ability to find information by googling was better. Please help.

c) And here is a new question. Is it reasonable to think that helium ash, produced during excess heat experiments, comes from alpha particles detected by SPAWAR team? This question is worth addressing. Suppose that excess heat is generated at the rate of 1 W. How many particles must be emitted each second? We know that each alpha particle contributes 23.6 MeV of energy (3.78 pJ). Thus the number of particles emitted per second must be 1 / 3.78*10^-12 = 2.64*10^11.

Let me make a rather unrealistic (and too optimistic) assumption -- tracks are uniformly distributed over the CR-39 area of 1 cm^2. It is easy to show that the average distance between tracks of particles would be d(cm)=1/sqrt(N), where N is the surface density, in tracks per cm^2. Thus, N=2.64*10^11 gives d= 1.94*10^-6 cm or nearly 0.02 microns. Most tracks would be on top of each other, even if the CR-39 was exposed to the cathode for only one second. An exposure lasting 100 seconds would produce 100 times more tracks and the mean distance between tracks would be sqrt(100)=10 times smaller (0.002 microns). Yes, estimations of N are not likely to be easy.

d) But let us ignore this, for a moment. Suppose three SPAWAR type experiments were performed and excess heat was measured. The results were 100, 10 and 1 Joule. Suppose that CR-39 chips were used in these experiments. Wouldn't it be desirable to estimate values of N for each of these experiments. Yes, indeed. If excess heat is due to cold fusion of two deuterons then each track would be associated with production of 23.6 MeV (3.8 pJ) of heat, and of one atom of helium. But, as shown above, experiments in which excess heat is measurable would produce chips with highly overlapping tracks. A new method of measuring N must be invented. Any idea?

e) Yes, I know, we are not yet ready for experiments of that kind. A less ambitious short-term goal, in my opinion, should be to offer a protocol for a reproducible-on-demand demo of a nuclear activity triggered by a chemical process. How close are SPAWAR people from being able to offer a persuading protocol to mainstream scientists? How reproducible their tracks have been so far? I know that different kinds of experiments were performed at SPAWAR, and many results were published. By "persuasive protocol" I mean a protocol for a single, "most reproducible experiment, demonstrating tracks of nuclear particles."

Appended on 4/29/08

14) According to my Unit #347, SPAWAR team works under the hypothesis that nuclear tracks, produced during their electrolysis experiments, are due to alpha particles of ~1 MeV. Referring to this I posted the following message on the Internet discussion list for CMNS researchers.

" Here is an idea based on that paper of Khayrat and Durrani. What would I do to confirm Pam's hypothesis -- that tracks produced during electrolysis are due to alpha particles of about one MeV?

a) First I would try to replicate the experiment of Khayrat and Durrani (using alpha particles of at least three energies:

5.5, 3 and 1 MeV and etching for two hours only). Suppose my results also showed that tracks due to alpha particles of ~1 MeV are nearly two times larger than those due 5.5 MeV.

b) In that case I would start testing the hypothesis. First one corner of a CR-39 chip would be irradiated by alpha particles from 241Am. Then I would conduct a codeposition experiment, using that chip, as described in SPAWAR last paper (*). But instead of etching the chip for 9 hours, I would etch it for 2 hours.

(*) Mosier-Boss, P., Szpak, S., Gordon, F., Forsley, L, "Use of CR-39 in Pd/D Co-deposition Experiments," European Physical Journal, Applied Physics , Vol. 40, p. 293–303, (Dec. 13, 2007)

c) After that I would compare sizes of tracks due to 241Am with sizes of tracks created during electrolysis. Suppose sizes of tracks created during electrolysis were nearly twice as large as those due to 241Am. That would be a confirmation of their hypothesis.

Does this make sense? I am assuming that tracks, attributed to nuclear particles, are nearly always produced in at least one kind of SPAWAR experiment. That seems to be the case, according to their publications."

15) In subsequent message, on the same forum, I wrote: "Suppose the following question is asked. Why are tracks due to ~ 1MeV alpha particles nearly twice as large tracks due to 5.5 MeV particles after 2 hours of etching while at much longer etching (for example, ~7 hrs) sizes of tracks are nearly the same (according to Dorschel)?

I already tried to answer this question.But here is a simpler answer. It is well known that the degree of damage created by an alpha particle in CR-39, is higher near the end of the latent track. The range of alpha particles of ~ 1 MeV is close to 4 microns while the range of 5.5 MeV particle is close to 30 microns. Two hours of etching is enough to reach the bottom of a latent track of a 1 MeV particle but not enough to reach the bottom of the latent track of a 5.5 MeV particle. The highly damaged region, of the 5.5 latent track, is not etched and that is why the track is not as large as it would be after etching for 6 or 9 hours.

This probably captures the essence of the explanation without addressing many details. I would very much like to know if simulated tracks, after 2 hours virtual etching, agree with experimental data of Khayrat and Durrani."

348) A message from a student

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 21, 2008

1) Three days ago I received a message from an American college student. He wrote: “Dear Dr. Kowalski, My name is X and I am a student at Y. I am impressed with your website. You seem to have been investigating ideas in this field for several years.

I've read some introductory material from lenr-canr.org and read some of your numbered items (#1, #2, #3, #4, #22, #24, #25 and several others). I already have the seminal Fleischmann, et. al. paper but I'm writing to you hoping that your years of experience may help guide me (and other interested students) in finding those papers which you think are essential reading (studies).

The cf information available from various sources seems voluminous. I have tried to just starting reading whatever I find but I think a more directed approach would be more fruitful. Would you be willing to identify a few such studies that I should probably start with? I've already read some of the history, "pathological science" and surrounding controversial stuff and have not yet been dissuaded. I'm skeptical but still wanting to find the science, i.e., credible evidence. I'd like to focus on the studies and thought I'd turn to you for some advice. Any direction would be helpful, X”.

The message is authentic but I am deliberately using X and Y because no permission was asked to quote the message. That student is probably not the only one to wishing to learn about the ongoing CMNS controversy. Here is how i responded to this message (with the CC posted on the Internet list for CMNS researchers: “Dear X, It is difficult to advice without knowing your background. Here is what one of my colleagues suggested:

"Ed's reviews and summaries were most helpful when I first sought
information about CF:

http://www.lenr-canr.org/PDetail10.htm#2937

There's even a student's guide:

http://www.lenr-canr.org/PDetail10.htm#2944

And CF for Dummies:

http://www.lenr-canr.org/PDetail10.htm#2954

And the book of course."

Ed's book is an extensive review of the field. But the level of presentation is advanced. The review of that book, written by a Danish chemist, Dieter Britz, can be found at:

http://pages.csam.montclair.edu/~kowalski/cf/344britz.html

On the other hand, do not believe everything you might find on the Internet. Some people like to mix serious scientific issues with deceptive advertising, as in:

http://www.apfn.org/apfn/free_energy.htm

I strongly suspect that the device described at that unit never existed. The article was probably written to attract naive investors. Serious cold fusion researchers, like Ed Storms, are making progress and trying to understand how excess heat was produced by Fleischmann and Pont. The original claim for excess heat has been confirmed in more that 100 experiments. But, in most cases the rate of generating such heat was close to 1 watt. There are other indicators, in addition to excess heat, that nuclear processes of some kind can indeed be triggered by chemical processes. What we need is at least one "reproducible on demand" demonstration of this. Technological advances would probably be made quickly after basic science is understood. Keep your eyes open on this developing field, no matter what your long-term plans."

3) Shortly after sending the reply, I read a message posted by Steve Krivit. It contained a link to the list of books about CMNS that he compiled.

http://newenergytimes.com/Books/books.htm

I wish I saw this link earlier; it should be given to anyone interested in CMNS topics. References to papers which are likely written to promote fraudulent claims are also worth showing to students. Here is a quote from an article entitled "Inventor claims discovery of free energy," written by Kevin Smith (in 2002). The entire article can be downloaded from <http://www.apfn.org/apfn/free_energy.htm>

"In a demonstration for Reuters, a prototype -- roughly the size of a dishwasher -- was run for around 10 minutes using four 12-volt car batteries as an initial power source. Emitting a steady motorized hum, the machine powered three 100-watt light bulbs for the duration. A multimeter reading of the batteries' voltage before the device started up showed a total of 48.9 volts. When it was switched off, a second reading showed 51.2 volts, indicating that, somehow, they had been reimbursed. The machine went on to run for around two hours while photographs were taken, with no diminution in the brightness of the light bulbs, which remained lit during a short power cut. 'The draw on the batteries was estimated at more than 4.5 kilowatts. With any existing technology the batteries would have been drained flat in one and a half minutes,' the inventor said."

A knowledgeable student would probably notice that something is wrong with the last sentence. One of the parameters of a car battery is Ah, usually 50 Ah or more. Suppose that four 12 volt batteries are connected in parallel. What is the total current needed to support three 100 W light balls, of matching voltage? The answer, based on Ohm's law, is I=300/12 = 25 A. Each battery would contribute 25/4=6.25 A. Thus, in two hours, each battery would use only 6.25*2=12.5 Ah. This is only 1/4 of its assumed capacity, 50 Ah. On what basis should one expect a battery to "have been drained flat" under such conditions? The same question would be asked if batteries were connected in series, supporting three 36 volt light bulbs (of 100 W each). I see nothing unusual for using four car batteries to power three 100 W light bulb for 2 hours. The draw on the batteries powering three 100 W light bulbs is 300 W, not 4500 W.

Another claim, that most likely was a fraud, is mentioned in Unit #279, at this website. Let me end this unit by quoting from what I wrote in unit #236, at this website. "Getting more out of a physical system than is put into it has been a persistent dream of humankind. Those who have tried to do this honestly -- by inventing their own 'perpetual motion' machines -- have invariably failed. The only people who have come out ahead in his area are those who claimed success and then got others to pay to see it. That it seems, was not difficult to do. In 1812 Charles Redheffer traveled through Philadelphia and New York, charging a dollar admission (a dollar was a lot of money in these days) to see his perpetual motion machine made up of wheels, gears, and pulleys which kept moving continually with no apparent source of energy. He did very well until someone discovered a little man in a back room turning a crank.

Another method of making money is to 'invent' such a device and then get people to invest in it. So gullible are some people, and so anxious to get something for nothing, that they will put money into all kinds of money-making schemes." The iESi company was certainly not the first instrument to get money from greedy people; and most likely

not the last one. Even people who studied science are not always immune to preposterous claims. They know that many ideas that turned out to be good were initially rejected as nonsensical. The germ theory of disease, for example, was ridiculed when it was first introduced by Pasteur. Today bacteriology is an essential part of medical science.

Or think about Wright brothers' idea of airplanes. It was ridiculed by those who believed that only balloons "lighter than air." could fly. But the brothers did not give up and their persistence paid off. How can one deny this today when heavier than air machines fly all over the world? Dismissing an idea which seems to be in conflict with what is already known may or may not be justified. That is why scientists are often reluctant to reject unreasonable claims. Sometimes it pays off and sometimes it leads to disappointments.

349) How are visible tracks created in CR-39

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 30, 2008

Introduction
Being retired often means that one is able to turn a hobby into a full time occupation. Fortunately, I am still healthy enough to do this. So let me describe what I think about the CR-39 track-formation process. Ideas presented here are closely linked with contents of units 346 and 347. They represent an attempt to to develop my own simulation of etching. I will begin with a very simple model and try to make it more realistic, one step at a time. For the time being, each of my models is for latent tracks perpendicular to the surface of the CR-39 chip. What is a latent track? It is cylinder, containing damaged CR-39 material (broken molecules, etc. etc.)

I will use the following notation:

E <--- (in MeV) kinetic energy of the incoming alpha particle
L<---(in microns) the length of the latent track created by that particle.
Vt <---(in microns per hour) the etching rate in the damaged CR-39 material. The Vt is caller track etching speed.
Vb <---(in microns per hour) the etching rate in the CR-39 material undamaged by the particle. The Vb is called bulk etching speed.

Model 1 (not realistic):
Let me make some assumptions:
a) The damaged material is in a cylinder (centered on the latent track axis) of very small diameter, centered on the latent track axis.
b) The damaged material is uniformly distributed within the latent track cylinder.
c) Bulk etching speed, Vb, is zero while the track etching speed, Vt, is 4 microns/s.
d) L=16 microns

Since Vb=0 , the track diameter does not change with the time of etching. The dry track will consist of an air cylinder whose length is y = Vt * t, where t is the etching time smaller than 4 hours. (the time to dissolve all damaged material, t' = L / Vt = 16 / 4 =4 hours). Nothing changes after 4 hours of etching.

Model 2 (Vb > Vt or Vb=Vt):
No track will be seen because the CR-39 material, surrounding the latent track cylinder, will be dissolved faster than the damaged material. The invisible latent track will disappear in 4 hours if L=16 microns and Vb=Vt=4 microns per second.

Model 3 (starts to be realistic):
Assumptions are the same as in Model 1, except that Vb (smaller than Vt) is no longer zero. In order to produce conical tracks I will assume that vertical etching (direction parallel to the latent track) proceeds with the constant speed Vt while horizontal etching proceeds with the constant speed Vb. This crude approximation is probably valid for etching times that are not too long; experimentally determined track profiles (1) were found to be conical, for of not-overetched tracks. A track can be said to be overetched when the etching time is longer than t'= R / Vt, where R is the range of particles in CR-39. For alpha particles of 5.5 MeV, R is about 30 microns. Thus, t' is 10 hours, when Vt=3 microns per second. Profiles of overetched tracks, according to (1), tend to be come spherical and their radii seem to

increas at the Vb rate. This observation is part of Model 3. Fot t > t', the diameters of tracks are assumed to grow at the same rate as for lower t (see below).

Figure 1 shows the expected evolution of the visible track of a 5.5 MeV alpha particle. Consecutibe profiles refer to etching times of 2, 4, 10, 30 and 40 hours, as indicated. These profiles correspond to Vb=1.2 and Vt=3.6 microns per hour. Note up to t=t'=10 hours, all tracks are conical. The half-angle, A, at the tip of each cone, 18.4 degrees; the tangent of that half-angle is nothing else but the Vb / Vt ratio. The hight of a cone, y, for any given t < t' (t'=10 hrs) is given by

y = (Vt - Vb) * t. = 2.4 * t

The corresponding diameter, D, at time t, is given by

D = 2 * y * tan(A). = 1.6 *t

= = = = = = = = = = = = = = =

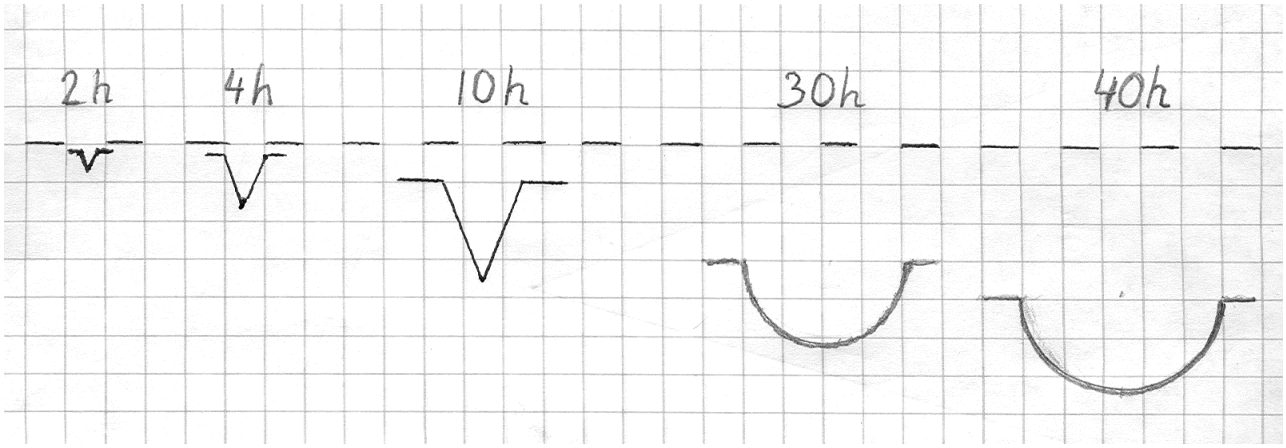

Figure 1
Cross sections of track profiles after different etching times. The dashed line shows where the top surface of the CR-39 chip was before etching. Two horizontal segments, at each profile, show where the CR-39 surface is after etching. The bottom of the 10 h cone coincides with the end of the invisible latent track. Note that after 40 hours of etching the latent track layer is totally disolved. The right-side pit, located below that layer, is growing radially at the rate of 1.2 microns per second.

= =

* * * * * * * * * * * * * * * * * * * *

That observation made me think about SPAWAR results described in my Unit 347. http://csam.montclair.edu/~kowalski/cf/347new.html According to Figure 3, in that unit, the measured diameters of tracks produced by alpha particles from 241Am became 40 microns after about 22 hours. According to the above formula, D after 22 hours is 35 microns. That is not very different from 40. I consider this to be a good indicator that my model is reasonable. But it is too eraly to start playing with Vt and Vb, in order to get a perfect agreement.

* *

Model 4

Damaged material, surrounding a latent track, is probably not uniform. Material closer to the latent track axis is likely to be more damaged than material further away from the axis. Likewise, material closer to the end of a latent track is likely to be more damaged than material closer to the beginning of the track. I am saying this because I know how density of ionization is distributed along the path of an alpha particle in air. That topic has been studied by Bragg, more than one hundred years ago. In the Model 3, the Vt was assumed to be constant; in this model I will assume that it changes along the latent track.

I will simulate evolution of a track due an alpha particle of E=5.5 MeV (R=32 microns). Simulation steps will be 15

minutes each. The Vb will remain constant but Vt will be assigned a predetermined value for each step. In my simple computer program, the Vb will always be 1.2 microns per second. But my set of Vt values, for consecutive steps, will be treated as a set of adjustabl parameters. This should provide great flexibility. I would be able to see the cross section of a track at any desired etching time. To test the program (to discover and correct hidden errors) I will compare its output with Model 3. The results should be nearly identical, provided Vt=constant=3.6 microns/hour (as above), and time steps are very short, for example, one minute each. That is my plan. The results will be shown later.

Model 5
This model will be similar to Model 4 but it will have an additional assumption. The value of Vt will also have a radial dependence (larger values near the latent track axis and smaller values at larger distances from the axis.

Another thing worth doing is to perform experiments in which CR-39 chips are bombarded with alpa particles of several energies. The chips would then be etched for different times, for example, 2 hrs, 4 hrs, 8 hrs, 16 hrs and 32 hours. Plotting diameters of tracks versus etching time will produce curves to be compared with simulations. Yes, this is a big and ambiguous project. If all goes well, I might be able to publish the results. The project has nothing to do with CMNS; but results might be useful to CMNS researchers.

Appended on 5/1/08
Several things became intuitively clear to me, after I tried to compose an algorithm for Model 4. Let me enumerate them.

a) Strongly overetched tracks will have semi-spherical profiles, as in Model 3.
b) Suppose t' again stands for the etching time needed to dissolve the CR-39 layer in which the latent track was located. Profiles of tracks etched during times t shorter than t' will not be exactly triangular; they will resemble profiles of inverted Eiffel towers. But that is not a very big difference.
c) Time t' in Model 4 will be shorter than what it would be if the value of Vt were not increasing with the depth of the pit. The difference between t' of Model 4 and t' of Model 3 increases when the rate at which the Vt changes with the depth became larger.

I do not think that the overall results of Model-3 simulations will be very different from the results of Model-3 simulations. The diameters of strongly overetched pits will keep growing at the same rate close to 2 * Vb=2.4 microns per hour. The pits produced during the etching times shorter that t' will no longer be proportional to t. But consequences of this will be hard to measure. One thing is clear, Model 4 will not allow me to explain why diameters of tracks created during codeposition stop growing when the etching time is increased.

The same is likely to be true for the Model 5. Here too the diameters of profiles, of strongly overetched pits, should be increasing linearly at the rate close 2.4 microns per hour. Some nuances will probably be different at $t < t'$ but they will be difficult to notice. Intuition tells me that Model 5 will also not going to explain the experimental fact reported by SPAWAR team -- diameters of tracks, created during codeposition, stop growing when the etching time is increased.

Considering all this I decided not to commit myself to this project. What I learned so far gives me enough confidence to make the following observations.

a) Diameters of tracks due to alpha particles from 241Am increase with the etching time as expected. I know that I can simulate the reported curve; it is shown in Figure 3 at:

http://csam.montcllair.edu/~kowalski/cf/247new.html

b) The diameters of tracks created during codeposition, shown in the same Figure 3, stop growing when the etching time exceeds 20 hours. This experimental fact is not likely to be explained by my model. In fact, I suspect that the model of Nikezic and Yu, used by Pamela, also does not explain this experimental fact. But this is only a suspicion. Perhaps I am not aware of some important effects. Perhaps latent tracks created by alpha particles of ~ 1 MeV are very different from latent track due to common alpha particles. Something is not right somewhere. What is it?

350) My notes based on SPAWAR paper

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
May 3, 2008

INTRODUCTION
This unit contains notes I made for myself while rereading the SPAWAR paper (published in EPJAP, December 2007). I do not know why that paper is only listed in our CMNS library at

http://www.lenr-canr.org

instead of being downloadable from it. Perhaps it has something to do with copyright. So here is the reference again:

Mosier-Boss, P.A., et al., *Use of CR-39 in Pd/D co-deposition experiments.* Eur. Phys. J. Appl. Phys., 2007. **40**: p. 293-303.

The supplementary part of that paper, that was published online, is available (if you pay, or belong) from:

http://www.epjap.org/index.php?option=article&access=standard&Itemid=129&url=/articles/epjap/olm/2007/12/ap07222/ap07222.html

Part of what I wrote has already been written in Unit 347 but it is now better organized and better formulated, I hope. The bottom line is essentially the same -- I do not think that tracks created during SPAWAR-type experiments are due to alpha particles. That was the conclusion reached on the basis of my own experiment (as reported at the March 2007 APS meeting).

INTRODUCTION AND CONCLUSION (THEIR SECTIONS 1 AND 4)
1) The paper's introduction describes the CR-39 detection methodology and shows that authors are aware how it was used in several fields. They give credit to CMNS researchers who also detected unexplained particles, for example, 11-16 MeV alphas and 1.7 MeV protons (Lipson), huge clusters of tracks during light water electrolysis (Oriani and Fisher), and emission of particles when deuterium gas was diffusing through Pd (Li).

2) Here is the last sentence from the introduction: "Evidence is presented that shows that these **pits are tracks caused by the emission of charged particles** and that these tracks are not due to either radioactive contamination; or from the electrolysis of heavy water; or from chemical reaction with D_2, O_2, or Cl_2."

3) In the concluding Section 4, the authors wrote: "**The experiments are reproducible.....**Quantitative analysis shows that there are three populations of pits (0.1–0.5μm, 0.9–4.0μm, and 4.1–12μm) and that the pits can be either perfectly circular or elliptical in shape. These **features are consistent with those observed for nuclear generated pits**. In this communication, it has been shown that the pits formed during Pd/D co-deposition are **not due to radionuclide contamination** of the cell components nor are they caused by impingement of gas bubbles on the surface of the CR-39. Since electrochemical plating of $CuCl_2$ did not result in pits, production of pits in a Pd/D co-deposition experiment **cannot be attributed to chemical attack** of the surface of CR-39 by either D_2, O_2, or Cl_2

present in the electrolyte."

THE MAIN BODY OF THEIR PAPER (SECTIONS 2 AND 3)

4) Is the description of the protocol sufficient to guide someone? I think it is. In the simplest case the cathode was an Ag or Au wire (wrapped around the CR-39 chip) while the anode was a wire made from Pt. A nickel screen has also been used as a cathode on which the Pd/D was deposited.

5) Figure 2 shows the cathode surface from experiments without magnetic field (a) and with magnetic field (b). **The Lorenz force in the magnetic field is said to be responsible for structural surface differences. Electric field is also said to produce structural changes.**

6) By Lorenz force they certainly mean q*(vXB), where q is the charge of the ion, on which the force is acting, while vXB is the cross product of the ion's velocity, v, and the field strength, B. The field on the order of 2500 Gs, probaly measured with a gaussmeter, was created with two strong neodymium magnets, outside the cell.

7) The value of B between two magnets (inside the cell) is certainly not strongly affected by plastic walls from which the cell is made (see Figure 1) or by presence of the electrolyte. But the same is not true about the electric field, E. That field was created by applying 6000 volts to two copper plates outside the cell. The distance between plates was close to 3 cm. In the vacuum (or in air) the field strength would be only slightly smaller than 6000/3=2000 V/cm. But presence of electrolyte (a conductor) and plastic walls (dielectric) probably reduces E to less than 0.002 V/cm. How can such field affect the co-deposition process?

8) It is interesting that, in the case of a Ni cathode (Figure 3d), pits appear "only when either an external electric or magnetic field is applied." Nickel is known to be a ferromagnetic material. Is this significant? I do not know. The authors report that "the overall size and shape of the pits are similar to nuclear tracks reported by Oriani and Fisher [10], Li [9], and Lipson et al. [11, 12]."

9) The picture in Figure 3a shows the CR-39 but the picture of Figure 3b shows the photographic film. The film was protected from the cathode by mylar. Dark spots on the photographic film are believed to be due to X-rays emitted during electrolysis. Figure 3d shows copious CR-39 tracks. Some dark circles have diameters of about 4 to 8 microns.

10) **I am puzzled by Figure 3a**. Commenting on it, the authors conclude: "It is therefore possible, that the hollows observed in the CR-39 detector, Figure 3a, are the results of damage due to the soft X-ray emission." The density of ionization due to an X-ray photon is known to be very low, in comparison with that due to an alpha particle. What X-ray dose would be needed to produce a detectable damage in CR-39 material? Intuition told me that the dose must be very large. But how large?

Intrigued by this question I went to the reference 25 (Amemyia et al.,"Soft X-ray imaging . . . ", Nuclear Instruments and Methods B, vol 187, 2002, page 361) and found the answer. The dose has to be "more than kGy." The unit of dose, Gray, translates into 100 rads. In other words, 1kGy is 100000 rads. My recollection is that about 50% of experimental rats die shortly after receiving the whole-body dose of 500 rads. This is only 0.5% of one kilogray. Fortunately the danger to SPAWAR researchers was not as great as one might think. First the X-rays were highly localized; each hollow was about 1 mm, as shown in Figure 3a. Second, soft X-rays would be stopped inside the cell (or in the skin of a rat). Third, the film shown in Figure 3b would be much darker without the mylar film. How thick was the mylar film?

11) **Was the CR-39, shown in Figure 3d, also protected from the cathode by mylar?** Several CMNR researchers suggested (about a year ago, after phase 1 of The Galileo Project) that in some experiments CR-39 should be separated from the cathode by a mylar film of about 5 microns. Such film is commercially available; it is thin enough to transmit alpha particles. The film would protect the CR-39 surface from suspected chemical reactions at the cathode. This topic is discussed in Section 3.2, named "Nuclear tracks vs. chemical damage." The main argument is that tracks, as shown in Figures 5, are not different from tracks due to alpha particles from radioactive sources (Figure 4). Tracks due to chemical corrosion would be "lighter in appearance and irregular is shape." This is a powerful argument for the central CMNS claim -- a nuclear process of a new kind is triggered by electrolysis.

By the way, I also observed alpha-particle-like tracks produced during the co-deposition electrolysis. This was during the phase 1 of The Galileo Project. But I was troubled by the fact that tracks created during electrolysis were usually more than 2.5 times larger than tracks due to alpha particles from my 241Am source.

12) At the end of section 3.2 the authors refer to experiments in which CR-39 chips were etched incrementally. They conclude: “The incremental etching result support the conclusion that the pits observed in the CR-39 detector as a result of the Pd/D co-deposition process are nuclear in origin.”

13) The rest of the paper describes additional experiments. One learns, for example, what happens when KCl is used instead of LiCl, when light water is used instead of heavy water, when cathodes made from different metals are used, etc. etc. Was one particular setup found to be much better that the setup described in the original protocol, nearly two years ago? Are authors ready to offer the world a protocol for a simple and convincing demonstration of a nuclear activity caused by a chemical activity? I hope they are. I would be happy to participate in the new phase of The Galileo Project.

COMMENTS ON INCREMENTAL ETCHING AND ON RATIOS OF DIAMETERS

14) Let me comment on results from incremental etching experiments, mentioned in point 12 above. These results confirmed my old conclusion -- tracks created in SPAWAR-type experiments cannot possibly be due to alpha particles. That is what I reported at the APS meeting in Denver. The recent EPJAP paper offers a chance to return to this topic on the basis of new SPAWAR results.

15) Two photos below are from Figures S1 and S2, of the online version of SPAWAR paper.

= = = = = = = = = = = = = = =

Figure S1
Picture of CR-39 tracks (after 9 hours of etching) due alpha particles from 241Am. Macroscopic magnification was reported as 1000.

= =

= = = = = = = = = = = = = = =

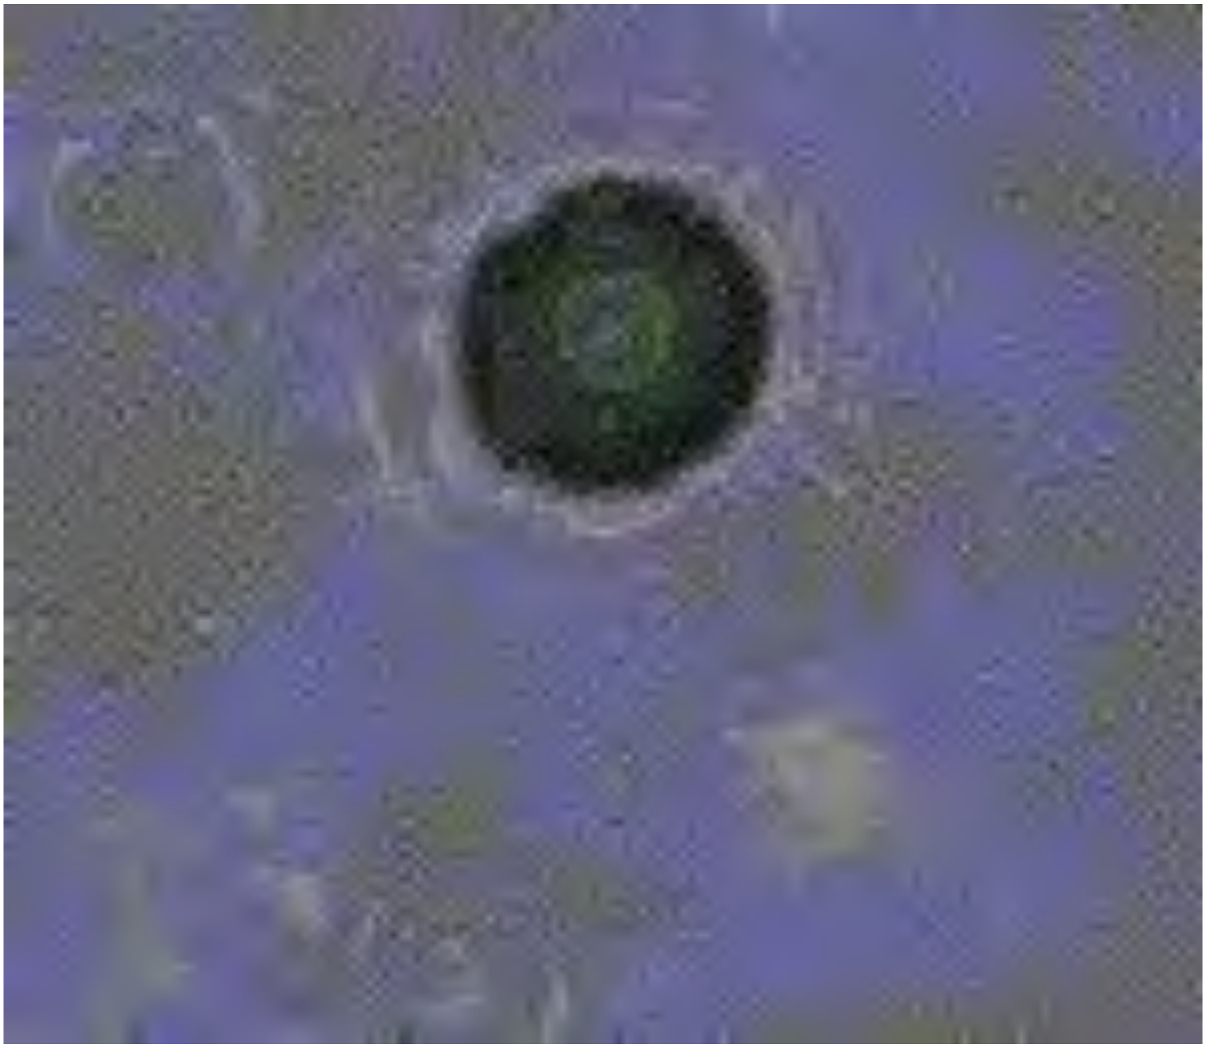

Figure S2
Picture of a CR-39 track (after 9 hours of etching) due an particle emitted during electrolysis. Macroscopic magnification was reported as 1000.

= =

Macroscopic magnifications under which these pictures were taken was 1000. The photographs taken from the supplement also showed the same tracks after 12, 16 and 20 hours of etching. Fortunately, the same chip was used to record alpha particles of 5.5 MeV (near the CR-39 corner) and particles emitted during electrolysis (in the CR-39 center). Comparing sizes of these two kinds of tracks would be much more difficult if etching conditions were not identical. Figure 3 shows how the widths of tracks changed with time of etching. The size of a track is defined as its diameter, when the track is circular, or as its width when the track is more or less elliptical. The length of the major axis depends on the angle of incidence, its width does not depend on that angle.

= = = = = = = = = = = = = = =

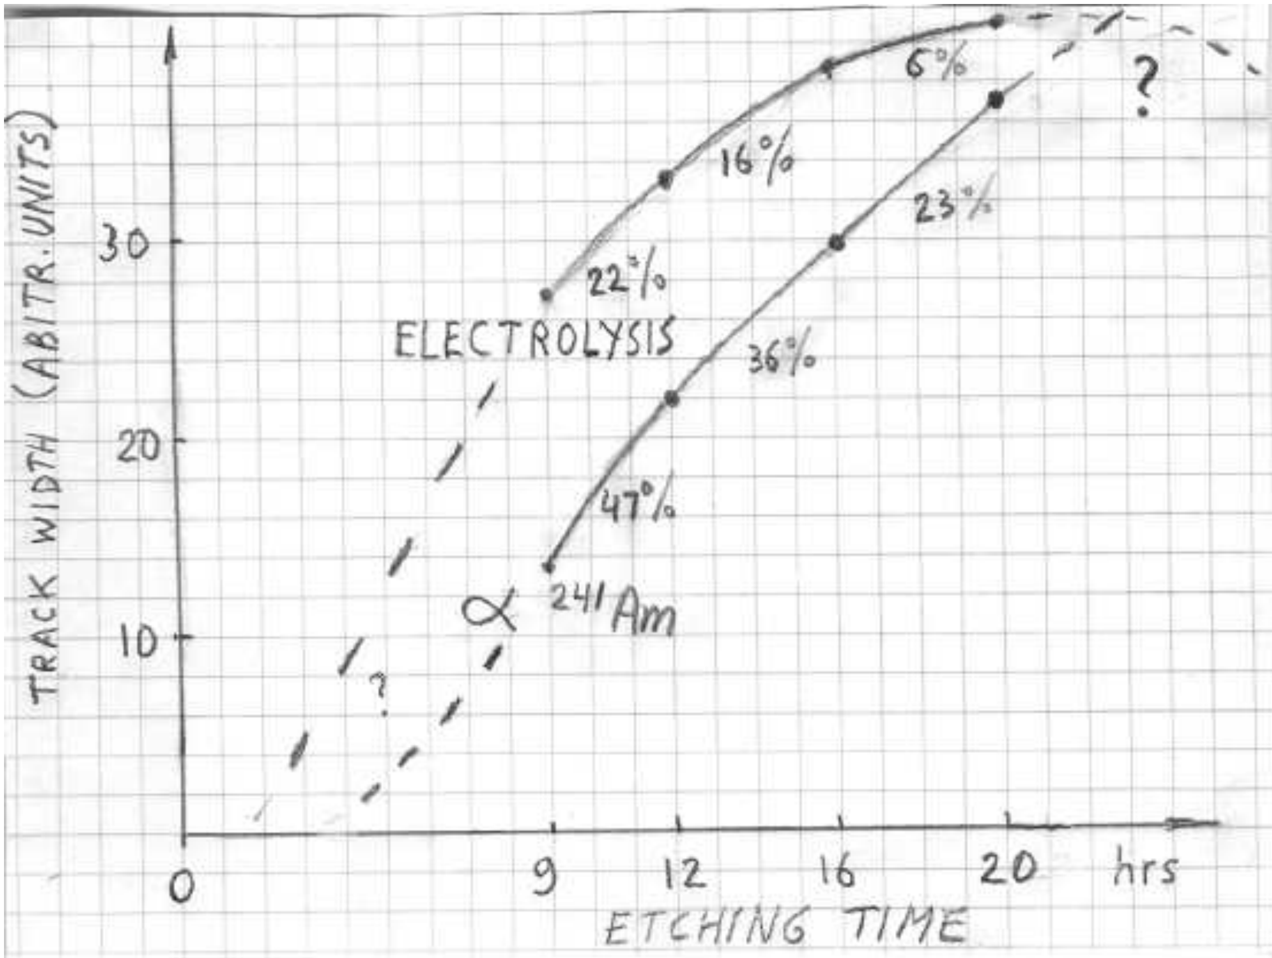

Figure 3
Depenedence of the track sizes on time of etching. For example, what does the 23% represent? The total width of an alpha track, was 30 units after 16 hours of etching and 37 units after 20 hours of etching. The ratio, 37/30=1.23, shows that the increment was equal to 23% of the final size.
==============================

16) In what follows I will explain why, in my opinion, the large track shown in Figure S2 should not be attributed to an alpha particle of ~1 MeV, as tentatively assumed by SPAWAR team. Figure 3 and Figure 4 will be used to justify my position.

One thing becomes obvious at once; sizes of tracks created during electrolysis tend to stop growing, after 20 hours of etching, but tracks due to alpha particles from the radioactive source keep growing. This difference seems to be very important. According to recognized CR-39 experts, such as Nikozic and Yu (see reference in my unit 346), diameters of overetched tracks due to nuclear projectiles keep growing infinitely, at the 2*Vb rate. The value of Vb depends on the etching conditions (temperature and molarity of NaOH); Vb is usually between about 1 and 2 microns per hour. SPAWAR experimental curve for alpha particles seems to be consistant with the continous growth of the diameter. The average rate of growth, between 9 and 20 hours, is close to 2 microns per hour; this corresponds to Vb=1. Note that the etching temperature of the SPAWAR etching solution was said to be between 65 and 72 degrees C. Drifts in the temperatur could be responsible a slow chage of Vb.

But how to explain the second experimental fact? Why does the diameter of the upper curve tend to stop growing after 20 hours? I do not know how to answer this question. But one thing is clear; the second experimemental fact is not consistent with the idea that tracks produced during electrolysis are due to alpha particles emitted from the Pd/D deposit on the cathode. That argument has nothing to do with the argument I used before to justify the same conclusion.

17) Let me now return to the old argument; it was based on comparisons of track sizes. Would the same argument be

defendable in light of new experimental data? I think it would, considering what I wrote in Unit 346, at this CF website. A quick look at tracks in Figure S1 and S2 shows that their sizes are very different. At first I thought that the diameter of the track in Figure S2 was more than twice as large as the width of a track in Figure S1. Both photos were taken at the magnification of 1000. That would be close to what I found more than one year ago. But I learned, from one of the authors, about additional zooming factors. The true diameter of the pit in S2 was close to 7.5 microns while the true width of tracks in S1 was close to 5 microns. The question becomes: is the ratio of diameters equal to 1.5 consistent with my claim? It was easier to denend the claim on the basis of my own experimental data, when the ratio of diameters was close to 2.5. But now I am better prepared to adress the question. Before I was guided by intuition, now I can be quided by experimental data of those who studied how diameters of alpha particle tracks depend on their energies.

The figure below shows experimental data of that kind. It was found in a paper (1) published by two teams of researchers, one from France and another from Germany.

===============

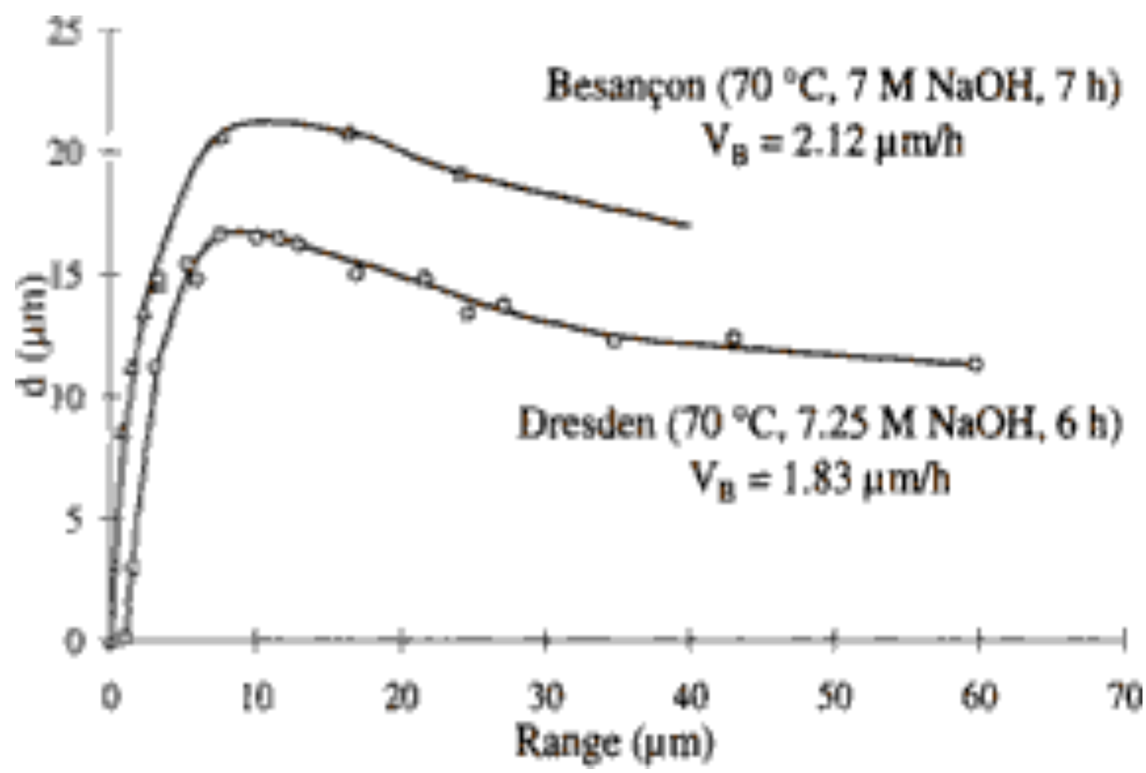

Figure 4
Diameters of etched alpha particle tracks in CR-39 versus their ranges. Even though the etching conditions are not the same for the two teams, the shape of the curves are very similar.

==============================

18) Slightly different etching conditions in two laboratories explain differences in absolute diameters. But positions of maxima (at R~10 microns) are nearly identical. Also nearly identical are ratios of diameters, for example diameter at R=10 and at R=25 microns. In what follows I will use the lower curve because is covers a wider range of experimental data. To convert ranges in CR-39 into energies I will use the following data:

Alpha energy . . . Range in CR-39

5.5 MeV ....33 microns
4.0 MeV ....20 microns
2.4 MeV ....10 microns

1.6 MeV .....7 microns
0.8 MeV .....3 microns
0.0 MeV .....0 microns

The Dresden curve shows that the diameter of tracks af 5.5 MeV is about 13 microns. The diameter at the maximum, corresponding to 2.4 MeV, is about 15.2 microns. That shows that the diameter of an alpha particle track can exceed the diameter of an alpha particle of 5.5 MeV by no more than a factor of 15.2/13=1.2. That is considerably smaller than the factor 1.5 reported by the SPAWAR team, suggesting that the track in Figure S2 should not be attributed to an alpha particle. But the difference between 1.5 and 1.2 is not enormous. How reliable are Dresden data? The precision in measuring diameters was certainly very high, otherwise the data point would fluctuate more widely around the smooth curve. I read the paper and I am satisfied with the method by which energies were determined. My guess is that the uncertainty about the 1.2 ratio is smaller than +/- 0.05 (which is 4%). The uncertainly associated by the 1.5 factor is probably close to 16%. To calculate that value I simply assumed that the uncertainty in each diameter is 0.5 microns.

19) These considerations lead me to a conclusion that the difference between the ratios of diameters (1.5 versus 1.2) cannot be taken too seriously, in the context of the new paper. Also note that the 1.5 ratio was calculated on the basis of a questionable assumption. I assumed that the diameter 7.5 microns (from SPAWAR Figure S2) is typical for particles created during electrolysis while the diameter 5.0 microns, taken from their Figure S1, is typical for alpha particle. Taking this for granted was probably a mistake. To correct this mistake let me refer to Figure 7 of the new SPAWAR paper. According to the scatter plots, shown in that figure, the mean value D1 (width of an alpha particle track) is close to 10 microns while the mean value of D2 is close to 6 microns. These mean values give the D2/D1=0.6. It is two times smaller (not 1.5 times larger) that the maximum expected ratio of 1.2 (for alpha particles). The difference between 0.6 and 1.2 is likely to be more significant than the difference between 1.5 and 1.2.

20) I wish the actually-calculated mean values were reported. That would probably reduce the uncertainty in 0.6 to less than 5% (because each scatter plot is based on more than 300 data points). My estimated mean values are likely to be less precise. But they seems to be sufficiently precise to take the difference between 0.6 and 1.2 seriously. I expect mean values to be reported at the upcoming cold fusion conference, ICCF14, in Washington DC. At present I am mostly disturbed by discrepancy between the new data and my own results described at

http://csam.montclair.edu/~kowalski/cf/319galileo.html

These results showed that mean sizes of tracks, created during electrolysis, were much larger than sizes of tracks due to alpha particles. This was consistent, more or less, with the old SPAWAR results, also presented at the 2007 APS meeting. But new SPAWAR results show that the opposite is true. Tracks created during electrolysis are now much smaller than tracks due to alpha particles. I hope that this (apparent ?) contradiction will be explained at the ICCF14. For the time being I will stick to my old results. They show that the mean D2/D1 ratio was slightly larger than 2.5. The difference between 2.5 and the expected 1.2 ratio was certainly highly significant. My ratio and SPAWAR new 0.6 ratio cannot be correct at the same time.

21) Another reason for tentatively rejecting the SPAWAR idea -- tracks created during electrolysis are due to alpha particles -- has to do with the “chopped meat” structure of tracks produced during electrolysis (but not tracks due to alpha particles). I suspect that SPAWAR people also saw the “chopped meat” regions; but the article does not mention this. Ignoring troublesome issues, let me ask the following question. Which of two arguments is more convincing, the one based on long etching times or the one based on ratio of diameters? I think that the first argument is more convincing. It is also more powerful. The second argument would be about a hypothetical claim (that co-deposition electrolysis tracks are due to alpha particles), the first argument is against the actual claim made in SPAWAR paper (that tracks are due to nuclear particles).

23) P.S. By criticizing the SPAWAR paper I am trying to be useful. Yes, I know that my help might not be needed; they have been studying tracks for more than two year. But, hopefully, my critical comments might be useful to some readers. I would be very happy to applaude the SPAWAR success. That would be a great scientific contribution. The topic is too important to give up, after encountering first difficulties. But one must be careful in forging ahead.

351) High Voltage Electrolysis Updates

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
August 26, 2008

1) Introduction
About three years ago I was deeply involved in replicatios of Mizuno-type of excess-heat experiments (high voltage electrolysis). Several units on my CF website (see point 2f below) are based on this research. My involvment ended about two years ago, when I became one of participants of The Galileo Project (replications on SPAWAR-type experiments) organized by Steve Krivit.

But Pierre Clauzon, and his French colleagues, continued exploring the excess heat claim made by Mizuno and his coworkers. The purpose of this unit is to summarize recent results of French researchers, and to append descriptions of their future results, when they become available.

2) Current Status
a) During a private conversation in New York City, Pierre Clauzon updated me on his high voltage electrolysis research and mentioned additional experiments he hopes to conduct in the future. About one year ago we met in Pierre's laboratory in Paris. We performed the experiment together (using the old watt-meter) and the COP was again significantly larger than 1.0, for example 1.3 at 350 volts. The difference between 1.3 and 1.0 is statistically significant, considering reproducibility of the results.

b) New results, similar to those reported at ICCF12, were reported by Pierre in Sochi. But the claim of significant excess heat, reported in Yokohama and Sochi, is now withdrawn because an important systematic error was discovered. Pierre told me that measurements of the input energy were incorrect. The instrumental systematic error was due to unsuspected limitations of the Unigor-390 watt-meter. That instrument is reliable up to frequencies of 0.1 MHz while current fluctuations apparently contained much higher frequencies.

c) In new experiments, this instrument was replaced by D6000 Norma Goerz wattmeter; it is said to be reliable up to the frequency of 2 MHz. New experiments were performed by using a "boiling water calorimeter." The principle of measuring heat energy is the same as before (from the amount of steam produced during electrolysis) but the cell is surrounded by boiling water, rather than by air. The size of the cell, in these experiments was 1 liter. In these experiments excess heat was insignificant at all voltages, between 150 V and 350 V.

d) But that was not the end of the story. In the most recent high voltage electrolysis experiment, however, a significant excess heat was again discovered. The D6000 watt-meter was used in the latest experiments. The COP (coefficients of productivity) at 250 V were 1.09, 1.00, 1.10 and 0.97. At 300 volts, the COP values were 1.06, 1.08, 1.04 and 1.01. These results are very preliminary. They were obtained in an electrolytic cell (actually a dewar) whose volume was 5 liters. Pierre thinks that mechanical perturbation of plasma, in his small cell, were interfering with generation of excess heat.

e) In other words, the tentative "no excess heat" conclusion (see point 2c above) remains uncertain. Hopefully, the situation will become clear next month (after another sequence of experiments with the large dewar cell).

Nuclear or not nuclear: how to decide?

Ludwik Kowalski
Montclair State University

Kowalskil@mail.montclair.edu

Fourteen's International Conference on Cold Fusion
Washington, D.C, August 10-15, 2008

Introduction

The first version of this paper was devoted to my participation in The Galileo Project. More specifically I wanted to explain why, in my opinion, alpha particles, or less massive nuclear projectiles, could not be responsible for copious pits discovered by the SPAWAR team. I wanted to justify this conclusion not only on the basis of my own experimental data but also on the basis of SPAWAR results published in (1). It occurred to me, after writing the first version, that my manuscript could be published in a mainstream journal.

Not counting on success, I decided to submit the paper as soon as possible. Surprisingly, my paper (2) was accepted; it will probably be published in September or November of 2008. This presentation briefly summarizes my investigations of SPAWAR results and addresses some topics of general interest.

Investigations of SPAWAR results

In 2007 I was one of several researchers who used SPAWAR protocol, distributed by Steve Krivit, and reported the results (3) at the APS Winter Meeting (Denver, 2007). These results, and results reported by other researchers, demonstrated that dominant pits discovered by SPAWAR researchers are reproducible. No one disputed this fact. As far as I know, everyone who used the protocol observed copious pits on the face of the CR-39 detector that was in contact with the silver cathode during electrolysis.

But disagreements emerged about how to explain these pits. Are they due to nuclear projectiles created during electrolysis or are they due to something else? If copious pits are due to nuclear projectiles then what kind of projectiles are emitted? Can they be alpha particles and protons, as suggested by SPAWAR researchers (4)?

Taking the nuclear origin of copious pits for granted, I convinced myself that SPAWAR-type pits could not possibly be due to alpha particles, or to less massive projectiles, such as protons. That conclusion, based on my own experimental data, was reported in (3). In the paper to be published (2) I show that SPAWAR's experimental data, reported in (1), lead to the same conclusion.

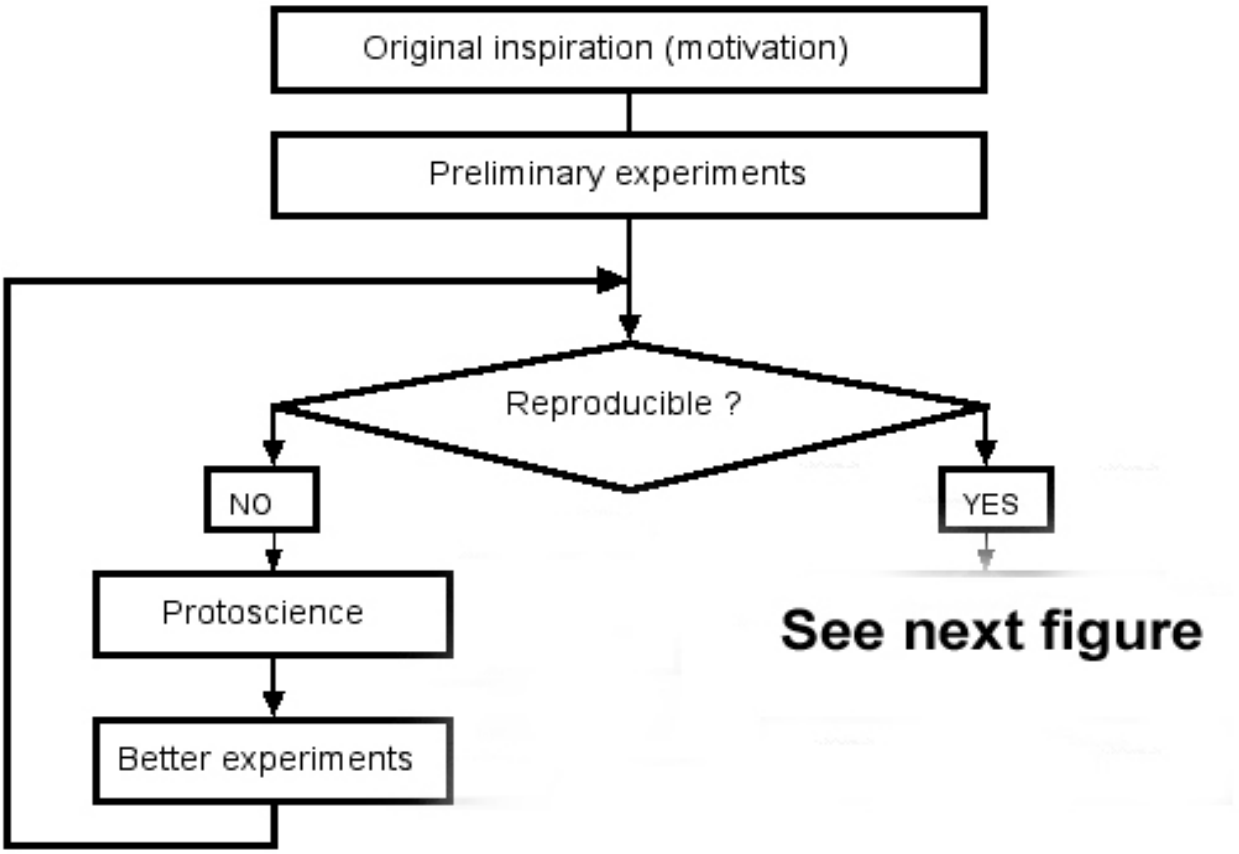
The paper (2) also refers to experimental results reported by several CMNS researchers. In an experiment conducted by Tanzella et al. (5), the CR-39 detector was surrounded by a six-micron mylar film. This was done to eliminate direct contact between the CR-39 detector and the cathode (or the electrolyte). The film

was sufficiently thin to allow alpha particles (with energies higher than 1.5 MeV) to be transmitted. No copious pits were observed in this experiment. I consider this to be a direct proof that SPAWAR-type pits are not due to alpha particles with energies higher than about 1.5 MeV.

The most interesting result of (5), however, was the presence of another kind of pits, on both sides of the CR-39 detector surrounded by the thin mylar film. These pits were not as abundant as SPAWAR-type pits (only about 100 per square centimeter versus millions per square centimeter) and they were considerably smaller than copious pits in SPAWAR-type experiments. A subsequent investigation (by Lipson et al.) showed that sizes of pits, on the mylar-protected CR-39 chip, are about the same as sizes of pits due to protons with energies between 2 MeV and 3 MeV. In my opinion, proton-like pits offer a more convincing evidence of a nuclear process due to electrolysis than much more abundant SPAWAR-type pits, near the cathode.

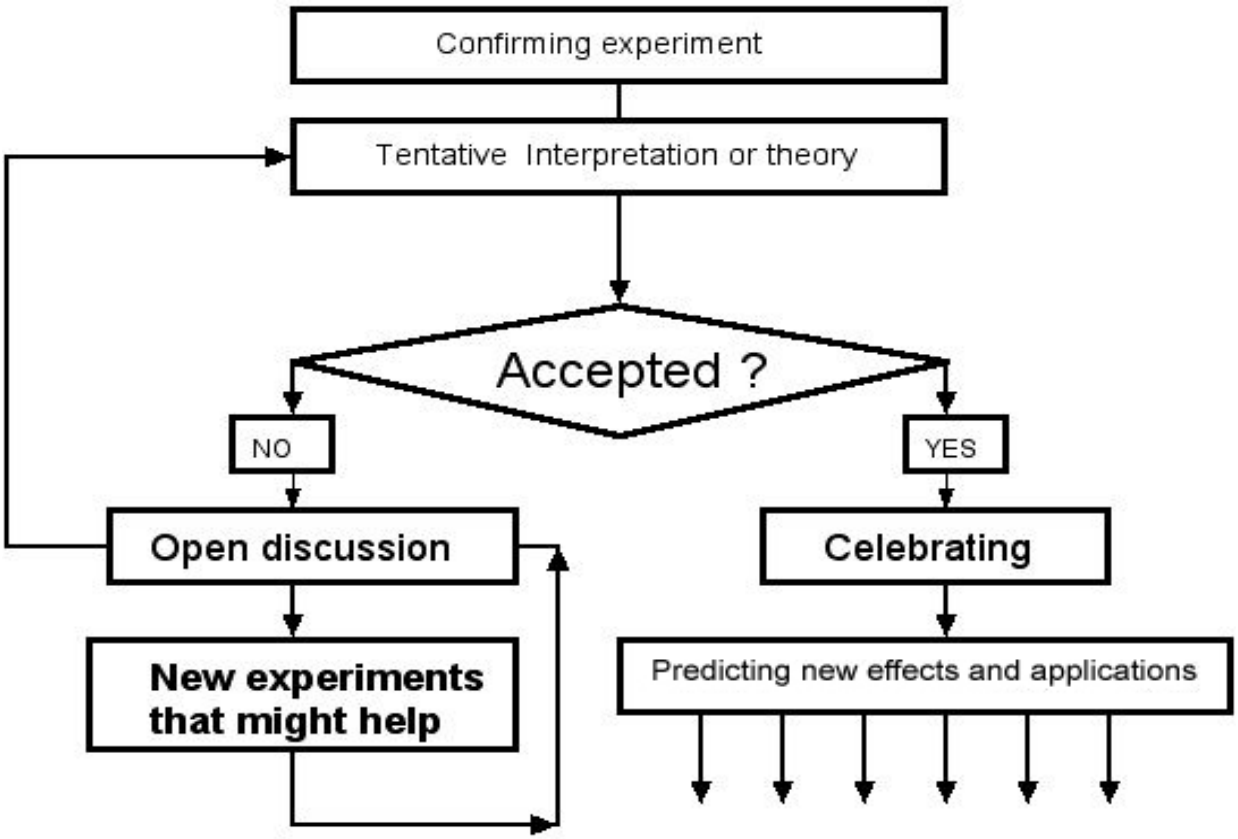
General observations and suggestions

1) Problem of reproducibility: science versus protoscience
Use of scientific methodology of validation, in a given field, is not sufficient to make a field scientific. At least some demonstrations of new phenomena must be reproducible on demand. Without this a field should be characterized as protoscientific. The expected evolution of a protoscience into science is schematically represented by the flowchart below.



2) Struggle for recognition

A field in which scientific methodology of validation is used, and in which some new phenomena are reproducible on demand, is scientific. The expected evolution of a new scientific field, toward general acceptance, is schematically represented by the flowchart below:



Evolution of protoscience into science (the first flowchart above) can be very slow because experiments are not reproducible and because researchers are not guided by a reliable theory. Theories based on ad hoc assumptions are not reliable. Success depends on sheer luck in accidentally identifying necessary preconditions for reproducibility.

But the path from reproducibility of a new effect to general acceptance (the second flowchart above) is likely to be much faster. Starting with a reproducible experiment one can quickly learn how different parameters influence the effect. Some parameters will have only negligible effect on the outcome while others will have dramatic influence. Success will no longer depend on chance; it will become a matter of skill in systematic investigations.

3) Coordinated research versus working in isolation

It is unfortunate that, except for The Galileo Project, initiated by Steve Krivit (7), CMNS researchers work in isolation from each other. This is understandable; each researcher does what matches his/her expertise and limited resources. This kind of work has been going on for 19 years. It produced remarkable protoscience, in the subfields listed below:

---

1) Excess heat, sometimes orders of magnitude larger than what can be attributed to known chemical reactions.

2) Excess heat correlated with production of 4He (generated at a rate close to 23 MeV per atom of produced helium).

3) Chemically-induced changes in isotopic composition of elements. Note that the term "chemically" is very broad; it covers all atomic and molecular processes, including diffusion of gasses through solids.

4) Production of new elements, either stable or radioactive, in amounts high above what can be attributed to omnipresent impurities.

5) Chemically-induced changes in the rate of radioactive decay.

6) Production of high energy photons, for example, gamma rays, during chemical processes.

7) Emission of energetic nuclear particles

But the task of turning protoscience into accepted science is still waiting for us. How to approach this difficult task and how to proceed more effectively? In my opinion, well-focused cooperative investigations, as in The Galileo Project, are likely to be more productive, in the next two or three years, than uncoordinated efforts of many individuals. Who should select the one or two most promising effects on which to focus? Who should coordinate these investigations? And who should cover the costs (probably not more than three to five million dollars)?

I think that the task of selecting one or two effects, on which to focus, belongs to us; our CMNS discussion list, run so well by Haiko, seems to be an ideal platform to debate various proposals. A decision is likely to emerge after about three months of intensive debating. But the two other tasks, coordination and providing financial support, belong to our governments. Acting as a group, we should approach government organizations, such as NSF, National Academy of Science, or DOE, and ask for coordination and support. That is the declared mission of such organizations. National laboratories best equipped for the selected projects should be selected, to minimize additional costs. That is the only way to get a clear yes-or-no answer about the new kind of nuclear activity.

How to convince governments that a relatively modest amount of additional money is worth investing to solve the puzzle? By being organized and acting as a group rather than as independent individuals. This kind of action was already tried, about five years ago, and it produced a result; the second DOE investigation of CMNS would not have taken place without such initiative. Unfortunately, that investigation turned out to be a failure. The reason is obvious; the DOE decisions were based on voting, rather than on experimental data. Scientific decisions should be based on available data, obtained by the most qualified scientists in the most suitable laboratories. Voting is not part of scientific methodology.

4) Which experiments would I recommend?

If only one experiment were to be selected, my choice would be from the second subfield (see the above table), preferably the protocol of Mike McKubre et al. Several independent, highly qualified, investigators reported production of helium during electrolysis. Each of them reported that results were reasonably reproducible in consecutive experiments. If two experiments were to be selected then the second experiment would be from the last field, preferably the protocol described in (5). But at least one more replication of the Tanzella-type experiment would be needed; a single experiment is not enough to make the decision. Production of helium and production of protons are undeniable nuclear signatures. No matter which experiments will be selected, for coordinated investigations, the purpose should be the same, to

demonstrate a nuclear activity resulting from a chemical process.

Will we be able to act in unison and accomplish the first task quickly? Will at least one team of scientists emerge, ready to cooperate with mainstream scientists in a national lab? Will they obtain the necessary support from in at least one country? All this remains to be seen. In the final analysis, the outcome will depend on our willingness to fight for a clear yes-or-no answer.

5) **Post-confernce addendum (8/17/08)**
Contrary to my expectations, no new CR-39 results (in comparison with what was reported in Catania) were presented by SPAWAR team or by Francis Tanzella. Oriani's CR-39 paper was read by John Fisher.

353) From my ICCF14 notes

Ludwik Kowalski (8/17/08)

Montclair State University

This unit is based on what I wrote while listening to several ICCF14 presentations. Many sessions of the conference were named to match the CMNS subfields. The names were (a) Heat Results, (b) Measuring heat (calorimetry), Materials, (d) Gas and gas loading, etc.

1) What is FPE?

It is interesting that both David Nagel (conference chairman) and Dennis Lett (one of the presenters) defined the Fleischmann-Pons Effect (FPE) as "electrochemical excess heat." I like this definition because it does not refer to the origin of excess heat. Most scientists of my generation would probably say that FPE is a "nuclear reaction of some kind, triggered by electrolysis." Fleischmann and Pons speculated about nuclear origin of excess heat but they had no evidence for it. It is not hard to imagine how different history of our field would be without their premature speculations. No one would object to their isoperibolic calorimeter data and only highly qualified electrochemists, such McKubre, Szpak, Miles and Boss, would continue studying the new effect. First they would demonstrate reproducibility, then they would test interpretational predictions. Premature speculations of F&P were responsible, at least in part, for the tragic situation in which one field of research was unjustly pronounced as unscientific.

2) Superwaves

I was impressed by the report of S. Lesin (Israel). He described electrochemical experiments in which excess heat, at the power level between 0.5 and 1.0 watts, was observed (in more that 20 experiments) at levels of reproducibility between 75% and 80%. In all of these experiments the electric current was periodic (superwaves) and cathodes were bombarded with ultrasound. This should not be confused with rare experiments yielding much more spectacular results. In the best of these experiments, lasting 40 days, the excess power was said to be 32 watts. Multiplying 32 watts by the duration of the experiment one gets the total excess energy of 110 MJ. But reported value was 35 MJ. That probably means that 32 Watts was the highest power, not the mean power. The mean power was probably close to 10 W, which is spectacular.

That spectacular result was obtained by using superwaves (but without bombarding the cathode with ultrasounds). The idea of using superwaves, suggested by Dr. I. Dardik, an Americal medical researcher, has been used in Israel for many years. According to T. Zhilov, a large number of tests have been made (in the past) to show that cells powered by superwaves produce more reproducible results that identical cells powered by constant currents. According to another scientist, superwaves are also used to influence solidification of metals. Unfortunately, I am not aware of any quantitative theories explaining superwaves. Let me also mention that Preparata medal was awarded to Irving Dardik, for introducing superwaves.

3) A pectacular results to be confirmed

Another set of spectacular excess heat results were described by a Russian scientist, A. Karabut. (Unit 13, by the way, was also devoted to his results). He used an electrolytic cell powered by "periodic input" current (rather than d.c.). I suppose that periodic current consisted of nearly rectangular pulses separated by zero current, as in another paper presented by Karabut. That would be equivalent to superwaves--short pulses consist of many frequencies. The cell was made from quartz, two kinds of palladium (pretreated and not pretreated) were used as cathode and the electrolyte was made by using light water. Unfortunately, chemical composition of the electrolyte is not specified in the paper. The meaning of the "pretreated" and "not pretreated" is not at all clear. How can anyone try to replicate the experiment without such information?

But reported results are indeed spectacular. Excess heat produced with the "pretreated" palladium was produced at the rate of ~300 W for nearly 3 hours. The amount of excess heat produced was 8.1 times higher that what was used. Excess

heat produced with “not pretreated” palladium, was produced at the rate of ~100 W for 6 hours. The amount of excess heat produced was 3.1 times higher that what was used. The results were said to be reproducible on demand. Potential differences between the anode and the cathode, in these experiments, were between 800 V and 1000 V.

In both cases the electrolysis was turned off when the temperature of the electrolyte reached the level of 80 C. Does it mean that generation of excess heat, at the rate of 300 W, would continue if excess heat was efficiently removed from the cell, for example, to produce electricity? I do not know haw to answer this question. But I am surprised that no replications of Karabut’s results were made by other Russian CMNS researchers.

4) Working against all odds

During the medal-award ceremony (8/13/08) Irving Dardik referred to us as “a community of dedicated people working against all odds.” This is a profound observation. How can it be interpreted? One can say that, due to unfortunate circumstances in 1989, a situation was created in which the level of scrutiny for CMNS claims is much higher than for claims in other areas of research. This can be summarized by the well known rule formulated by Carl Sagan -- “extraordinary claims require extraordinary proofs.” How can one disagree with such rule? But the rule has often been abused. Scientific journals should not refuse sending CMNS manuscripts to referees and granting agencies should support proposals formulated by reputable scientists.

Added on 8/19/08)5

Another spectacular claim of A. Karabut

This claim has to do with generation of X rays during the glow discharge. It is not a new claim; I listened to an earlier version of it in Albuquerque (Summer 2002). But new results are much more impressive. I am not sure that the term “glow discharge” is appropriate. In a private conversation I learned that the setup operates on the right side of the Pashen curve, far away from the minimum. I would say the system operates in the controlled electric arc region. The high voltage pules are so short that the arc does not have time to develop.

On one illustration I see pulse-periodic waveforms: (3500 V and 200 mA lasting 2 ms), followed by zero volts and zero mA (lasting 8 ms). In other words, the period of repetition is 10 ms. Most laser-like beams of X-rays, presumably emitted from monocrystals embedded in cathodes, exit during the 2 ms, when the voltage is applied. But some exit when the voltage is zero. Should this be called X-ray emission after death?

In addition to laser-like X-rays (coherent and mono-directional) Karabut observed incoherent X-rays. Their intensity decreases with the distance according to the 1/r^2 law. Energies of all X-rays are between 0.5 keV and 10 keV. In other words, some photons have much more energy than one would expect at 3500 volts. The only way to understand this is to assume that multiple excitations of atoms take place at very high currents. Some of the excited levels must be long-lived, to allow for the “inverse population” of levels, a precondition for lasering.

By the way, Pamela Boss, in a presentation honoring a SPAWAR scientists, Stanislaus Szpak, reminded us that X-rays with broad energy distributions, with occasional peaks (at 20 keV and between 8 and 12 keV), were observed in electrolytic experiments as early as in 1996. The peaks were attributed to known energy levels in Pd and Ni. Presence of keV-level photons, in a low voltage cell (probably less than 10 V) could not possibly be due to chemical reactions. The same is true for production of tritium in low voltage cells, as reported by SPAWAR researchers, in 1998.

Karabut’s impressive X-rays investigations, conducted at “FSUE Luch” laboratory (near Moscow), involved a large number of cathode materials (Al, Si, Ti, Ni, Nb, Zr, Mo, Pd, Ta and W) and several gasses (H2, D2, He, Kr, and Xe). How many other Russian scientists tried to replicate his spectacular results?

6) A good overall review of CMNS

I was very impressed by a paper presented by Mike McKubre. He promised to send me excerpts from his paper. I will insert them here, as soon as they arrive.

7) Iwamura-type transmutations.

Iwamura transmutations, occurring when D2 gas permeates through a Pd multilayer complex, offer the most convincing evidence of a nuclear process due to a chemical process (in this case accumulation of deuterium ions near a CaO layer in palladium). According to the progress report, presented by Y. Iwamura, highly collimated beams of X-rays were used to study distributions of nuclear reaction products. Evidence of hot spots (places where reaction products are concentrated) was obtained. This investigation is still going on.

Two other Japanese teams of researchers presented reports on ongoing Iwamura-type projects. According to one team (T. Yamaguchi et al.), no evidence of transmutation products was found "up to now." The other team (T. Hioki et al.) did confirm appearance of molybdenum but its isotopic distribution was not the same as in Iwamura's experiments. This weakens our confidence that molybdenum was produced from strontium. These two negative reports made me think about the dilemma facing anyone whose results, or interpretations, do not agree with positive CMNS claims made by other researchers.

One has to be brave to present a negative CMNS report at a formal gathering of CMNS researchers. Most attendees want and expect positive results and convincing interpretations. Reporting something negative is likely to produce discomfort and personal friction. What fraction of CMNS researchers prefer to report nothing instead of reporting negative results? I hope that this fraction is small; reporting negative results is just as important as reporting positive results. We all know this. But how does this influence what we actually say, and not say, in public? Friendship and other considerations ("that is bad for CMNS reputation") might play a role, in practice. That, hovewer, would be bias.

8) To make future conferences more effective

ICCF14 was great; a lot of interesting papers were presented, both orally and in the form of posters. Unfortunately, most of us are not able to penetrate contents of papers heard for the first time. Our conferences (including the next one in Rome, September 2009) would probably be more productive if papers, to be presented orally, were submitted ahead of time and posted at the conference website several weeks in advance. In that case formal presentations could be shortened and more time could be devoted to open discussion, after each presentation.

Conferences would also benefit from dedicated Internet discussion lists. Suppose a list is created in connection with each conference. It would be a perfect forum for post-conference comments and debates. Many people are not able at attend faraway conferences but would like to participate. Posting papers before each conference, and offering a forum to discuss them after the conference, would be a big help for them. In fact, all would benefit from broader participation.

354) Excess-Heat Cell of John Dash

Ludwik Kowalski; 10/5/2008

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

(1) On 9/24/08, John Dash posted the following message at a private Internet discussion list for CMNS researchers:

" Scott, In Aug. 2003 my students (3 high school students and 1 graduate student) demonstrated 0.8 W excess thermal power in Peter Hagelstein's lab at MIT during ICCF-10. I believe we can do the same demo on demand, anytime, anywhere. It is now more than 2 years since you began to evaluate our experiment. When can we expect a report on your findings ? "

(2) On 9/25/08, Marissa Little, who works with her father, Scott, replied: "John, we have discussed the conclusions with you on multiple occasions. While we did see an apparent excess heat signal, we identified two mundane causes for it. Our conclusion is the same as it was at the end of testing in 2006. Thanks for reminding me that the final report was never made available. I will post a link to it on CMNS in a few days and everyone can read the details of our testing and the results.

(3) I was not aware that Scott and John cooperated to validate excess heat from a cell similar to that displayed at MIT during the first cold fusion conference I attended. Units 98 and 103 were composed after my return from the conference. Replying to the above I wrote:

"John, I was very impressed by your 2003 demo at MIT. It is worth showing in as many places as possible, and as often as possible. If I had such "demo on demand" I would aggressively invite many respected scientists to my lab. I would bet with them and used the gained money to support further research. Here is a constructive suggestion. Please describe the protocol for this demo and offer help to anyone who decides to replicate your results. The goal would be to confirm that your simple experiment can be replicated "anytime, anywhere" and by any competent person. Just imagine what would happen, after ICCF15, if several people independently reported positive results using your protocol. Describe it here (with all details) as soon as possible. I might be one of those who decides to follow your footsteps. Nothing is more urgent that a simple reproducible CMNS experiment."

(4) On 9/26/08) Mike McKubre wrote: " John has a long career in experimental science so I don't think Marissa would have communicated her conclusion of 'two mundane causes' for excess heat without significant substantiation in hand. We need to know the reasons and arguments. If there are systematic errors that can be demonstrated quantitatively to have caused (or even contributed measurably to) the excess heat effect in John's (mostly) closed cell calorimeter I (for one) would like to know what these are. If there are not, or if John does not agree, that I would also like to know. The Little calorimeter is of unusual design and may be capable of resolving errors that could cause confusion in other calorimeters. Or it may have systematic problems of it's own. It would be nice to know. Until such time as this is resolved I don't see the point of more discussion of what, where, when and who. I am much more interested in how.

(5) On 9/29/08, Pierre Carbonnelle, who is not a CMNS researcher, wrote: "Let's beware of pseudoskepticism, i.e. of 'making counter-claims based on plausibility rather than empirical evidence, of assuming that criticism requires no burden of proof, or suggesting that unconvincing evidence is grounds for dismissing it' ".

(6) On 9/30/08, Marissa Little (who works with her father Scott Little) posted the result of their investigations. She wrote: "Thanks to John's recent reminder, we've finally completed the report of our effort to verify the excess heat claims of John Dash and Wu-shou Zhang.

http://earthtech.org/experiments/DZ/report.htm

Here is the conclusion from the report:

We did see an apparent excess heat signal from the Dash-Zhang cell when operated with their protocol. It took the form of a broad pulse that started just as the cell was reaching equilibrium temperature and always died away to nothing after about 8 hours of operation. The maximum apparent excess heat power for a closed cell (DZ8) reached 0.2 W while the total input power was about 15 W. We found two separate mundane causes for this heat pulse.

1. The release of heat energy stored in the cell during the high-power period at the beginning of the run. This effect is made larger by the use of insulation around the cell such as the cardboard box recommended by Dash and Zhang.
2. The heat of wetting released when ~100 g of recombiner pellets is wetted by water vapor rising from the nearly-boiling electrolyte.

We also conducted a number of experiments using electrodes supplied by Dash and Zhang mounted in standard ET cells. None of these runs showed any signs of excess heat above MOAC's detection limit, which is approximately 30 mW.

John, if you have new cells which avoid these problems and show substantial persistent excess heat, we would be delighted to test them in our calorimeter."

(7) Several other CMNS researchers contributed to this thread. Many important details, with which I was not familiar, were emphasized. John Dash wrote that his improved protocol, and personal help in implementing it, is available to any CMNS researcher.

(8) On 10/1/08 Mike McKubre wrote: ". . . John you are using a very large amount of recombiner. Why? Would you care to comment on Marissa's observations? No matter how stated there is information and learning there and it is up to you to understand quantitatively what Marissa is reporting and get back to us with agreement, rebuttal or uncertainty. Marissa; I don't think anyone doubts your observation, just your interpretation and the forcefulness of your conclusion. I don't pretend to be an expert or superior in this matter but . . . I have not read your web-paper yet but, however rigorous your energy calculation, you apparently observed little more than a 1% peak effect. This is not (as I understand it) the Dash-FP effect."

(9) On 10/1/08 John Dash wrote: "Marissa, I should have read your report before I responded. It does have the numbers ! Sorry. You did some excellent work on our behalf. Thank you and thank Scott. What I am wondering is, did you calibrate MOAC with the calibration cell in the cardboard box ?

(10) On 10/2/08 Marissa Little wrote: "Ed and Mike, the DZ cell is quite unique – it contains 100 grams of recombiner pellets (our typical cells use 30 pellets which weighs just over ONE gram). Before each of the DZ runs, the pellets are placed in an oven overnight, so they are very dry. The DZ cell contained far more recombiners than needed, most get wet and stop working. But a few stay dry and continue to work. Here is a picture of a cell immediately after power was cut.

(11) On 10/2/08 Ludwik Kowalski posted the following message:

Dear all, Please provide data for the summary of reported results (replace question marks with wattages below).

A) John Dash ----->MIT demo 2003
Input power ~10 W, excess power 0.8 W (+/- 0.15 W)

B) Scott and Marissa Little-----> 2008
Input power ~15 W, apparent excess power 0.2 W (assuming 0.2 W was not due to two "mundane causes" suspected by the authors.)

C) Chang Chun University, China ----> 200?
Input power ???, excess power ??? (+/- ???)

D) Italy two high schools ---> 200?

(12) On 10/4/08, Scott Little sent me a private message explaining that my use of the word "suspected" (in item B above) did not properly refer to what they did. Scott wrote.

"I have a quibble with the wording of your recent statements about our efforts on the Dash-Zhang experiment. It's not worth taking up the time of everybody on the CMNS list so I'm writing privately. [quoting item B shown above]

Back in late 2006 when we were running the Dash-Zhang cell in our calorimeter, the first time we observed a temporary excess heat signal while using the cardboard box around the cell, we "suspected" that the box might be partly responsible. We then set up the differential equations for an insulated mass being heated by a declining input power and plotted the temperature of the mass vs time. As discussed in our report, this computer simulation "demonstrated" results that qualitatively matched the behavior of the DZ cell. But that's a transient effect which should have integrated to zero. In the case of the DZ cell, the integrated energy totals always came out a little positive. We then began to "suspect" the 100 grams of recombiner pellets, mainly because that was the only other unusual aspect of the DZ cell. At the time we had never heard of "heat of wetting". As discussed in our report, we set up a special experiment in our calorimeter to measure the heat of wetting of 100g of dry recombiner pellets. The result was 2760 joules, which closely matched the net energy integral we were seeing from the DZ cell.

Summarizing, we "suspected" the two mundane causes first, then we proceeded to "demonstrate" that they were both present and that they qualitatively and quantitatively accounted for the observed apparent excess heat signal.

Ludwik, we are making a concerted effort to state our conclusions properly and with appropriate reservation. I will be the first to admit that our negative results do not prove that the DZ cell does not work. But I do not think it serves us well to soften the results as you have done above. We saw an apparent excess heat signal and we demonstrated that it was due to mundane causes. That sort of reporting is exactly what the CMNS field needs if we are ever to be properly recognized by mainstream science."

(13) On 10/5/08 Ludwik Kowalski wrote: " It is great that John offered to help anyone willing to replicate his demo, and that Marissa offered access to their superb calorimeter. Will there be at least one new team of electrochemists to take advantage of the offers made by John and Marissa? This remains to be seen.

In any case, I hope that the ongoing cooperation between John and Marissa will continue till they agree on presence or absence of excess heat, in a cell constructed according to John's protocol. It would be a big waste to stop their cooperation at this time; John has great experience in building excess heat cells, Marissa and Scott have experience in measuring excess heat with their calorimeter. The instrument is not only very sensitive (able to measure small amounts of excess heat); it is also very accurate (small systematic errors--drift etc.) and very precise (small random errors--standard deviation).

I guess that more than ~95% of necessary investments (time and money) have already been made by each team. That is why I think that stopping the ongoing cooperation would be highly regrettable. Finding the truth is much more important than any other possible factor. Am I the only one to think that John and Marissa should continue to cooperate? "

(14) On 10/5/08 Ed Storms wrote: "It seems to me we have two issues. The first is whether the calorimeter and cell design John uses has demonstrated real excess energy. The heat of absorption of water on the large amount of catalyst is a worry, as shown by Marissa. The second is whether the cathodes made and used by John are nuclear-active. Since

creating nuclear-active cathodes has proven to be very difficult, any success in making active material would be a major accomplishment. Therefore, I think the emphasis should be placed on testing a Dash cathode that has made excess heat previously in his calorimeter. I would volunteer to do this using a well characterized Seebeck calorimeter. I can also examine the cathode for various characteristics before and after the run. Since my setup has in the past detected excess energy, we can be sure it can do the same in the future."

15) On 10/5/08, Marissa Little wrote: "Very good points Ed. I think that John may have moved away from the large amount of catalyst, though I could be wrong. I noticed in a poster (W.S. Zhang, Dash, Z.L. Zhang) at ICCF-14 that the catalyst was on the order of a few grams instead of ~100 grams. Here's a comparison of the "old" cell and what I think is the "new" cell (shown in an isoperibolic calorimeter) [Two photos displayed]. John, was this a unique setup or do most of your cells now use smaller amounts of catalyst?

16) On 10/5/08 Ludwik Kowalski wrote: "I agree with Ed that 'we have two issues,' excess heat and its nuclear origin. I will be happy to provide CR-39 chips and to perform the tedious task of counting tracks, if any, for anyone who observes excess heat."

17) **Final wish**
Let us hope that John and Marissa (helped by others) come to an agreement about excess heat, and publish the result in a mainstream paper. I am not going to write about details that are still being discussed. I am not an expert in electrochemistry and recombiners. But the discussion is interesting.

355) Discussing SPAWAR neutrons, etc.

Ludwik Kowalski; 10/31/2008
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

1) Introduction
There was an exchange of interesting messages about CMNS phenomena on a private Internet discussion list for researchers. After showing four messages posted today I will show the abstract of a paper that Takahashi attached to his message.

2) Message posted by Ed Storms (from USA)
I would like to throw an idea into the discussion pot and see what kind of soup results. We all know that a few neutron have been detected from CF cells. When tritium is measured at the same time, the ratio strongly favors tritium. The challenge has been to explain this behavior.

If the neutrons result from a hot fusion reaction, such as caused by fractofusion, why is the tritium not made in the amount expected to result from hot fusion [where the number of neutrons is the same as the number of tritons] ?

Helium is produced when excess heat is detected. Suppose the helium starts with enough energy to produce neutrons from the well known alpha/n reaction. Most efforts to detect neutrons have failed because the basic helium-energy producing reaction was not initiated. Most successful studies that actually produced the helium-heat reaction did not use neutron detectors. Therefore, this emission was missed because the number of neutrons is too small to be noticed without a sensitive
neutron detector.

In other words, helium and tritium are made by the NAE [Nuclear Active Environment favoring CMNS phenomena] and neutrons are emitted in small amount because the resulting alpha can have enough energy to cause the alpha-n reaction with impurities within a F- P cell {Fleischmann-Pons cell], such as B or Li.

Takahashi is one of the few people who measured the energy of emitted neutrons under conditions that produced some heat. These neutrons had an energy that could have been produced by an alpha/n reaction. What do you think of this idea, which is counter to what we have assumed to be the case?

[Ed Storm is the author of a book about CMNS phenomena (1)] :

3) Message posted by Mahadeva Srinivasan (from India)
There seems to be strong evidence to suggest that tritium appears invariably after a neutron burst. We have gone on record to suggest that both neutron and tritium occur simultaneously. I can pull out all our results which support this contention for you.

In your alpha to neutron model where does the tritium come from? Keeping in mind the experimentally confirmed branching ratio anomaly, I would therefore propose that what ever be the origin of tritium, neutrons seem to be a small byproduct or side reaction of that process.

P.S.
* We had pointed out in our ICCF1 paper that many groups at BARC seem to have independently noted that invariably tritium is observed in the electrolyte only after a large neutron burst is recorded. See for example Figs 3 and 7 of the Overview paper by Iyengar et al at ICCF1. So I continue to support the notion that tritium and neutrons are coupled.

* Whether tritium also arises from the same NAE which generates helium is worth examining. Ed has a good point!

* The very concept of an NAE proposed by Ed suggests hot spot behaviour. We had observed hot spots through autoradiography in Ti tagets in very many TiD targets. (See our Provo meeting paper of 1990 titled "Observation of Tritium in Gas/Plasma Loaded Ti Samples". (This paper has just been uploaded by Jed in the lenr site. THANKS JED!)

* Our papers on Statistical Analysis of neutron emission published first at ICCF1 and repeated on a different Milton Roy cell in 1994 and published in ICCF5 once again pointed out that there are many instances of bunched neutron emission suggesting that there seem to be events where hundreds of neutrons are emitted.

* So what does all this mean? Neutrons are localised in time; Tritium is localised in space (hot spots & NAE); Tritium and neutrons are coupled.

* Superimpose on this the branching ratio anomaly of 10**(-8) you come to the tantalising conclusion that micronuclear explosions seem to be occurring, highly localised in space and time.

* So far I have not seen any evidence that He and Tritium are coupled, meaning that they are both occurring in the same event. But Eds hunch that there cant be two categories of NAE forming sounds quite plausible. May be they are all coupled and all emanating from micronuclear explosions!

* This is where I come back and once again emphasise the importance of statistical analysis of the neutron emission. As far as I can see neutron diagnostics is the only tool through which we can investigate the concept of cascade events.

* I have been trying to convince Pam and the SPAWAR group that they are well placed experimentally to verify this independently !

4) Message posted by John Fisher (from USA)

Polyneutron theory predicts exothermic reactions between a polyneutron An and deuterium 2H that generate reaction products ^{1}H, ^{3}H, and n. Reaction energies depend on whether the polyneutron contains an even or an odd number of neutrons. Reaction is favored by increased energy and is inhibited by a correlation barrier for An ---> AH (in which a proton is substituted for a neutron in a polyneutron).

For odd-A polyneutrons the reactions in order of their rates are

An + 2H ---> (A+1)n + ^{1}H + 8.9 MeV (favored)
An + 2H ---> (A-1)n + ^{3}H + 3.6 MeV
An + 2H ---> (A+1)H + n + 8.9 MeV (inhibited).

For even-A polyneutrons the reactions in order of their rates are

An + 2H ---> (A+1)n + ^{1}H + 0.5 MeV
An + 2H ---> (A+1)H + n + 0.5 MeV (inhibited)
An + 2H ---> (A-1)n + ^{3}H – 4.8 MeV (endothermic).

(Energies are written only to the nearest 0.1 MeV because experiment has not provided more accurate experimental evidence for polyneutron masses.) For reaction energies above 1 MeV we expect 1H and n with energies 8.9 MeV, and ^{3}H with energy 3.6 MeV; and we expect the neutron reaction to be strongly inhibited by a correlation barrier. For reaction energies less than 1 MeV we expect ^{1}H and n with energies 0.5 MeV and again we expect neutrons to be strongly inhibited. Overall we expect more tritium than neutrons. (In an earlier communication I have accounted for helium in proportion to heat without direct or indirect generation of neutrons: most heat comes from the 8.9 MeV 1H reactions and the helium comes from polyneutron decay.)

I appreciate that polyneutron theory is unpopular. By this communication I do not expect to change the situation in the short term. But I have hopes for the cumulative influence of polyneutron predictions in the long term.

[John Fisher has been promoting the idea of polyneutrons for many years. The latest version of his theory is described in the proceedings from a 2008 conference (2)]

5) Message posted by Akito Takohashi (from Japan)
Dear Ed and all; this is good idea. As you know, my past group at Osaka University made serious efforts, under the Japanese New Hydrogen Energy Project (1994-1998), to search possible correlation between excess heat, He-4, neutron, tritium and X-rays. We used most sophisticated method available at that time. I am attaching a summary paper, for people who do not have it.

We had some results to draw what was taking place, but it was not definite. We used only Pd-plates for the cathode of D_2O electrolysis (c.f. H_2O). The main difficulty was low level of excess heat, very low [rate of] nuclear emissions and [poor] reproducibility.

Now, in 2008, we have had some [progress with] reproducibility. The nano-size-Pd samples have shown encouraging results by the Energetics-SRI-ENEA method of US+SW electrolysis, The SPAWAR co-deposition electrolysis method, The Arata-type nano-particle D-gas loading method, The Celani-type nano-wire D-gas loading method, etc.

If we can combine again these newer methods and the past sophisticated diagnosis methods (see the attached paper), [then] we will have a good chance to [study] the correlation between the observed products. That would lead to understanding of the underlying mechanism. Unfortunately, funding to support such investigations is not available.

I do have some theoretical ideas but will not touch upon them today.[Akito Takahashi used to be an experimental nuclear physicists. But, after retiring, he decided to focus on theoretical considerations, as illustrated in (3)]

[Akito Takahashi used to be an experimental nuclear physicists. But, after retiring, he decided to focus on theoretical considerations, as illustrated in (3)]

6) Abstract for the 1998 paper by Takahash et al. (4)**:**
Using two electrolysis systems based on D_2O/Pd electrolysis,experimental searches were tried to find correlation between excess heat and possible nuclear products (neutrons, X rays,tritium and helium). One was the open electrolysis system, with twin cells to study correlation between excess heat, X-rays and neutrons The other was the closed electrolysis system to study correlation between D/Pd ratios, excess heat, neutrons and helium. No very clear correlation between excess heat and any nuclear products have been observed, but several marginal-level data were obtained to show helium-4 production when excess heat were observed in the closed electrolysis system. In few cases by the open electrolysis experiments, clear excess heat was observed with no visible increases of characteristic X-rays and neutrons over the background. Burst events of soft X-rays and neutrons were observed in few cases, being independent of excess heat production.

7) Horace Heffner wrote: (from USA)
Ed wrote: “To summarize, Horace, an energy difference exists between the three reaction paths that you expect to influence the reaction rates. This difference does not have an influence when the reaction is initiated at high energy. Why not?”

The energy difference does have an influence because the mass deficit from the final products limits the energy available from the reaction. If specific strong force bonds do not form then no kinetic or radiant energy results from their formation. If a strong force bond forms that must be broken in order to make some final fusion product, then the energy must be available in the excited nucleus to break that bond, i.e. to undo it, else the reaction is not feasible. Energy is key.

Further, in a vacuum initiated kinetic fusion reaction there is no electron in the excited He* intermediate product reducing the amount of available energy. This makes the reaction pathways fairly simple. In the lattice it is feasible for electron catalyzed fusion to occur. A catalytic electron has an energy related influence on the final products feasible, and this influence varies with time.

Ed also wrote “In addition, until the reaction is initiated, how do the nuclei know how much energy will be released, hence what the rate should be? “

The energy exciting the intermediate ^{4}He* comes primarily from formation of strong force bonds.

Ed also wrote “The He reaction is suppressed in a vacuum because emission of the required gamma violates several rules, hence is hard to initiate.”

Yes, there is a momentum problem and maybe a long half life for any gamma emission that allows the other branches to occur first. Again, this problem doesn't exist if there is an electron in the He*. The electron can radiate away the energy to the lattice in small increments.

Ed also wrote “In contrast, the He reaction is very favored in a solid. Obviously, the environment plays an important role.”

Yes indeed, but here it takes the Deflation Fusion model to understand this I think. The deflated state is very brief - too brief to provide electron catalysis for high energy vacuum collisions except at energies so extreme fusion is otherwise expected. Electron catalyzed fusion in the vacuum is thus just not readily observable. Though it is brief, the deflated state repeats rapidly enough (has sufficient observation probability) when in an appropriate lattice environment to make fusion observable.

Ed also wrote “Why would the environment not also affect the tritium reaction, independent of any energy considerations?”

The environment does affect the tritium reaction, the branching ratio, but just not independent of energy considerations. The key to understanding the branching ratio in detail is being able to model tunneling probabilities, lattice electron wave functions, and
catalytic electron behavior, including radiation, sufficiently to estimate the mean value m and deviation s of the catalytic electron energy deficit through time. This is undoubtedly a very large undertaking, both theoretically and experimentally. The underlying concepts are fairly simple though.

Ed also wrote “After all, the tritium is generated with only a small fraction of the total energy just like the helium.”

I don't think this is right. The mass deficit of the resulting products differs. The energy of the tritium reaction, 4.03 MeV *is* the available energy, not 23.9 MeV or some large number (ignoring any vacuum energy exchanges that might occur). It actually takes a lot *more* energy away in the form of mass (19.87 MeV) to form tritium from the He* than helium. See discussion below.

Ed also wrote "The process of distributing the energy, I expect, would be similar in the two cases. Therefore, the energy associated with the total, ideal process would not be operating on the actual reaction products. Why then should the total energy play a role?"

Because the breaking of a strong force bond, or the failure to form such, changes the final mass deficit and thus the reaction energy available. Again, the mass deficit energies are given by:

D(D,p)T 4.03 MeV
D(D,n)^{3}He 3.27 MeV
D(D,gamma) 23.9 MeV

A small waveform electron in the He* intermediate product reduces the above energy by an amount depending on the electron waveform size at the time of the final product formation.

If the electron wavelength is sufficiently small to momentarily impose a 6 MeV additional deficit, then at that time the energy to permit the D(D,p)T or D(D,n)^{3}He reactions is not available.

Another way to look at this is to assume the ^{4}He* activated nucleus is created upon fusion, having 23.9 MeV energy embodied in the thermalized motion of the constituents: two neutrons, two protons, and an electron. The highly non-linear motion of the constituents places various amounts of strain on each of the bonds until some energy is radiated away and the process continues, or one or more of the bonds is broken an reaction products result. Under this assumption the bond breaking to enable the D(D,p)T reaction requires 23.9 MeV - 4.03 MeV = 19.87 MeV. Similarly the bond breaking to enable the D(D,n)^{3}He reaction requires 23.9 MeV - 3.27 MeV = 20.63 MeV.

If in a given environment at some point, we suppose the catalytic electron creates and energy deficit -E(m,s), where m = -6 MeV, and s = 0.25 MeV, then T production would be a 4 sigma exception event, and neutron production would be a 7 sigma exception event.

It is notable that the catalytic electron wave function can be expected (at least in my framework) to expand until it can occupy a chemical energy sized orbital. It can also radiate energy in the process. The energy for the expansion and radiation is supplied by a combination of the action of the zero point field and fusion energy.

8) Peter Gluck wrote: (from Romania)
[Responding to Ed Storms] Just to mention that the optimal form of Pd samples was not tested yet. In my opinion it is metallized fibers- e.g. carbon nanotubes coated with Pd and probably other metals in layers- really monodimensional, kind of Patterson beads in one dimension. This is logical if we accept that LENR happens at the surface, in limited areas. The difficult part is the manufacture of these metallized fibers, despite a great experience existent the field. But actually it is no progress in higher heat effects obtained and reproducibility is still white (or gray) magic rather than a science. My explanation- poisoning with gaseous impurities from air that inactivate NAE is ignored. O.K- but if we do not believe in occult phenomena we have to find some explanation and prove it experimentally. Each year I am getting older and more worried for the future of the field.

[Responding to Akito Takahashi] Volume is useless, we need surface, therefore Pd coated on some nanofiber at a minimum thickness and protected with a monomolecular layer of some material is ideal. I think that all really strong heat release events as Mizuno's historical unquenchable cathode or cathode 64 of Energetics had some aleatory protective layer and avoided poisoning.

9) Akito Takahashi wrote

[Responding to Peter] I agree with your view "mono-dimensional Pd samples". Actual forms are of maximum-surface & minimum-volume as nano-wire, nano-particle or complex composite, nano-fabricated (designed) fractal samples, etc. We will try many forms of such materials. Man must get aging every day after day, but try to get something new.

10) Ed Storms (responding to John Fisher)
I agree, the polyneutron theory has some useful features and predictions. The next step is to show that polyneutrons actually exist based on some measurement outside of CF and show the conditions that cause the predicted reactions to occur. Without such supporting information, the idea has no greater benefit to the field than the other equally unsupported ideas. Can you think of a way to demonstrate the actual existence of polyneutrons? What exactly has to happen in a F-P cathode to start the sequence of events you predict?

11) Drew Meulenberg wrote: (from India)
I believe that Horace has the essentials of a correct model for LENR. See italicized comments interleaved with his story. These comments are mainly based on K. P. Sinha's and my paper at ICCF-14 (and the consequences).

> "... in a vacuum initiated kinetic fusion reaction there is
> no electron in the excited He* intermediate product reducing
> the amount of available energy. " The "starting energy of the
> He* nucleus is also higher. This means that there is more
> time for (therefore more chance of) fragmentation before the
> nuclear energy drops below the critical values. Therefore,
>2 channels dominate.

He also wrote "This makes the reaction pathways fairly simple. In the lattice it is feasible for electron catalyzed fusion to occur." KP and I feel that 2 electrons (a lochon) are required to catalyze the LENR.

> "A catalytic electron has an energy related influence on the
> final products feasible, and this influence varies with time."

The closer the deuterons approach, the higher the electron energy (1-D effect) and, therefore, the smaller its orbit and Compton wavelength.

>"...The electron can radiate away the energy to the lattice in
> small increments."

This post-fusion action of the electrons / lochon is the critical ingredient that blocks the fragmentation channels by dropping the nucleon energies below threshold. The energies drop below the D(D,n)He3 threshold (3.27 MeV) first; then the D(D,p)T threshold (4.03 MeV). If the process is too slow, fragmentation will occur.

> Though it is brief, the deflated state repeats rapidly enough

I'm assuming this refers to the phonon frequencies, which may exceed 1E14/second.

> The environment does affect the tritium reaction, the branching

KP and I have done all this in our ICCF-14 presentation and subsequent work.

> including radiation, sufficiently to estimate the mean value m

> and deviation s of the catalytic electron energy deficit through time.

Radiation coupling of excited nucleons with the lattice (via the electrons / lochon) is not straight forward since it is an interaction of the nucleon near-field radiation with the "inside" of an electron wave function. Nevertheless, that is our goal over the next few months.

12) What started this thread?
The answer to this question came in the form of a message posted today by Akito. The attached file (quoting earlier contributions to this thread) reminded me that the discussion was triggered by a claim, made by the SPAWAR team, that their triple-prong tracks, in CR-39 detectors, are due to neutrons of several MeV. Responding to their message I wrote: "Most of [the interactions with fast neutrons would consist of] scattering (elastic and inelastic), the rest [would] consist of several competing reactions, such as ^{12}C(n,p), ^{12}C(n,d) etc. One of these reactions might be ^{12}C(n,alpha)^{8}Be, where ^{8}Be always fissions into two alpha particles, immediately. That would indeed produce three alpha particles outgoing from a single point..... Most triple-prong events would originate deep inside the CR-39, rather than at its surface. Multiple-etching technique (used by SPAWAR people and by Oriani) would either confirm or refute this expectation."

I also wrote "But how certain are SPAWAR people that neutrons with energies exceeding 6 MeV are emitted during electrolysis? Hopefully, the answer will emerge before the ICCF15." In another place I speculated about projections of the tripple-prong events, seen in CR-39. In most cases one of the projected ^{12}C(n,alpha)^{8}Be prongs would be considerably shorter than two other prongs. This observation was based on the old angular distribution data published by Takahashi.

356) The 20th Anniversary of CMNS is approaching

Ludwik Kowalski; 12/6/2008
Department of Mathematical Sciences
Montclair State University, Upper Montclair, NJ, 07043

Robert Park, the author of the 2000 book, "Voodoo Science: The Road from Foolishness to Fraud," has a website named What's New."

http://bobpark.physics.umd.edu/

On Friday 28, 2008, he posted a piece called "Cold Fusion: Or Is It The 'Fleischmann-Pons Effect.' " He wrote:

" It's been almost 20 years since the March 23, 1989 announcement that cold fusion had been discovered by two chemists at the University of Utah. By June, cold fusion was an object of ridicule. A small band of embattled defenders retreated to holding annual conferences of like-minded scientists to which skeptics were not welcome. The story now seems to be entering a new chapter. Believers have begun showing a willingness to confront skeptics, submitting papers to open meetings of major scientific societies. They no longer use the term 'cold fusion,' preferring the less contentious 'low-energy nuclear reactions' (LENR) to describe their field; LENR more accurately describes what, if anything, is going on. However, the use of LENR has been undone by referring to 'excess heat' as the Fleischmann-Pons effect. This only serves as a reminder of the outrageous conduct of the university administration and the incredibly sloppy research on which the claim was based.

This year, there is great excitement over the work of Yoshiaki Arata, a respected professor at Osaka University. In May Arata demonstrated the production of excess heat to an audience of 80, but there have been many such claims over the years and until it is replicated by someone outside the LENR community and a plausible explanation is advanced, it will change few minds."

It is interesting that Robert Park, whose specialty is surface science, prefers to attack the field as a journalist rather than as a scientist. As far as I know, he was personally invited to attend at least two scientific conferences devoted to Cold Fusion, one in Boston and one in Washington D.C. Both locations are relatively close to where he lives (Maryland). Why didn't he come to at least one conference? His background seems to be perfect to discuss various topics from the scientific point of view.

Why was the original name, Cold Fusion, replaced by other names, such as CMNS or LENR? Because it became clear, during the last decade, that nuclear reactions, if any, induced by chemical processes, are very different from what is often called hot fusion (thermonuclear fusion). This was far from being obvious twenty years ago.

Am I the only one who feels that the term "small band of embattled defenders" is insulting. I have nothing but admiration for those who continue a difficult fight for a clear yes-or-no answer about reality of CMNS claims. The term "group of researchers" or "group of scientists" would be much more appropriate. Why should recognized Ph.D. scientists, from several countries, be called a band? Why shouldn't we admire those whose motivation is to contribute to the common good? Most of them work without any financial support. They do this in the climate of discrimination; their advances are usually ignored by the wider scientific community.

What follows is a slightly revised version of two flowcharts I showed at the last International Conference on Cold Fusion (ICCF14 in Washington D.C.). Using this diagram, I can say that CMNS scientists are still at the stage of

protoscience (the lower left corner loop). The field hopes to be recognized as scientific but this is not easy. Progress is slow because individual researchers, or small groups of researchers, work in isolation. In my opinion, progress would be faster if their efforts were coordinated, if funding was available, and if there were no discrimination, as written in a recent OpEd. Click below to see it.

357) Interpreting SPAWAR-type pits: Comments

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055

Abstract:
A recent claim demonstrating a nuclear process triggered by electrolysis is challenged. An analysis, based on relative diameters, is used to demonstrate that predominant pits could not possibly be attributed to alpha particles, or to less massive nuclear projectiles. This conclusion is supported not only by positive results from a replication experiment, but also by results from the experiment on which the original claim was based. While the numerous SPAWAR-type pits seem to be highly reproducible, their interpretation is not yet clear.

= =

Today is January 8, 2009. I am revising this unit. Instead of showing a slightly abbreviated version on my paper I am now providing a link to the entire paper (the first link below). The second link below will download the entire rebuttal paper published by the SPAWAR team.

Addendum (January 11, 2009)

Let me comment on the rebuttal, and on some private remarks received by e-mail. This brief addendum is for people familiar with SPAWAR articles (links 2 and 3 above) and with my article (link 1 above).

a) Criticism of SPAWAR interpretation, presented at the 2007 ACS meeting, was based on my own experimental data. Dominant SPAWAR-type pits I saw were typically 2.5 times larger that pits due to my alpha particles of ~ 4 MeV. In other words the ratio of measured mean sizes was R1=2.5. The symbol R2 will be used below for the expected ratio of sizes.

b) Suppose the pits created during electrolysis are due to alpha particles of ~1 MeV, as claimed in a subsequently-published SPAWAR paper. In that case the ratio, according to the calibration curve used in my paper, would be R2=1.30. (The R2 would be even smaller for alpha particles of other energies.) The big difference between R1=2.5 and much smaller R2 allowed me to say that SPAWAR-type pits should not be attributed to alpha particles.

c) A subsequently-published SPAWAR paper had photographs of dominant post-electrolysis tracks, and tracks due to alpha particles of 5.5 MeV (on the same CR-39 chip and under the same magnification). Using these photos, I concluded that their R1 was close to 1.7. That is significantly smaller than my value R1=2.5. I do not know how this can be explained. (P.S. See item f below.) By the way, I was not the only one to successfully replicate the experiment. It would be desirable to compare R1 values determined by other participants of The Galileo Project.

d) Is it possible that the calibration curve, which I used to determine R2, does not apply to CR-39 chips manufactured in Japan, as suggested in the rebuttal paper? In my opinion, the shape of a calibration curve of CR-39 should not depend on where the material was manufactured. That shape reflects the energy dependence of the dE/dx (sometimes called the stopping power, or ionization density). But I know, from what has been reported by several researchers, that CR-39 chips from different manufacturers do differ in several other ways. Let me accept the fact, reported in the rebuttal paper, that the value of R2 is 1.5 for chips from Japan and 1.3 for chips from UK. The difference of 0.2, between the two values of R2, does not weaken my claim (that dominant pits cannot be attributed to alpha particles of ~1 MeV) when R1 is 2.5. But, as indicated in the rebuttal paper, the argument is weakened when R1 is much smaller, for example, 1.7 or less. Hopefully, the correct value of R1 will be determined on the basis of additional measurements. (P.S. The dE/dx, for a given material, depends on its main chemical composition; it does not depend on composition differences at the ppm level. Such differences always exist among batches from different manufacturers.)

e) I am happy to see the new sequential etching curve (Figure 2c in the SPAWAR rebuttal paper). It shows that sizes of pits due to alpha particles of 5.5 MeV grow at the same rate (versus etching times) as SPAWAR-type pits. Would the same be true for alpha particles of ~ 1MeV? This remains to be seen.

f) How should the size of a pit be defined? For a circular pit the size should be identified by the diameter; for an elliptical pit, on the other hand, the size should be identified with the minor axis. Why do I suggest this? Because I know that the major axis of an elliptical pit depends on the angle of incidence. It is interesting that the SPAWAR-type pit in the Figure 2c is nearly two times larger that the pit due to an alpha particles of 5.5 MeV. In other words, their R1=2.0. This is larger than 1.7, and closer to the value of R1=2.5 I obtained in 2007. The hypothesis of "1 MeV alpha particles" was formulated in 2008, as far as I know.

g) Note that according to SPAWAR figure 2c the value of R1 increases when etching times become shorter. That is very interresting! Extrapolating to 6 hours of etching, used in my 2007 replication experiment, the value R1 approaches 2.5. In other words, new SPAWAR data seem to be consistent with my first result. Extrapolating to 22 hours of etching, the value R1 approaches 1.3. This makes me think think that the difference between R1=2.5 and R1 "close to 1.7," might be due, at least partially, to differences between our etching times.

h) Fortunately, as described in Section 4 of the next unit, (click here) , the SPAWAR hypothesis can be tested more directly. Will experiments with alpha particles of ~1 MeV validate the SPAWAR claim? That remains to be seen.

i) The “corona discharge” argument, only mentioned in my paper (reference 8 and 9), was developed by Lipson et al. I am not familiar with details of their experiments. Because of this I am neither for nor against their position.

j) P.S. In the past I measured sizes of alpha particles under very short etching times. The tracks, already countable after about 2 hours of etching, grow when etching times become longer. Suppose each line (see Figure 2c in the SPAWAR rebuttal paper) remains straight, down to the etching time of 3 hours. That would produce R1=4.3 after 3 hours of etching and R1=3.5 after 4 hours. I suspect that something important might be learned, about dominant codeposition pits, from examining their behavior after short etching times. Dependence of R1 on the etching time, illustrated in the SPAWAR Figure 2c, is puzzling. Is it consistent with the SPAWAR hypotheisis about post-electrolysis pits? How can it be explained?

k) It is well known that prolonged etching (12 hours versus 6 hours) changes small elliptical pits, due to alpha particles, into larger circular pits. This was illustrated in Figures 4 and 5 at http://csam.montclair.edu/~kowalski/cf/336cat.html . Suppose that copious codeposition pits also change from "mostly elliptical" to "mostly circular," for example, between 3 hours of etching and 5 hours of etching. That would support the idea that tracks are due to low energy particles. Most circular SPAWAR-type pits touch each other (on my photos and on similar photos shown at the ACS meeting in Denver). Would smaller pits, seen after only 3 hours of etching, also be touching each other? Would small elliptical pits be oriented randomly or would some patterns be seen? I am thinking about clusters of two or more radially oriented tracks (see SPAWAR rebuttal paper).

l) l) Another parameter worth exploring, in searching for useful indicators, is the effect of the co-deposition time on track density. My guess is that the co-deposition time of one hour, for example, will produce 24 times less tracks than the co-deposition time of one day, under identical conditions. I know that preliminary experiments of that kind were performed by SPAWAR researchers. (Parallel cathode wires were disconnected at different times.) Was it possible to reduce the co-deposition time sufficiently to dramatically decrease track densities?

m) In the rebuttal paper, SPAWAR researches show several theoretically simulated tracks due to alpha particles of very low energy. Does their simulation code predict transitions from "mostly elliptical" to "mostly circular" pits? What etching times should be used to observe such transitions? People who developed the code probably tested its predictions by experimenting with real particles. Was the code tested with alpha particles of very low energies? If so then agreements with theoretical predictions could be used as arguments supporting the SPAWAR hypothesis.

n) P.P.S. Why are you "casing doubt?"--someone asked me recently. Because I am trying to help. It is my obligation as scientist. Casting doubt is part of being helpful. On the basis of my own experience, long before cold fusion, I can say that criticism is likely to be more helpful than compliments. Criticism often helped me to overcome personal bias. It is unfortunate that The Galileo Project, triggered by SPAWAR discovery, died so early (after Denver meeting, about two years ago). Progress would be much faster if those who confirmed initial SPAWAR results continued studying the phenomenon in unison, and argued about interpretations. That would be a natural next step for working with a protocol yielding reproducible results. Each of us already had a working experimental setup. Why did we stop working in unison so early?

358) New phenomena or illusions?

Ludwik Kowalski (2/10/2009)

Montclair State University, New Jersey, USA

1. Introduction

How many readers remember the excitement generated by the announcement of the discovery of "cold fusion?" This event took place twenty years ago. The claim, made by M. Fleischmann and S. Ponds during a press conference in Salt Lake City (1), was that a nuclear process can be triggered by electrolysis (2). Deuterium nuclei, from heavy water in the electrolyte, were said to be so densely compressed, in the palladium cathode, that they could fuse despite strong Coulomb repulsion. The claim generated a lot of interest among scientists (3), as well as the general public (4). Laymen speculated about abundant, cheap, and pollution-free sources of energy; scientists were puzzled by the idea that a chemical process could produce a high concentration of atomic nuclei in condensed matter.

Many researchers attempted to confirm the Fleischmann and Pons results. But not all of them were successful. On that basis, and on the basis of theoretical considerations, the cold fusion claim was rejected by mainstream scientists (5). But more than one hundred researchers, worldwide, continue exploring the field. Cold fusion scientists meet regularly to discuss new experimental results and new theories (6). They no longer believe that cold fusion is similar to the thermonuclear fusion. For that reason the field is now called "Condensed Matter Nuclear Science," CMNS.

Like most nuclear physicists, I was excited by the possibility that a new kind of nuclear reaction had been discovered. And like most of them, I came to the conclusion that the original claim was totally unjustified, as claimed in (5). My professional interests were focused on nuclear reactions induced by heavy ions, and on the transmutation of highly radioactive nuclear materials. In 2002, at a scientific conference in Albuquerque (7), I heard several reports presented by CMNS researchers. Impressed by their qualifications, and by the content of reports, I decided to pay attention to their results, and to attend the upcoming CMNS conference (8). This was the beginning of my participation in CMNS activities.

The purpose of this article is to describe two kinds of experiments in which I participated; one had to do with the "excess heat," presumably due to a nuclear process, and others had to do with the chemically-induced emission of nuclear projectiles, presumably alpha particles or protons. The goal was to convince myself that at least one nuclear effect due to a chemical process was real.

2. Excess heat in high voltage electrolysis

An electrolytic cell, a device in which electric current flows through an electrolyte, converts electric energy into chemical and thermal energy. The amount of heat produced in the cell is expected to be smaller than the amount of electric energy received, unless chemical reactions are strongly exothermic. But, according to Fleischmann and Pons (2), the amount of heat produced in their cells greatly exceeded the electric energy received. The difference between the thermal energy released and the electric energy received was named excess heat (EH). The authors claimed that their excess heat could not be attributed to chemical reactions. The reality of EH, generated at the rate of about one watt, has been confirmed by numerous investigators (9). In most cases the potential difference between the electrodes was several volts while the current was a fraction of one ampere.

Excess heat was also discovered in cells operated at much higher voltages and currents (several hundred volts and more than one ampere). A schematic diagram of a cell operating under such conditions is shown in Figure 1. The cathode is a tungsten rod while the anode is a large platinum wire spiral, or a platinized niobium cylinder. The

electrolyte, in experiments in which I participated, was potassium carbonate (K_2CO_3) dissolved in distilled water. The concentration was 20 grams per liter. Decomposition of water, at high current, becomes so intense that yellow glow discharge and arcing can take place in the layer of gas-plasma surrounding the cathode.

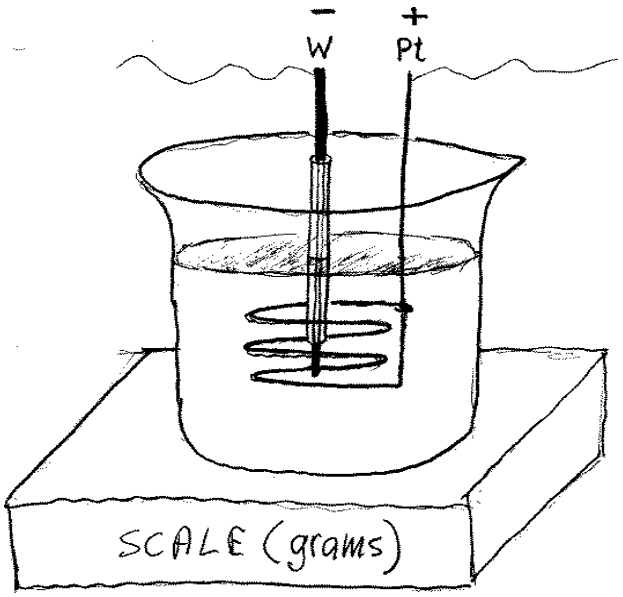

Figure 1

Generation of EH during the glow discharge plasma electrolysis was first reported by a team of Japanese scientists, T. Mizuno et al. (10). The phenomenon was then studied by other researchers, both in Japan (11, 12, 13) and in other countries (14, 15, 16). Most reports, but not all, confirmed generation of excess heat, as described by Eugene Mallowe (17). My first experiment of that kind was performed in cooperation with Scott Little. The cell was wrapped with an insulating layer of foam; the thermal energy released was calculated on the basis of the amount of evaporated water. Electrical energy received was calculated on the basis of recorded current and voltage, which fluctuated widely. Nominal potential differences were between 250 and 400 volts. No clear evidence of EH was found.

The same conclusion was reached when a similar experiment was performed in collaboration with Richard Slaughter. These findings, reported at a conference (18), were in conflict with those reported by Pierre Clauzon (19). The topic was discussed at length and Pierre decided to join us in another sequence of experiments. Working under his guidance, R. Slaughter and I were able to obtain nearly the same results as in (19), for example, about 30% more heat than electric energy, at 350 volts. This was accomplished by using Clauzon's electrical watt-meter. Two years later (Fall 2008), during another control experiment, Clauzon discovered a systematic error in measuring electric power with this watt-meter. His most recent results, obtained with a much better watt-meter, are consistent with negligible excess heat in high voltage electrolysis. Another team (16) also withdrew their excess heat claim for high voltage electrolysis. In both cases, inexpensive watt-meters were not able to deal with high frequency components of rapidly fluctuating currents.

I hope that new data, collected by Clauzon with a better watt-meter, will be formally presented at the ICCF15 next summer. Will this result in reinvestigation of earlier high voltage electrolysis experiments? This remains to be seen.

3. Emission of nuclear projectiles.

Emission of a large number of alpha particles, due to low voltage electrolysis, was reported by R. Oriani and J. Fisher (20, 21). The particles were discovered by using CR-39 track detectors. Many years ago I used track detectors (mica) to observe fission fragments. The principle of their operation is simple. Strongly ionizing particles create tracks in many solids materials; these tracks become visible under a microscope, after the material is chemically etched. According to (20), as shown in Tables 1 and 2, mean track densities in CR-39 chips inside the electrolytic cell were much higher than in control chips ourside the cell. Tracks in control chips were due to cosmic rays, radon and other possible radioactive contamination.

Impressed by the reported results, I quickly learned how to use CR-39 detectors. A year later Oriani sent me new results and additional details about the experimental method. The cathode in his small cell was a nickel foil, the anode was a platinum wire and the electrolyte was Li_2SO_4 dissolved in ordinary water. Subsequently Richard invited me to his laboratory and we worked together for one week. Two experiments were performed (22) and each produced results consistent with Oriani's claim. Unfortunately, my attempts to obtain similar results at home, using an exact replica of his cell, were not successful (23).

Several months later, again following Oriani's footprints, I started another sequence of experiments. In these experiment, described in (24), the nickel wire cathode was mechanically supported by the CR-39 chip while the platinum anode wire was above it. A thin layer of mylar (6 microns) prevented the cathode from direct contact with the chip. Oriani noticed that results become highly reproducible when the o-ring from a successful experiment is used in subsequent experiments. Richard started sending me his "seeded" o- rings and I used them in several experiments. Spectacular clusters of tracks, also reported by Oriani, were found on some of my CR-39 chips. One of the clusters is shown in Figure 2. Ten experiments were performed. Seven clusters of tracks were found in two out six electrolysis experiments; three clusters were also found in one of four experiments conducted to study emission of nuclear particles after electrolysis.

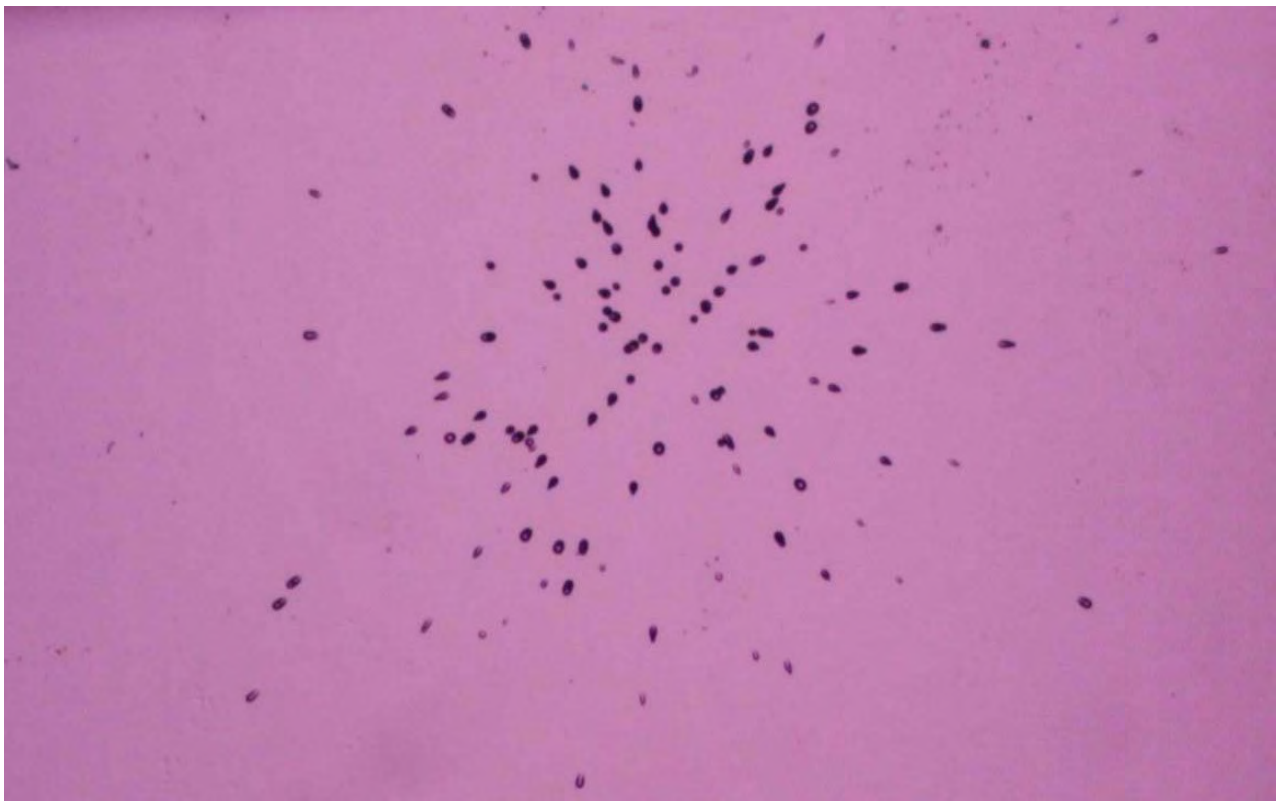

Figure 2

During the presentation (24), I said that a cluster with radially oriented tracks, as in Figure 2, could not possibly be due to contamination. But this point of view was challenged by two CMNS researchers. One of them invented the following scenario. "A gas bubble sits on top of CR-39 and a grain of alpha-radioactive material sits on top of the bubble. Ranges of alpha particles in the gas bubble are much larger than ranges in the electrolyte. That would produce a cluster whose size is much larger than ranges of alpha particles in the electrolyte, as in Figure 2. The tracks would be circular near the center and radial near peripheries, as in my Figure 2." The scenario invented by another researcher was similar; he was thinking about a small bubble trapped between the mylar film and the detector.

The issue of possible artifacts would be worth addressing if experimental results were reproducible. For the time being I am mostly troubled by the fact that four clusters were produced in Experiment I (lasting 5 days) and zero clusters were produced in Experiment II (lasting 21 days). Electrolyte, mylar film, cathode, and o-rings were unchanged

between the two experiments. Results which are not reproducible belong to proto-science, not to science, as illustrated in Figure 3. Two other CMNS researchers, John Fisher and Marissa Little, also observed clusters of tracks in CR-39 chips, using "seeded" o-rings received from Oriani. Suspecting radioactive contamination on the surface of the o-ring, Marissa exposed it to an electronic silicon detector (25). The energy spectrum of particles revealed peaks consistent with presence of Th-228, and its progeny. My attempts to discover alpha radioactivity on the o-ring surfaces, using CR-39 chips, were not successful. The origin of radioactive material on the surface of some "seeded" o-rings remains unknown. But I am troubled by high track densities on Oriani's control chips, reported in (20).

The most recent results of Richard's ongoing investigation were presented at ICCF14 (14th International Conference on Cold Fusion, Fall 2008, in Washington DC). The proceedings of that interesting conference should soon be published.

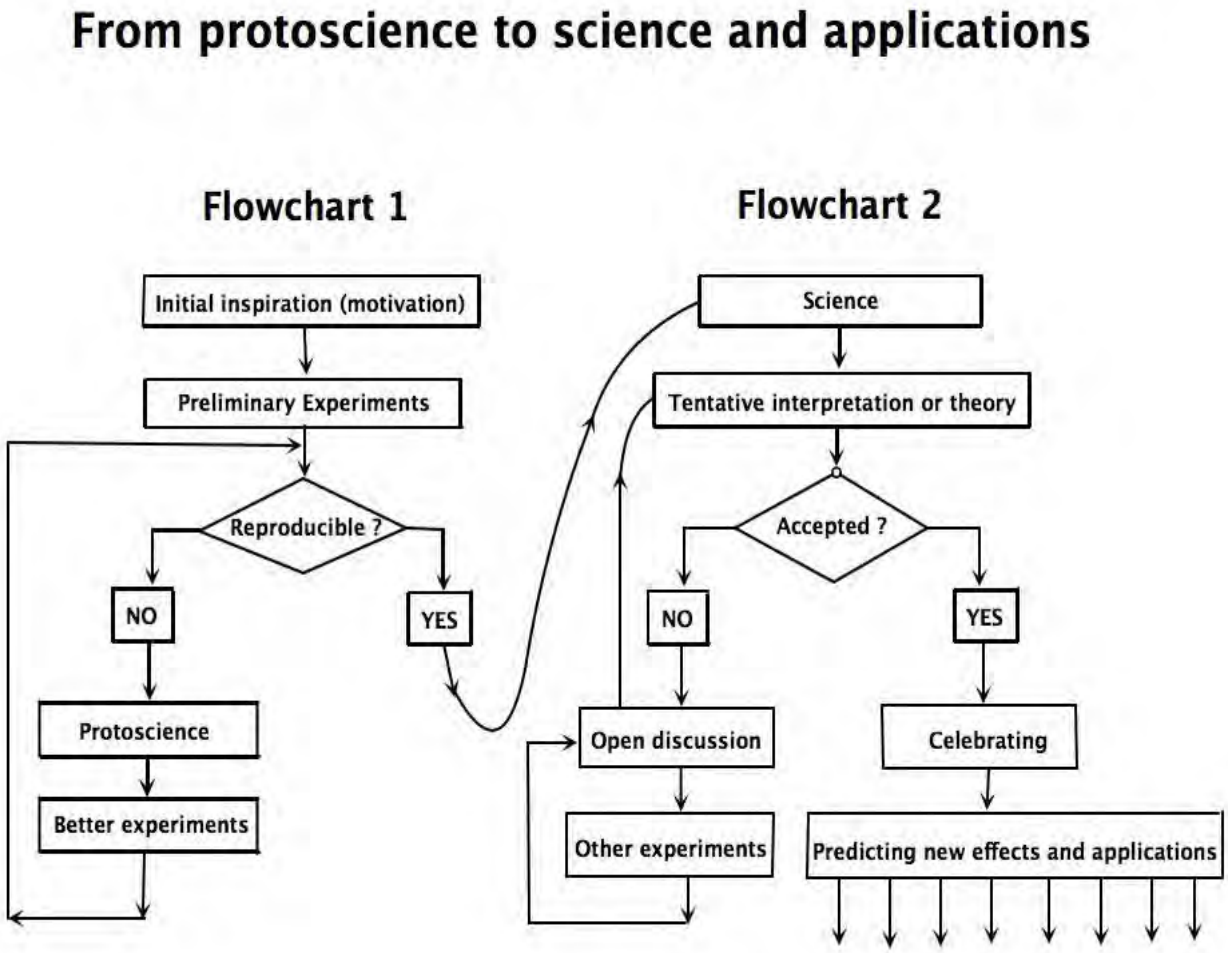

Figure 3

4. An Ongoing Controversy

At the end of 2006, researchers from a US Navy laboratory, SPAWAR, also announced detections of a large number of tracks said to be due to alpha particles emitted from the cathode of a low voltage electrolytic cell. These particles were detected in CR-39 chips that were in contact with cathodes, in the electrolyte (26). Helped by SPAWAR scientists, Steve Krivit, from the New Energy Institute, wrote the protocol for replication of one of the SPAWAR

experiments. That protocol was then distributed to those CMNS researchers who wanted to study the effect. All who were able to implement the protocol, including myself, reported seeing the SPAWAR-type tracks.

Some results were published at the ACS winter meeting in Denver, in March 2007. My slides shown at that meeting (27) were nearly identical with those shown by SPAWAR researchers. But our conclusions were very different; they speculated that dominant tracks were due to alpha particles, I speculated that our tracks could not possibly be due to alpha particles. In a subsequent internet discussion, and in a formal publication (28), they wrote that energies of alpha particles are likely to be close to 1 MeV. In my formal publication (29) I made two arguments against this tentative SPAWAR interpretation. Fortunately, the hypothesis of 1 MeV alphas can be tested by performing additional experiments. Alpha particles of approximately 1 MeV can be used and their tracks can be compared with tracks produced during electrolysis.

Suppose that the two kinds of tracks turn out to be very similar. That would reinforce the SPAWAR hypothesis and would justify more sophisticated experiments, for example, with electronic solid state detectors. SPAWAR type results are scientific because they are reproducible. The right diagram in Figure 3 shows how controversies are usually handled by scientists. Emission of nuclear particles of any kind, due to electrolysis, would be convincing evidence that a new kind of nuclear process has been discovered by CMNS scientists.

5. Final comments

The broad field of CMNS, recently reviewed by Ed Storms (9), remains controversial. But this did not stop research; many scientists continue searching for nuclear processes due to chemical reactions. Their progress would be faster if the field was not discriminated against, for example, by editors of scientific papers, and by various government organizations. In my opinion, most CMNS researchers are honest and competent and are motivated by the desire to promote science and technology. Several general observations about the field can be seen in (30). Here is one of them:

". . . What cold fusion really needs is a reliable demonstration experiment. That's what Ludwik Kowalski has been trying to find for several years now. We worked closely with him to see if Mizuno's incandescent W experiment (a la Clauzon et al) would do the trick. It didn't. That's what the Galileo Project was trying to establish. It didn't. .... or hasn't yet. That's what we are still pursuing right now in cooperation with Richard Oriani who continues to see relatively low level positive results from his PACA CR-39 experiments. That's why we continue to maintain our high performance calorimeter, MOAC, in good working condition so that cold fusion researchers can take advantage of our standing offer to test promising cold fusion cells free of charge.

Why go to all this trouble if we've never seen any real signs of cold fusion? Simple. If cold fusion is real, it will be of enormous importance to mankind. Lots of discoveries in science have come only after years of searching. Despite all our null results we still have some hope. But I also think that there is a finite chance that all of the apparently positive results that have been observed in cold fusion experiments are erroneous. i.e. the result of various artifacts. I know, it's hard to imagine how so many intelligent researchers could all be making such measurement errors. "

359) Cold Fusion Anniversary

Ludwik Kowalski

Montclair State University, New Jersey, USA
March 23, 2009

THIS UNIT IS TOO LONG AND NOT WELL ORGANIZED. BUT SOME PEOPLE MIGHT HAVE LINKED TO THIS UNIT FOR THAT REASON I AM NOT DELEATING IT.

TWO UNITS #261 AND #262 WERE COMPSED FROM FRAGMENTS OF THIS UNIT (ON 4/25/2009). TOGETHER THEY REPLACE UNIT#359

click to see unit 362

1. Introduction
The discovery of Cold Fusion was announced exactly twenty years ago. I read several interesting messages about this, on the private website for CMNS researchers. Unfortunately, I had nothing valuable to contribute. But then a science journalist, who I do not know, sent me a URL for a file containing a recent SPAWAR paper.

http://www.newenergytimes.com/Library2/2008/2008BossTripleTracks.pdf

This paper was published in Naturwissenschaften (2009) 96:135–142. The title is "Triple tracks in CR-39 as the result of Pd–D Co-deposition: evidence of energetic neutrons. The authors are: Pamela A. Mosier-Boss, Stanislaw Szpak, Frank E. Gordon, and Lawrence P. G. Forsley. I knew about this paper but I did not have a chance to read it. The journalist, Mark Anderson working for "IEEE Spectrum," asked me to comment on that paper.

Why did he ask me? He probably knows about my successful replication of an earlier SPAWAR experiment, and about what I wrote in

http://pages.csam.montclair.edu/~kowalski/cf/357epjap.html

2. My comments
a) The methodology used is basically the same as in the experiment I performed two years ago. But a large number of control experiments make the reported results much more acceptable. Instead of focusing on dominant overlapping tracks, as in an earlier paper, the author analyze rare triple tracks, said to be due to high energy neutrons (above 9.6 MeV) emitted during electrolysis. They write that "among the solitary tracks due to individual energetic particles, triple tracks are observed. Microscopic examination of the bottom of the triple track pit shows that the three lobes of the track are splitting apart from a center point. The presence of three alpha-particle tracks outgoing from a single point is diagnostic of the 12C(n,n')3alpha carbon breakup reaction and suggests that DT reactions that produce ≥9.6 MeV neutrons are occurring inside the Pd lattice."

b) This paper confirms, once again, that codeposition experiments yield reproducible results. In 2007 I was one of several researchers who used the SPAWAR protocol and confirmed the reported results. That is why I think that codeposition experiments, developed by the SPAWAR team, belong to science, rather than to protoscience, as many other CMNS experiments. CMNS, by the way, is a new acronym for CF--what used to be called Cold Fusion is now

called Condensed Matter Nuclear Science.

c) In one set of control experiments the authors used the electrolyte made from H_2O. The number of tracks was found to be at least three orders of magnitude lower that in identical experiments in which heavy water, D_2O, was used. They wrote: "Since the natural abundance of deuterium in light water is 0.015%, it is possible that the tracks observed in the light water experiments could actually be due to Pd–D interactions. Microscopic examination of the CR-39 detectors used in Pd–D electrolysis has been done in areas where the density of tracks is less. In these areas, what appear to be triple tracks are observed interspersed among the solitary tracks. The number of these triple tracks is very low—on the order of a ten or less per detector and they are only observed in heavy water experiments. These triple tracks have been observed in every Pd–D co-deposition experiment that has been conducted using Ag, Au, or Pt cathodes in both the presence and absence of an external electric or magnetic field. When Ni screen is used as the cathode, tracks and triple tracks are only observed when an external electric or magnetic field is applied."

c) Figures 1a and 1b show pits due to alpha particles from Am-241. Clusters of triple tracks observed are due to overlapping--rare coincidences when three alpha particles hit nearly the same spot. Triple tracks created during electrolysis (in subsequent figures) are shown to be very different. That is a relevant point; triple pits produced during electrolysis do occur among single pits; showing that they are not due to overlapping is very important.

d) Control experiments described in the paper speak loudly against possible alpha-radioactive contamination.

e) A significant difference between track densities in D_2O and H_2O is also a strong argument against the chemical origin of tracks.

f) The authors conclude that "no tracks, single or triple, were obtained when $CuCl_2$ was used in place of $PdCl_2$." Yes indeed; what can be a better demonstration that Pd plays an important role in the claimed new kind of chemically-induced nuclear proces. To elaborate on this the authors write that "the deuterium must be inside a metal lattice for these reactions to occur and not simply adsorbed on the surface of the metal. This implies that the metal lattice facilitates these reactions indicating that nuclear phenomena can be influenced by the atomic and electronic environment." This is no longer an abstract speculation.

g) Presence of triple pits on both sides of the CR-39 chips is consistent with the idea that they are due to neutral projectiles of some kind (able to penetrate about 1 mm of the CR-39 material). Neutrons are the most natural candidate.

i) What is needed is an independent verification of these results. My suggestion would be to organize coordinated replications, for example, in a national laboratory. The cost of several hundred dollars per experiment is negligible in comparison with costs of routinely performed experiments in these labs. Unfortunately, I do not know how to make this happen. Confirmation of SPAWAR results (nuclear origin of tracks) would the best anniversary present to society. Will this happen during this special year?

P.S.
I was not the only one who posted a comment on SPAWAR neutrons today. One CMNS researcher directed me to:

http://www.chron.com/disp/story.mpl/headline/nation/6333164.html

where I found out about Paul Padley, a physicist at Rice University who reviewed Mosier-Boss' published work.

"Fusion could produce the effect they see, but there's no plausible explanation of how fusion could occur in these conditions," Padley said. "The whole point of fusion is, you're bringing things of like charge together. As we all know, like things repel, and you have to overcome that repulsion somehow."

The problem with Mosier-Boss' work, he said, is that it fails to provide a theoretical rationale to explain how fusion could occur at room temperatures. And in its analysis, the research paper fails to exclude other sources for the production of neutrons.

“Nobody in the physics community would believe a discovery without such a quantitative analysis,” he said.

I tend to disagree. I believe that claims based on unexplained, but reproducible-on-demand experimental data, have their own intrinsic values, especially when established ideas are challenged by new data. Emission of nuclear projectiles during electrolysis does conflict with preexisting ideas. An accepted theory of CMNS is likely to emerge very quickly after the experimental data reported by the SPAWAR team are independently confirmed, for example, by two or three teams of qualified scientists. That is why I think that organizing independent replications is more important, at this stage, than theoretical studies. What should be done to convince our government that an attempt to find a clear yes-or-no answer is worth undertaking?

Added on 3/24/2009

Here is a link to another article on the same topics:

http://www.sciencedaily.com/releases/2009/03/090323110450.htm

It informs us that many papers, on several CMNS topics, will be presented at the ongoing American Chemical Society meeting this week. Maybe this will help to generate action toward independent replications of experiments which are said to reproducible on demand.

The author writes: “. . . One of their problems involved extreme difficulty in using conventional electronic instruments to detect the small number of neutrons produced in the process, researchers say.” The “small number of neutrons produced” may or may not be correct. Yes, the SPAWAR team reported only about ten triple tracks per experiment (lasting two or three days, I suppose). But this does not include the CR-39 area in which tracks are said to be practically on top of each other. Furthermore, detection of fast neutrons via triple tracks is likely to be highly inefficient; I would not be surprised to learn that, on the average, only one triple track is produced by zilloins of neutrons. Most high energy neutrons produce recoilong protons in CR-39 material.

To see more triple tracks I would modify the SPAWAR cell geometry. Their cell, as far as I know, is a small rectangular plastic boxes filled with electrolyte. Suppose the cathode is placed in contact with one of the walls, inside the box, while a CR-39 detector is placed in air, in contact with the same plastic wall. With this arrangement, nearly 50% of neutrons produced in the cathode would be emitted toward the CR-39 detector, only 1 mm away. Low energy alpha particles would be stopped in the wall. (With the present arrangement--CR-39 inside the electrolyte--copious particles are said to interfere with detection of triple tracks.) With the modified geometry one would see many recoiling protons for each triple track due to high a energy neutron.

Note that the modified geometric arrangement would allow me to replace CR-39 by a sophisticated electronic detector of neutrons. Scientists in National Laboratories have many decades of experience with sophisticated detectors of neutrons.

Added on 3/25/2009

Several CMNS researches posted comments about SPAWAR neutrons on our private discussion list. Here is my own contribution.

1) I do not think that focusing on energies of emitted neutrons (using electronic detectors) is the most desirable next step, as far as SPAWAR experiments are concerned. But let me speculate a little about electronic detectors. At the end of unit 359 I wrote: "To see more triple tracks I would modify the SPAWAR cell geometry. Their cell, as far as I know, is a small rectangular plastic box filled with electrolyte. Suppose the cathode is placed in contact with one of the walls, inside the box, while a neutron detector is placed in air, in contact with the same plastic wall. With this arrangement, nearly 50% of neutrons produced in the cathode would be emitted toward the CR-39 detector, only 1 mm away." I was referring to the CR-39 detector, because that is what Pamela et al. use. And I still think that this is the most desirable think to do.

2) A more sophisticated (and expensive) instrument would be a telescope of two Si detectors, thin and thick. Such commercially available setups are routinely used to detect energetic charged particles, such as protons, deuterons, alphas, etc. With proper electronics (also commercially available) one can easily accomplish three things at the same time: identify particles traversing two detectors, determine their energies, and count the particles. Note that a plastic wall of a SPAWAR cell contains hydrogen atoms. Neutrons colliding with these atoms produce protons. Information about neutrons can be obtained from what one learns about recoiling protons. A plastic wall of 1 mm, however, is too thick; it would have to be replaced with a much thiner window, for example, a window in which 10 MeV protons lose no more energy that 2 MeV. The thinner the window the highest the energy resolution is. Unfortunately, desirable high resolution goes together with undesirable low counting efficiency (for example 10^-4 protons per neutron versus 10^-8 p/n). A resolution of +/- 2 MeV would probably be sufficient, at this stage.

With the threshold of 6 MeV, the electronic noise (background to be subtracted) can probably be reduced (with proper shielding of preamplifiers etc.) to less than several coincidences per day. Suppose that a pre-calibrated multichannel analyzer (0.12 MeV/channel and zero intercept) shows a spectrum of protons with a peak at channel 85. That would tell us that 0.12*85=10.2 MeV neutrons were present. Suppose that 100 of such protons are recorded in two days. Suppose that the efficiency (calculated on the basis known elastic scattering cross sections, and the number of atoms of hydrogen in the window) is 10^-6 p/n. That would mean that 100/10^-6=10^8 neutrons passed the cell's window (580 neutrons per second, on the average). I wish I knew how to estimate the efficiency for producing a triple track in CR-39 by 10 MeV neutrons. My guess is that 10^8 neutrons would produce one such track or less. Counting neutrons via recoiling protons (in thick CR-39) is most likely to be more efficient than counting them via triple tracks in CR-39 (or via recoiling protons produced in a thin window in front of a telescope of Si detectors).

3) Fortunately, CR-39 can be used to detect recoiling protons of several MeV. It would be a waste of effort to abandon CR-39 detectors at this time. Reproducible-on-demand protons of several MeV, in a large CR-39 chip, located outside the cell, would be much more numerous than identifiable triple tracks, in already performed experiments. I am thinking about hard-to-recognize triple tracks in the region where single tracks are overlapping, as stated in the SPAWAR paper. Note that no thin window would be needed; neutrons have no trouble in traversing the cell wall and producing recoiling protons in CR-39. Placing the cathode foil next to the cell wall should be the only needed cell modification. Protons recorded outside the cell would be a sufficiently convincing evidence of a nuclear process due to electrolysis. The lower energy limit of these protons, for example, 5 MeV, can easily be determined from the effect of thin foils on the number of recorded tracks.

4) Use of expensive electronic detectors (spectrometers) will be fully justified after showing that recoiling protons are indeed produced in CR-39 chips, outside of SPAWAR codeposition cells.

Added on 3/26/2009

The journalist, Mark Anderson, who sent me the SPAWAR-neutrons paper (and who subsequently interviewed me on the phone), published a short article about cold fusion in IEEE Specrum

http://spectrum.ieee.org/mar09/8407

Appended on 3/31/2009

This evening Richard Oriani posted an important message, on the Internet list for CMNS researchers. Addressing SPAWAR team he wrote: **"You have reported finding triple tracks in CR39 detector chips that had been placed within operating electrolysis cells and have pointed out that three nuclear particle tracks emanating from one point indicate the occurrence of the reaction 12C(n,n')3 alphas, suggesting the production of neutrons of energies 9.6 MeV or greater. I have also found triple tracks going out from a central point, but I have also found double, quadruple, and higher-order multiple tracks emerging from a single point. (See the attached images). You may be right in you interpretation, but in view of the variety of the numbers of tracks with a common point of emergence that can appear after electrolysis it seems rash to ascribe to one member of the family a specific nuclear mechanism that cannot apply to the other members. I suggest that other supporting**

evidence is needed before your interpretation can be accepted."

Replying to this, I wrote: **"Attached is a file showing my cluster of "multiple tracks emerging from a single point." You can also see it in Figure 7 at**

http://csam.montclair.edu/~kowalski/cf/336cat.html

The attached picture was trimmed. The larger picture (Figure 7 under the above link) shows that the cluster is not surrounded by numerous single tracks. Suppose this cluster is due to a rare reaction induced in CR-39 by fast neutrons. In that case there would be a lot of single tracks due to elastic and inelastic collisions of such neutrons with hydrogen nuclei. Absence of tracks due recoiling protons is a valuable argument against the idea of high energy neutrons. Note that I was using Oriani's protocol, not the SPAWAR protocol. A clear yes-or-no answer, about the hypothesis of high energy neutrons can be obtained in the modified version of SPAWAR experiment, [as described earlier in this unit]. Does this suggestion make any sense? Is it worth implementing? "

I have observed recoiling protons in CR-39 chips exposed to a Pu-Be source of neutrons, many times. I would not fail to recognize them. These tracks are similar to those due to alpha particles from Am-241, but most of them are about one half the size of alpha tracks.

The lead article in the Science and Technology section of The Economist (March 28 2009) also has an article on SPAWAR neutrons:

http://www.economist.com/science/displaystory.cfm?story_id=13361472&CFID=49711510&CFTOKEN=42825308

The author, who was apparently present at the Salt Lake City conference last week, writes that **". . . most researchers in the field, though, do not accept that heat is sufficient evidence of fusion (if only because it was the basis of the Pons/Fleischmann claim). So to strengthen her case, Dr Boss placed a special plastic called CR-39 next to the hot electrode. If fusion was taking place, then neutrons flying through the plastic would cause protons within the material to recoil, leaving telltale tracks. Studying CR-39 under a microscope and counting the number of tracks is a standard way to assess how many neutrons bowled past."**

In reading the article, I realized that SPAWAR own experimental data can be used against the hypothesis that fast neutrons are responsible for triple tracks. Here is my tentative argument. Suppose the hypothesis is correct. In that case triple tracks would be surrounded by an overwhelming number of tracks due to recoiling protons. But, according to the SPAWAR published article, and according to their 2007 presentation in Catania, triple tacks were surrounded by single tracks due to alpha particles, not recoiling protons. Surrounding tracks were definitely too large to be attributable to protons. That confirms what Richard Oriani wrote, multiple tracks emerging from a single point are not due to neutrons.

Fortunately, SPAWAR experiments are said to be reproducible. Therefore a clear answer, about generation of high energy neutrons in co-deposition experiments, can be obtain by performing the experiment I suggested. What can be more scientific than this? Will such experiment be performed? This remains to be seen.

Appended on 4/3/2009

The current discussion of neutrons emitted during SPAWAR experiment reminded me of a 2007 report of Larry Forsley (at "8th International Workshop on Anomalies in Hydrogen/Deuterium Loaded Metals," in Catania, Italy). Larry is a member of SPAWAR team. I do not know why his report is not printed in the Workshop Proceedings. Perhaps this would conflict with plans to publish the paper in a journal).

But another paper (page 182 in the Proceedings), is related to neutrons emitted in SPAWAR-type experiments. The authors of the report are Lipson et al (Russia), and Tanzella et al (USA). Experiments were performed in SRI (Stanford Research Institute) but CR-39 were sent to be analyzed in Moscow.

The abstract states that it is a **"preliminary evidence for the fast neutron emission. The energy is estimated to be in the range of ~2.2 - 2.5 MeV with a rate of 1 - 3 n/s."** That evidence was based on recoiling protons, from scattering of neutrons. Protons produced during electrolysis were compared with protons resulting with collisions with neutrons from a Cf-252 source. No subsequent report was presented at ICCF14, last fall. It probably means that nothing more was done along this line of research. If neutrons of ~2.4 MeV are really emitted, at the rate of one per second, during SPAWAR type electrolysis, then triple tracks would be surrounded by tracks from single protons--probably millions of them per triple track. That is a puzzle.

The same report sheds light on another puzzling aspect of SPAWAR results. The first 2007 idea was that tracks (whose presence I was able to independently confirm) were due to alpha particles of several MeV. My analysis conflicted with this interpretation; tracks were too large for this. The Catania report of Lipson et al. informs us that one of the two CR-39 chips, sent to Moscow, was covered by a mylar film during electrolysis. Alpha particles of several MeV (but not 1 MeV) would travers the film and would produce tracks in CR-39. Some nuclear tracks (densities exceeding the background) were observed, but the number of tracks was orders of magnitude less than what is observed when a CR-39 is in direct contact with the cathode, during electrolysis. In other words, at least 99% of SPAWAR trcks, seen in our replication experiments, disappear when CR-39 is covered with mylar.

These results are in conflict with the idea that SPAWAR "copious tracks" are due to alpha particles of several MeV (or to other charged particles able to traverse the mylar film). That is how, I suppose, the interpretation shifted from alphas of several MeV to alpha particles of about 1 MeV. But that is my guess; SPAWAR papers do not mention the results reported by Lipson et al, and Tanzella et al. Why is it so?

Appended on 4/4/2009

I am surprized that no one on the CNMS list answered my question, even those who were involved (Tazella, Lipson, Boss, etc.) Why do they prefer to remain silent? Perhaps they do not read my messages. But I received a private message from Richard Oriani, who does cover CR-39 chip with mylar. He suggested that I try to replicate his recent PACA results, as described in unit 333 at my website (see the link below). This prompted me to post the following message on the Internet list for CMNS researchers:

Two CR-39 protocols have been used to discover, and to confirm, reality of nuclear-like tracks produced during electrolysis: Oriani's ordinary-water protocol and SPAWAR heavy-water protocol. I was lucky to familiarize myself with these protocols (helped by Richard and by Pam) and to observe tracks with my own eyes. Actually, there are two Oriani protocols; let me call them A and B. Protocol A, described at

http://pages.csam.montclair.edu/~kowalski/cf/333physrevc.html

can be used in a totally independent experiment." Results reported in Oriani's rejected manuscript (see the URL above) are more recent and they are said to be 100% reproducible. I know that many people on this list are able to independently replicate Oriani's protocol A. With this in mind, I would like to suggest a cooperation, to be called "Curie Project." The purpose of The Galileo Project, organized by Steve Krivit, was to independently confirm SPAWAR results; the purpose of Curie Project would be to do the same for recent Oriani's results (see the URL above). I am certain that Richard will be happy to assist those who need technical help. I have enough CR-39 for at least ten experiments. I can also perform microscopic examination of already-etched CR-39 chips, for someone who has no access to a microscope. The entire experiment, including etching, must be performed in different labs (a possible alpha-radioactive contamination is no longer a problem after etching).

We would give ourselves a deadline, for example, to finish experiments before the end of May or June. Then one of us would draft a cooperative paper to be submitted to a journal. All results, both positive and negative would be reported. Later we would discuss which paper to choose. More detailed reports, focusing on individual results, are likely to be suitable for ICCF15. Please reply by sharing what you think about this idea, even if you are not interest in participation in the Curie Project.

I think our experiments should be as identical as possible. Let us use a constant-voltage source of 12 volts (a car battery or an equivalent power supply). We all should be using Ni foils as cathodes (Pd is more expensive) and light distilled water (heavy water is much more expensive). Richard, confirm that these are good suggestions. If not then suggest something else.

2) Do you know people who are not on the list but able to participate in the Curie Project? If so then please share this message with them. In my opinion, any serious researcher, willing to conduct a CMNS experiment, should be recommended to Haiko.

Appended on 4/5/2009
No one (except Oriani, in a private message) replied to what was posted yesterday. This prompted me to post another message:

"1) In a private message, Oriani wrote (I have permission to quote): 'I applaud your effort to stimulate the replication of my results that showed reproducibility. I shall be glad to provide advice whenever needed to whomever is interested in carrying out the project. I emphasize that the demonstration of reproducibility of development of nuclear tracks in CR39 detectors placed in electrolysis cells is the desired goal. Therefore at least ten separate experiments with appropriate controls will be required from an experimenter.'

2) A list of what is needed (including prices), to replicate Oriani's protocol, can be seen at:

http://pages.csam.montclair.edu/~kowalski/cf/188oriani.html

Figure 1, next to the list, shows the cell, as we used it before Richard's PACA protocol was introduced. PACA stands for 'Protected Against Chemical Attack.' He introduced this protocol after SPAWAR CR-39 results became known in 2007. The setup is the same except for the following:

a) The CR-39 detector is no longer where it was (inside of the lower tube).

b) What is labeled "nickel" should be a CR-39 chip, separated from the electrolyte by a thin film (6 microns or so) of mylar.

c) A nickel cathode wire (with a foot resting on the mylar) is introduced into the cell from above, more or less like the anode.

Please correct me if I am wrong, Richard. Also provide additional details, if needed.

3) The photo of my cell, and additional details can be seen at:

http://pages.csam.montclair.edu/~kowalski/cf/192logbook.html

4) Another picture of my cell (for the experiment Richard wants us to replicate) can be seen in Figure 3, at:

http://pages.csam.montclair.edu/~kowalski/cf/336cat.html

Figure 2, by the way, shows a spectacular Richard's cluster; Figure 4 is a similar cluster from my replication experiment.

5) Do you see the question in Figure 1? The purpose of Curie Project would be to answer it. Is it true that nuclear-like tracks, not attributable to background, are reproducible on demand, when PACA protocol is used? The Galileo Project did answer this question positively for the SPAWAR protocol. Will the same be true for the PACA protocol? This is possible, provided at least three more sets of independent experiments are performed.

6) Please share what you think about the idea of performing replication experiments at the same time.

7) Yesterday I wrote: 'Do you know people who are not on the list but able to participate in the Curie Project? If so then please share this message with them.' Was it a good idea?

8) With some hesitation, I suggest we use nickel from the same batch, and from the same supplier. Perhaps Richard will be willing to order a box of foils and send one foil to each of us. This would lower the cost; suppliers do not sell single foils. Other expenses could be lowered in the same way, provided participants pay for what is sent to them, including postage.

9) Not everyone is likely to have time for ten replication experiments, suggested by Richard. What about only four, providing at least four people participate in the Curie Project? A person (or a team) deciding to participate should make a commitment within a week or two."

Appended on 4/7/2009

One person wrote that the suggested deadline in not realistic. Responding to this, I wrote: **"Let me push the suggested deadline (for making Curie-Project commitments) to the end of May. This would be four months before the ICCF15. We would report results, or preliminary results, at that conference, if we are ready. Otherwise we would continue working till a clear yes-or-no answer is found. Additional comments and suggestions would be appreciated. Is the Curie Project worth organizing? Is the task well defined?**

P.S. My last message referred to Ni foils. That was a mistake. I forgot that the cathode, in Richard's PACA experiments, is no longer a foil, it is a wire. Should we use wires from the same spool or is it better if each of us uses a nickel wires from a different manufacturer? Even very tentative commitment would be appreciated on this list. This could encourage others. Thanks in advance.

John Fisher, who worked with Oriani, and reported the results at ICCF10, posted the following comment: **"Although I think we could learn a lot from the Curie Project I doubt that it would convince a hard-nosed skeptic.**

*****>Even if all of the participants were to report positive results, the skeptic would note that they had selected themselves. The request for volunteers was submitted to a large number of individuals. Before committing to the project, many might have attempted to achieve a positive result. Those that failed may have declined to participate. In light of this potential bias the skeptic would reject a claim of reproducibility.**

*****>If some participants report positive results and some report negative results, the absence of reproducibility would be demonstrated. The skeptic would likely believe that unidentified and uncontrolled factors were responsible for the positive results.**

*****> The protocol does not include studies of radon contamination, of other radioactive contamination, or cosmic rays, to eliminate them as causes of the etch pits.**

*****>It has not been shown that in all cases the etch pits are actually associated with particle tracks, and the identities of the presumed particles making such tracks have not been determined.**

In light of such considerations a skeptic would probably conclude that although something odd my have been observed in some electrolysis experiments, there is no reason to believe that these observations are evidence of nuclear reactions.

If, however, we view the project as a means of educating ourselves, of discovering factors that disfavor or favor reaction and removing or enhancing them as appropriate, we then may be able to achieve a reliably reproducible protocol and a much stronger project.

This is an interesting observation. It seems to apply to all CMNS projects, not only to CR-39 work. I was not thinking

about the "hard-nose skeptics;" I was thinking about majority of honest scientists who would start performing reproducible-on-demand experiments, and start testing their theories against undeniable results.

Responding to John Fisher, I wrote **"I think that we should not worry about "hard-nosed skeptics." We should try to convince common scientists, most of them are honest and objective. Suppose four teams participate in the Curie Project, performing 16 experiments. Suppose that 15 of these experiments show nuclear-like tracks, at densities at least five times higher than the background. Suppose that this is published, for example in EPJAP or in Phys. Rev. Suppose that journalists write about our results in newspapers. I am certain that this would contribute significantly to the ending of discrimination against our field."**

And what if results are inconclusive, or negative? Negative results would convince us that Richard's tracks were not due to a nuclear process resulting from electrolysis. We would be disappointed but that would not prevent us from obeying the rules of the game. Would we still publish the results or would we hesitate, thinking that "this might hurt the field"? I would vote for publishing negative, or uncertain results. Uncertain results would prolong the agony; they would again indicate that something is going on but we do not know how to control it. A poisoning effect of some kind (as postulated by Peter Gluck) or an elusive NAE (Nuclear Active Environemtas postulated by Ed Storms)? Uncertain results would force us to continue, obeying scientic-method. Natural human emotions, such as tendency to deemphasize (or hide) negative (presumably explainable) results should be resisted at all costs. Yes, it is difficult to be objective. Based on my experience so far, I am afraid that some experiments will produce tracks while others will show nothing above the fluctuating background.

Appended on 4/10/2009

The 20th anniversary of the Salt Lake press conference prompted me to think again about the strategy needed to convince mainstream scientists that our claims are valid. I think that the issue is worth discussing. My advice would be not to inject theoretical interpretations until facts are recognized as real. Remember what happened in 1989. Instead of focusing on real experimental facts (generation of excess heat) discussion quickly shifted to theoretical considerations, such as coulomb barrier, expectations based on wrong models, etc. It would be much better if the new phenomenon were called UEH (unexplained excess heat) rather than CF (cold fusion), until the reality of UEH were recognized by most scientists.

Explaining facts in terms of unexplained ideas seems to be counterproductive, at this stage. But this is not something unheard of. I am thinking about the famous paradox of missing energy in beta decay. Calorimetric measurements of the mean energy per beta particle, conducted in 1930s, were not consistent with the law of conservation of energy. To explain these experimental results, Pauli invented neutrino, a particle of negligible mass that carries the missing energy. I suppose that many people had reservations about this, just like many of us resist premature explanations based on polyneutrons, erzions and magnetic monopoles. But Pauli’s ad hoc hypothesis was eventually shown to be correct by Cowan and Reins (1950’s).

In our situation, however, mixing experimental facts with theories might backfire again. What we are facing is more complicated than a conflict between valid nuclear theories and new experimental data. We are also facing a political conflict between two groups of scientists. We want people to look at our experimental data; we want them to perform experiments and to focus on critical analysis of results. Yes, pure empiricism is not science. Yes, theoretical debates are essential. Knowing what happens is not the same thing as knowing why it happens. Progress is faster when theory and experiment go hand in hand. But, like other powerful tools, theories can have both positive and negative effects. I am afraid that premature theoretical considerations can produce more harm than good at this delicate stage. Experimental data are easier to defend than ad hoc theories. Let us fight in terains with which we are familiar; let us avoid terains where we are weak. Theoretical people will probably do the same and the two tracks will coexist without interacting formally with each other, for the time being.

370) What is going on?

Ludwik Kowalski

Montclair State University, New Jersey, USA
June 11, 2009

1) What follows is a message I posted on the private list for CMNS researchers. It a reply to a comment on my ongoing attempt to verify Oriani's claim that pits he observes are indeed reproducible on demand. Three other researches are going to make the same attempt this year. I will certainly have a unit devoterd to this cooperative project. I am showing this message because it leads nicely to updating of the situation with SPAWAR-type experiments. I wrote:

"Yes, the first question is hard to answer because we do not know how particles are emitted. I suppose they are emitted continuously during electrolysis. But that might not be so. One thing, however, is certain--one long experiment will not produce less tracks than an experiment lasting only three days. Your comment about not counting tracks outside the o-ring was a useful reminder. Your ICCF14 paper reported tracks on the "other side" of CR-39. The side facing air, rather than mylar and the electrolyte, might contain tracks due to radon in air.

There are so many things to study, once results become reproducible on demand. Another parameter to investigate would be the effect of magnetic field, as in SPAWAR experiments. Showing that presence of magnetic field changes the density of excessive tracks significantly would be a very convincing argument against many artifacts. In the last paper SPAWAR people show how magnets are used to keep hold pieces together. I would very much like to know if their earlier observations (strong effect of magnetic and electric fields of production of tracks) were confirmed by more recent experiments. Perhaps Pamela will tell us something about this (I have strong neodymium magnets, ready to be tried)."

2) Two days passed and no one responded. This prompted me to post another message. I wrote: "Dear all, the most recent SPAWAR publication, at:

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

is worth reading and discussing on this list. About 90% of previously-observed pits disappeared when a thin mylar film was inserted between the cathode and the CR-39 detector. That simplifies the analysis of the remaining pits; they do not overlap as much as before. The mylar film absorbs alpha particles with energies up to 1.45 MeV. The previous hypothesis, that most pits are due to alpha particles of about 1 MeV, is thus rejected. The current thinking is that ""the majority of the particles formed as a result of Pd/D codeposition are 0.45-–0.97 MeV protons, 0.55-–1.25 MeV tritons, 1.40-–3.15 MeV 3He and/or 1.45-3.30– MeV alphas.""

This conflicts with results from another codeposition experiment, described in Section 5 of:

http://lenr-canr.org/acrobat/KowalskiLcommentson.pdf

A mylar film, of equal thickness was used in that earlier experiment. But results were dramatically different. First, the number of pits was orders of magnitude smaller. Second, the pits were identified as protons, suspected to be produced by 2.5 MeV neutrons. Is this a real discrepancy or are the different results (from two presumably identical codeposition experiments) due to something different in how the experiments were performed? Knowing what made

the difference seems to be very important. Were magnets used in both experiments? “

3) After posting the above I started to read the now-published proceedings from Catania conference. Then I posted this message:

“This question is answered on page 182 of Catania proceedings. No external electromagnetic field was used in SPAWAR-type experiment performed at SRI. The last paper of Pamela et al., on the other hand, shows that two magnets were used in their experiment (see the first link above). It seems that the difference (eliminating only about 90% of pits versus eliminating at least 99.9% of pits, by mylar) is due to the magnet. This is the only logical conclusion, provided experimental results are indeed reproducible on demand. What else can be responsible for the dramatic difference? I tentatively translation "200 tracks in 15 days of electrolysis" into "at least 99.9% pits were eliminated by mylar." Is this acceptable?

P.S.
(a) Actually, the magnetic field is not the only parameter that has a dramatic effect on the number of tracks created in SPAWAR-type experiments. Nearly all tracks disappear when D2O, used to make the electrolyte, is replaced by H2O, and when PdCl2, also used to make the electrolyte, is replaced by CuCl2. These are extremely powerful arguments against many suspected artifacts. Details are in Section 1 of

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

(b) Why is the report by Lipson, Tanzella et al. not even mentioned by Pamela et al. in their paper

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

published two years later? Is there a good reason for ignoring what was independently reported in Catania? If so then please let us know.

(c) Who else, besides the SRI team, continued replicating SPAWAR-type experiments, after phase one of The Galileo Project? We have an ideal situation, at least three parameters influencing the unexplained nuclear activity, have been identified. Perhaps it is time for initiating phase two of that project.”

4) I am still hoping that Pamela, or someone else from SPAWAR team will comment on what I wrote. Meanwhile, oneCMNS researcher (Ed Storms) posted the following observation: “

“You should consider that the radiation produced by SPAWAR conditions is not produced by the same conditions that produce heat and helium. In other words, the conditions determine the nuclear product. Consequently, this experiment says nothing about the other aspects of CF.

When neutrons are detected, they are always produced at a very low rate compared to tritium and even lower compared to helium. In fact, these three products appear to have no relationship to each other. Helium seldom occurs with tritium or neutrons. Tritium and neutron can occur at the same time, but with a t/n ratio that is highly variable with an average near 10^6. In other words, the conditions giving the different nuclear products should not be used in theories to explain all nuclear products. The SPAWAR conditions are producing the least active of the possible nuclear reactions.”

5) Responding to the above, I wrote: “This might be true. But ‘the least active’ does not bother me. We are not yet at the stage at which scientific understanding can lead to useful devices. Reproducibility on demand, confirmed in phase one of The Galileo Project, seems to be more important, at this time. Information from experiments that are not reproducible is not very reliable. What other experiments, demonstrating presence of unexplained nuclear particles, reached the same status as SPAWAR-type experiments, as far as reproducibility on demand is concerned?”

Responding to Ed Storms, a theoretically-inclined researcher (Andrew Meulenberg) posted several messages about significance of “the least active.” I am not going comment on their ongoing debate. But here is how Ed responded to

my message above: “My point Ludwik, is that an effect, although reproducible, must be applied properly to understand CF. I suggest this result may be caused by a mechanism that has no relationship to the main CF effect. While it is unique and gets people's attention, it may not give any insight into the major reaction, which is helium-heat production. In other words, people may be chasing a distraction even though this distraction is interesting from a scientific point of view.”

Here is my reply: “My recollection is that excess heat was measured in earlier SPAWAR-type experiments. Is this correct? In my opinion, any electrolysis, based on D2O, is a potential candidate for understanding helium-heat production. Other CMNS reactions, described in your book, are also worth studying”

”Ed responded “Although heat was claimed, my efforts to replicate this claim have revealed many problems with such a measurement. I don't think this claim can be accepted until it is replicated at higher levels when these problems are eliminated.”

I wrote: “Scott Little made an offer to measure excess heat with his sensitive instrument for other researchers. If I were Pamela, I would bring the cell to Texas and would perform at least two experiments inside Scott's calorimeter. The instrument is probably available on short notice. It has more than enough space for several SPAWAR cells, used at the same time. They can be connected in series.”

In another message I wrote: “What would I do if I were a powerful NSF director? I would release the following solicitation for proposals: "It has been reported that SPAWAR-type CMNS experiment, demonstrating a nuclear process triggered by electrolysis, reached the level of reproducibility on demand. To verify this claim, and to promote further research, NSF is now willing to support further investigations. Financial support for five grants, $50,000 each, is available to qualified scientists. Please submit your proposals as soon as possible; the deadline is December 30, 2009."

6) Several hours later I asked another question: “Another question to authors of paper

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

I have no doubt that pits shown in Figure 6 resemble tracks of nuclear particles. Looking more carefully, I see that sizes of dark pits in Figure 6, are much larger than sizes of pits in Figure 7.

All pits in Figure 7 are due to alpha particles (of several energies). The photo in Figure 6a and all photos in Figure 7, cover an area whose height is 100 microns. Unfortunately, the magnification 500 is specified for the Figure 6a only. Should I assume that pictures in Figure 7 were taken under the same magnification as the picture in Figure 6a? If not then what was the magnification for pictures in Figure 7?

7) We were informed that magnification was 500, as I assumed.

8) My next post: “Please tell me what is wrong with the following argument.

a) Both Figure 6a and Figure 7d are self-calibrated (by 100 micron arrows along borders). Therefore diameters of pits, shown on these figures, can be determined independently of each other, and independently of magnifications under which the pictures were taken.
b) I zoomed on a dark pit in Figure 6a (near the upper right corner); that pit is due to a post-electrolysis particle. Then I determined its size on my screen (in millimeters). After that, under the same zoom, I determined the size of the largest pit in Figure 7d (also in millimeters on my screen). Pits in Figure 7d are due to alpha particle of very low energy; they were nearly stopped by a mylar filter of 24 microns.
c) I divided the first size by the second size and the ratio happened to be 2.0. I concluded that post-electrolysis pits are typically twice as large as pits due to alpha particles of very low energy.

The sizes could have been expressed in microns (by measuring the length of the 100 micron arrow on my screen). But I do not think that this is necessary; I am interested in ratios of sizes not in individual sizes expressed in microns.

Where am I wrong?

P.S.

d) Who else can confirm that sizes of pits due to alpha particle, recorded two different batches of Fukuvi CR-39 material, can occasionally differ by as much as a factor of two, under the same etching conditions? I would certainly noticed this, using Fukuvi chips from different batches for several years. My chips are also irradiated with alpha particles, at a little corner spot. The first thing I always do is to look at that spot, to verify that etching was successful.

e) Unless convinced by missing information, I will continue claiming that dark pits in Figure 6a are about two times larger than pits on Figure 7d.

9) Let me review the evolving interpretations, based on reproducible on demand SPAWAR data.

a) The first hypothesis was that "copious pits" are due to alpha particles of several MeV (which was not consistent with my own successful replication results, under The Galileo Project. The pits at the little corner spot were 1.7 times smaller than typical post electrolysis pits.

b) The second interpretation, emerged after our Catania conference, nearly two years ago, was that pits are due to alpha particles of about 1 MeV. Please confirm or deny that this resulted from information provided by F. Tanzella et al. As far as I know, they were the first to use a thin mylar filter in a co-deposition experiment.

c) The interpretation presented in the most recent SPAWAR paper (April 2009), based on new information, is different. Some tracks are now attributed to protons and tritons while others are attributed to 3He and alpha particles with energies between 1.5 and 3.5 MeV.

d) Changing interpretations, after learning more from new experiments, is a sign of health, especially in our situations. Taking (c) for granted, one is led to believe that large pits in Figure 6a are due to alpha particles. That is why I expected sizes of pits in Figure 6a be the same as sizes of pits in Figures 7e and 7d.

e) But dark pits in Figure 6a seem to be twice as large as pits due to alpha particles of 1.5 to 3.5 MeV. How can this be interpreted? The only thing I know is that pits due to heavier ions, such as fission fragments, are about two times larger than pits due to alpha particles. Yes, it is crazy to think about fission. But this is not less crazy than thinking about fusion. Reproducible acts, should always be respected. Correct interpretation will emerge, sooner or later. I think that we are making progress.

f) The new design of SPAWAR electrolytic cell, shown in Figure 1 of

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

seems to be perfect for replacing the CR-39 chip with a commercially-available silicon detector. That is what I would recommend to do next. ”

Let me summarize the most recent SPAWAR paper, available at

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

That paper, submitted on January 15 , was published in April 17, 2009. Suppose my note is submitted tomorrow (June 12); would it be published in the middle of September? That would three weeks before our next conference (ICCF15).

a) The authors remind us that CR-39 detectors are widely used in hot fusion research. Their reference 13 points to a recent review article. After describing previous uses of CR-39 in CMNS research, they describe their own codeposition method. Here is a quote: “In these experiments, a non-hydriding cathode substrate, such as Au, Pt, or Ag wire, is placed in direct contact with a CR-39 detector. The cathode is then placed in a solution of PdCl2 and LiCl in

D2O. When cathodically polarized, Pd metal plates out on the cathode in the presence of deuterium gas. At the end of these experiments, tracks were observed along the entire length of the cathode. The density of tracks was greater than that obtained for the Pd wire experiments indicating that the nanostructures created as the result of Pd/D co-deposition exhibit greater activity than bulk Pd."

b) What follows is a description of control experiments. First they verified that cell components are not contaminated with an alpha-radioactive substance. Their electrolyte consists of PdCl2 and LiCl. They showed that PdCl2 is essential; an experiment conducted without that substance did not produce tracks on the CR-39 detector. That experiment convinced them that tracks are not due to D+ ions reacting with CR-39 material. In some experiments PdCl2 was replaced by CuCl2. No tracks were produced. Track formation rate was reduced by four orders of magnitude when heavy water is replaced with light water. These important observations are then used to argue agains suspected artifacts.

c) I would like to know what the track density was when electrolyte was made from light water. Is it comparable with what was observed by Oriani? In an experiment lasting three days he often observes at least hundred tracks per square centimeter. How as the "four orders of magnitude" estimated from experiments in which counting of tracks was practically impossible, due to overlapping? The same question can be asked the effect of th e mylar filter on the number of recorded tracks. They say that ~90% of particles were stopped in mylar. How was this estomated? I suspect it is just a reasonable guess. It may be 90% and may be 99%. Both numbers show that most particles were stopped.

d) Their electrolytic cell, made from butyrate plastic, has a hole, civered with a thin mylar window. "A silicone-based cenent was used to epoxy that film to the flat cell surface. (I did not know that the word epoxy can be used as a verb. In my limited vocabulary, epoxy is the name of a very strong glue.) Two strong neodymium magnets are used to keep the CR-39 detector very close to the mylar film. A rubber band would probably be eqaually effective. Based on what SPAWAR people published earlier, I will assume that the main purpose of using magnets was to create a magnetic film inside the cell. But that aspect is not emphasized in this paper. In an earlier paper they reported that, with a nickel cathode, tracks were produced only when magnetic field was appled. This is an extremly important discovery--no tracks are formed unless PdCl2, D2O, and magnetic field are present.

e) Etching of chips after electrolysis, and microscopic examinations of pits are described in Section 2.4. In addition to human examination of pits they used an automated scanning track analysis system. In this case decisions about what to count and not to count is made by sophisticated software. A scanning electron microscope was used to observe the surface of gold cathode after electrolysis.

f) Here the description of the electrolysis protocol: "Typically 20–25 mL solution of 0.03 M palladium chloride and 0.3 M lithium chloride in deuterated water is added to the cell. Palladium is then plated out onto the cathode substrate using a charging profile of 100 microA for 24 h, followed by 200 microA for 48 h followed by 500 microA until the palladium has been plated out. This charging profile assures good adherence of the palladium on the electrode substrate. After the palladium has been electrochemically
plated out, the cathodic current is increased to 1 mA for 2 h, 2 mA for 6 h, 5 mA for 24 h, 10 mA for 24 h, 25 mA for 24 h, 50 mA for 24 h, 75 mA for of 0.4 cm2. Given the amount of plating solution placed in the cell, the density of Pd is estimated to be $9*10^{20}$ to $1.1*10^{21}$>/sup> Pd atoms/cm^2.

g) Next section, named "Results and discussion," shows photographs of what was actually observed. Figure 4.1, for example, shows that pits near the cathode no longer overlap as strongly as in the case of experiments conducted without mylar. I have no doubt that pits shown if Figure 6 resemble tracks of nuclear particles. But what kind of particles are they? Looking more carefully, I see that sizes of dark pits in Figure 6, are much larger than sizes of pits in Figure 7. All pits in Figure 7 are due to alpha particles (of several energies). The photo in Figure 6a and all photos in Figure 7, cover an area whose height is 100 microns. Unfortunately, the magnification 500 is specified for the Figure 6a only. Should I assume that pictures in Figure 7 were taken under the same magnification as the picture in Figure 6a? If not then what was the magnification for pictures in Figure 7?

11) Another appeal for a clarification (appended on 6/23/2009)
On June 19, 2009, I posted this message on the Internet list for CMNS researchers

Waiting for clarifications, I would like to reconstruct recent history of experiments said to demonstrate a nuclear effect due to electrolysis. I will begin The Galileo Project (ignoring very important earlier publications). Please correct me if something is wrong.

a) SPAWAR team started using CR-39 detectors in codeposition experiments. The discovered a large number of pits said to be due to nuclear projectiles.

b) The Galileo Project, to confirm presence of reported SPAWAR-type pits, was organized by Steve Krivit.

c) Most participants, including Richard Oriani and myself, independently confirmed presence of such pits.

d) Detailed investigations convinced Oriani, that dominant SPAWAR-type pits are due chemical corrosion, as he reported on this list.

e) Instead of using the codeposition method, invented by SPAWAR team, Richard returned to his old method (using Li_2SO_4 electrolyte based on light water). But he borrowed one element of SPAWAR design; his cathode was put next to CR-39. To minimize a chance of corrosion, Richard protected the CR-39 by a layer of Mylar. The layer's thickness was six microns; this corresponds to the range of alpha particles of about 1.5 MeV.

f) Meanwhile SPAWAR team continued studying pits resembling tracks of nuclear projectiles, and publishing results. Their report was presented at the ACS meeting in 2007. It was followed by a publication in a refereed journal (The European Physics Journal; Applied Physics). That paper can be downloaded from:

http://lenr-canr.org/acrobat/MosierBossuseofcrinp.pdf

g) Ludwik Kowalski, one of several participants in The Galileo Project, also observed SPAWAR type pits. His first report was also published at the ACS 2007 meeting. But he presented evidence that dominant pits could not be attributed to alpha particles, or to less massive projectiles. That interpretation was also published in The European Physics Journal; Applied Physics. The paper can be downloaded from:

http://lenr-canr.org/acrobat/KowalskiLcommentson.pdf

h) Arguments against that interpretation were developed in another paper, published by SPAWAR team:

http://lenr-canr.org/acrobat/MosierBossreplytocom.pdf

i) Another team of CMNS researchers, Francis Tanzella et al., also conducted a SPAWAR type experiment. But, like Oriani, they used Mylar to protect the CR-39 chip, as reported at out Catania Workshop (October 2007). Their protected CR-39 chip was exposed to the cathode for 15 days. Only about 2000 pits were recorded. In other words, at least 99.9% of pits seen without a Mylar filter were eliminated. What remained, however, was much higher than on the control chip. The 2000 pits were identified as protons, with energies close to 2 MeV. That number of pits seems to be consistent with numbers of pits observed by Oriani.

j) SPAWAR team also started protecting their CR-39 detectors with Mylar films of six microns. This was reported in their 2009 paper, downloadable from:

http://lenr-canr.org/acrobat/MosierBosscharacteri.pdf

That report states that a Mylar filter eliminated only about 90% the previously observed pits. Their analysis of pit sizes resulted in the following conclusion: "the majority of the particles formed as a result of Pd/D codeposition are 0.45–0.97 MeV protons, 0.55–1.25 MeV tritons, 1.40–3.15 MeV ^{3}He and/or 1.45–3.30 MeV alphas" No reference to Tanzella's experiment was made in the last publication.

k) Richard Oriani was not successful in trying to publish results of his experiments in a refereed journal. But his earlier results were presented at our Catania workshop (October 2009).

http://pages.csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

l) Ludwik Kowalski was able to confirm reality of clusters of tracks, reported by Oriani. But results were not reproducible on demand. That was also reported at our Catania workshop (October 2009).

m) Motivated by The Galileo Project, Ludwik Kowalski tried to find CMNS researches willing to replicate Oriani-type experiments. This initiative was named The Curie Project. Unable to succeed, he appealed to teachers (on the Phys-L list for physics teachers) and found three participants. Results from the four ongoing studies, including his own, will probably be known before ICCF15.

But the list remained silent, conrary to my expectation. On June 22 I made another appeal, to break the silence. Quoting the above I added:

n) I forgot to include another very important piece of data. Looking at the first two lines of Oriani's first table in:

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

I see that he also performed two SPAWAR-type experiment in which CR-39 were protected from the cathode. The first experiment lasted 168 hours (7 days) and produced 284 tracks/cm^2 on the side facing the cathode and 150 tr/cm^2 on the other side. The second experiment lasted 172 hours (7.2 days) and produced 156 tracks/cm^2 on the side facing the cathode and 160 tr/cm^2 on the other side. As far as I know, Richard was using the same CR-39 from Fukuvi that I am using (background ~13 tr/cm^2).

The total number of tracks he observed was probably close to 750*4=3000, where 4 cm^2 is the total area over which tracks were observed. Like in Tanzella's case, the total number of observer tracks was much higher than the background. And Richard's 3000 number is surprisingly close to 2000 tracks found on Tanzella's Chip #7. Each of these two numbers is probably orders of magnitude smaller than the 10% of the remaining tracks, observed on SPAWAR chips, as described in the most recent SPAWAR paper.

What else should be mentioned in my summary? Is the discrepancy between what was seen on Tanzella's Chip #7, and what was published recently by SPAWAR, real or is it apparent? Please share with us what you know, and what you think.

Appended on 6/25/2009

Why is no one responding to my questions about the apparent discrepancy between the new SPAWAR results (CR-39 was protected with mylar) and results from a similar SRI experiment (F. Tanzella et al) and from two similar experiments of R. Oriani? All participants, including Russian scientists, are on this list. Do authors and coauthors of reports know something that I do not know?

This sudden silence reminds me of another episode of silence. This was in 1940, when scientists decided not to publish results connected with nuclear fission. They realized that a chain reaction could possibly be used to produce a new weapon. They did not want Germans to benefit from research conducted in other countries. I do not think that SPAWAR-type experiments are already yielding practically useful (patentable) results. But who knows; they are in a miltary lab. Perhaps they received an order to stop sharing. But who knows; perhaps this can explain silence.

P.S. How many people on our list know that conspicuous silence about nuclear fission research (in 1940) was noticed by a Russian scientist G. Flyorov? Guessing the reason, he wrote a letter to Stalin and provided a possible explanation. This was in April of 1942, at the early stages of Manhattan project. Soviet governmental preoccupation with nuclear fission was probably triggered by this letter. K. Pietrzak and G. Flyorov, by the way, discovered spontaneous fission of

uranium; this was in 1940. After the war, Flyorov became an academician, and the director of the heavy ion acceleration laboratory in Dubna.

Appended 12/5/2009
1) My article, replying to the reply from SPAWAR, submitted to EPJAP, was rejected during the ICCF15. On October 12 I submitted it to JCMNS (Journal of Condensed Matter Nuclear Science). It is our own peer-reviewd journal. Two days ago I received comments from the referees. Let me show them here, to illustrate that CMNS researchers do not belong to a mutual admiration society.

Referee #1
In reviewing this paper for publication I do not concern myself with the question of the reality of the production of nuclear particles by electrolysis. My sole concern is to judge how well the author has succeeded in invalidating the assertion by the authors of refs. 1,2 and 4 that the etch pits that they observe were caused by alpha particles.

This paper is almost impossible to understand due to the author's manner of writing. The author refers to the measurements by the Spawar group of the etch pits produced by Am-241 alpha particles and those produced by the alleged nuclear reaction during electrolysis. The latter are one-half as large as those produced by 2.2 MeV alphas from Am, and therefore the electrolysis produced pits can not have been caused by 2.5 MeV alphas. In this the author is correct, but those results do not preclude alphas of energies larger than 2.5 MeV, and this is what the Spawar group claims in ref.1.

The author attempts to contradict the Spawar group assertion that the calibration curves of Brun et al. (ref.7) do not apply to Fukuvi CR39 plastic because the curves were established with a different detector plastic. The author does this by pointing to the similarity of the ratios of pits sizes for alphas of two different energies for two kinds of CR39 plastic. However, this is a weak argument because size ratios for alphas of two energies are functions of etching time and conditions.

I conclude that the author has not succeeded in invalidating the Spawar group's contention that alphas of 1.45 - 3.30 MeV are involved, although the Spawar group's assignment may in fact be incorrect. Because the attempted invalidation is the purpose of the paper, this paper should be rejected.

Referee #2
This paper gives unprejudiced critical view on SPAWAR results and it will be very desirable to publish it in JCMNS.

Referee #3
I find Kowalski's paper very difficult to follow. The logic is poor and it is all expressed in a very unscientific way. I do not know what the Spawar tracks are due to. pretty much agree with Kowalski that they most likely are not due to alpha's - but he does not make the case very well - and I don't know who claims that they are. A strong statement such as "cannot possibly be" needs much stronger support. The title MUST be changed. It is not clever - it is insulting and unscientific. All in all I guess the paper does not advance any case and I would be just as happy to not see it in JSCMNS.

Referee #4
I think that some version of the manuscript by Kowalski might be publishable, but that it should not be published in its present form. The SPAWAR group has attributed some of their tracks to low energy alpha particles, based on their interpretation of track diameters in experiments which they have published in several papers. We know from the experiments of Lipson and Roussetski that the primary signals that they see included the dd fusion products, as well as energetic alphas above 10 MeV. If the SPAWAR interpretation is correct, then the energetic particles that are seen are different from those reported by Lipson and Roussetski.

Hence, the interpretation of the tracks attributed to the low energy alpha particles are of interest, and worthy of discussion. In essence, we would like to be sure as to what they are. Kowalski has published on this previously, challenging the interpretation of the tracks as due to alphas, and the SPAWAR group has responded. In the new manuscript of Kowalski, comes back to similar arguments. One thing that is new is the speculation that the tracks are

due to more massive particles than alphas.

I would recommend for publication if some significant changes are made in the manuscript.

[***] The title is inflammatory, and is not supported by the text. It needs to be changed.

[***] The conclusion section is only weakly connected to the paper. Some of the nontechnical discussion should probably be eliminated; or if kept, it should probably be moved to an introductory section.

[***] It would be helpful to change the Conclusion section to a Summary and Conclusion section. In this section, a short summary of the key arguments should be given. This should be followed by the comments regarding the use of a silicon SSB detector. Note that Kowalski's suggestions along these lines are understood by everyone involved, and he is contributing essentially nothing to the discussion. He has apparently not worked with such detectors previously himself, or else he would be less enthusiastic about the noise issues that accompany the use of such detectors.

[***] Kowalski appears to be mistaken that the SPAWAR group has retracted results. As this is inflammatory as written, it should probably be removed. If Kowalski has a point to be made in this regard, it needs to be made in such a way as to not be inflammatory, and stated in a way in which there is general agreement. If these changes are made, then I would support the publication of the paper.

2) I modified the article and sent it to the editor last night, with the following note: “I agree with Referees 1 and 3 that my manuscript was difficult to follow. I rewrote it completely, de-emphasizing the old topic (comparisons of diameters) and emphasizing the new one (results reported in Catania, my reference 6). I also agree that the term ‘cannot possibly be due to ...’ was not appropriate. I am not using it anymore.”

Physics Teachers Discuss the Energy Problems (April 6 and 7, 2009)

Ludwik Kowalski, Montclair State University, Montclair, NJ

It would be interesting to read these comments, posted on Phys-L (an Internet list), in ten or twenty years. Unfortunately, I will not be around. Like other items on this website, this one is for future generations. Discovery of cold fusion was announced twenty years ago; will cold fusion become a promising option in twenty years? This remains to be seen.

Contribution 1
You wrote: "In 50 years we will probably have used up most of the oil, but then, if nothing else is available, we will switch to coal, of which there is enough to last a few hundred years." Are you sure of that? On a worldwide basis?

When I do the numbers, it looks like if present trends continue within a few decades we will have used up all (not just most) of the world's oil, all of the world's coal, all of the world's natural gas, and all of the world's 235U.

The numbers might /appear/ different if you include only the current US trends, because the US has a disproportionately large share of the world's coal yet is burning it at a disproportionately low rate, preferring (for the moment) to burn imported oil.

To repeat: On a worldwide basis, including coal does not solve the problem, and even including 235U does not solve the problem.

There are only two ways out: renewable energy and/or breeder reactors.

Breeder reactors can get energy from 238U, which is 200 times more abundant than 235U. Also thorium. This could provide energy for a few centuries (not just a few decades). However, almost* nobody wants to propose this as a solution, because it makes the weapons proliferation problem so much worse. Also the track record for breeder reactor safety is not good.

(*) There are folks in India who want to build a thorium-based breeder. Apparently India has indigenous supplies of thorium but not much uranium. The safety and proliferation issues remain.

Contribution 2
This brings up some excellent points. Personally, I see nuclear power as an intermediate step. Not because of technology but because of humans. To convert to a system that is dependent on renewables will require changes in our behaviors and in our ability to accept responsibility for our actions and impacts on the planet -- including population control, the 200 kg gorilla in the room. I don't see that as happening quickly unless there is a crisis. It would also take tremendous political will to move the country in that direction quickly (10 to 20 years). One or two politicians with vision and knowledge and will is not enough. Look what happened to Gore for example.

As for nuclear power, we are in some serious trouble. The power plants that were built in the 60's and 70's were made to last for 30 years. Well, that "warranty" has expired. The metals are getting brittle, the containment buildings are getting weaker, and on and on. Those are also old designs with fewer safety features. Yet, we cannot afford to turn them off as Hugh has pointed out.

I visited the Idaho National Laboratory a few years ago and was quite impressed with the technology of newer designs for nuclear power plants. (The name of this lab is a curious example of public pressure and fear in its own right. The name has changed several times to make it sound more cuddly. Swapping the word "nuclear" for "environmental" and

then dropping that all together.) https://inlportal.inl.gov/portal/server.pt?open=512&objID=255&mode=2

They have developed a system that results in glassified nuclear waste that they claim is very hard to reprocess into weapons material or to leak into the ground water. That said, the technology is new and experience with it is limited.

I'd love to see the shift straight to renewables, but I just don't see that happening. I agree with the closing quote that Hugh uses from Chip Giller. But I just don't see the USA heading in that direction because it requires personal change and thinking long term. (I just saw the movie **"Idiocracy" which is crude and** vulgar in many ways but is disappointingly accurate in even more ways. Maybe that is coloring my thinking right now...)

In the meantime, I'd like to learn more about what INL has developed and see if we have some new options for nuclear power.

Even so, we would still be left with issues like uranium mine tailings. I come from a state (Utah) that has one of the worst mine tailings problem on the planet with the old Atlas mine tailings next to the Colorado River near Moab, Utah. A legacy of our 1950's rush to all things nuclear. So even new technology nuclear plants is at best a stop gap measure. But, as Hugh points out, there are loads of problems with coal too.

Short of a national, in your face, crisis that directly impacts the "average Joe" in obvious and direct ways, I just don't see a direct conversion to renewables.

Contribution 3
One of the biggest asset of nuclear power during the transition period from fossil to renewable is HIGH DENSITY. The current energy infrastructure relies on siting power plants in high population/land use areas. Coal/gas/nuclear power plants can be sited on a couple square miles of land and produce 2000 MW of power. It would take 4000 1.5MW wind generators to AVERAGE that much (with 33% operational efficiencies--with are typical) and you'd still have periods of no wind in the region. It will take decades to build up an infrastructure where HUGE wind/solar farms can produce, STORE, and TRANSPORT our total energy needs. The North-East (Boston to DC) is always going to be a problem area.

One should be a bit skeptical (another thread) of Fusion power at this point since 50+ years of research has yet to yield anything remotely practical. The researchers are always saying "10 more years", but that has been the mantra for the past 30 or so. When my class does their energy project (supplying U.S. energy 100 years from now without the use of oil or gas) we don't allow any 'deus ex machina' solutions. We work with proven technology. It can be done, for 10s of trillions of dollars, and several hundred thousand square miles of land. But nuclear, 'clean coal', and as much hydro as possible are part of the program along with hydrogen as a storage medium and portable fuel. What can be done in the U.S. can be more difficult elsewhere. Japan for example has land problems. They really need some high density energy sources.

Contribution 4
President Obama's Secretary of the Interior announced today that the use of wind energy on the east coast could replace all the coal powered electrical power plants in the US. When asked how many windmills would be required he said "I haven't done the calculation yet". Good grief!

We can't get the Cape Wind project going here in New England because of people like Ted Kennedy opposed to seeing windmills in the distance of the coast of Cape Cod. The promoter of the Cape Wind project estimates that it will take several hundred thousand windmills to match the output of coal fired plants, but that they will accomplish that only 1/3 of the time because of the periods when the wind is not strong enough. The coal plants will still have to be kept on line as a backup. I hope Mr. Obama's economic advisors are more competent than his energy advisors.

Contribution 5
You wrote: “Personally, I see nuclear power as an intermediate step. Not because of technology but because of humans. To convert to a system that is dependent on renewables will require changes in our behaviors and in our ability to accept responsibility for our actions and impacts on the planet -- including population control, the 200 kg

gorilla in the room."

First, nuclear power just isn't in the cards as an "intermediate" step. It takes about 10 years or more to go through the planning, designing, licensing, building and certification process before a nuclear plant can come on line, and we need change *now,* not 10 or 12 years from now (there are plants in other parts of the world that have been 20 years and more in the building and still aren't completed--we don't have that kind of time to fool around with a problematic technology, that may be abandoned before it even can have an effect). Second, I don't see how renewables will require much in behavior change. The goal is primarily to keep the electric power (and other needed energy sources) coming when and where they are needed. I agree that if we try to create a system that requires massive lifestyle changes, the problem becomes dramatically more complicated. The object is to integrate renewables and efficiency into the fabric without making a big deal about it, so that the main thing people will notice it their utilities bills decrease (overall--there may be increases in one sector or another, but the total utilities costs should come down), and the air getting cleaner. If we electrify the railroads and make it economically feasible to shift most long-haul shipping away from trucks and onto the railroads, the costs of maintaining our highway system should decrease by up to 40%, and the roads will become less congested. The net effect should be to make life better and at lease a bit less expensive. This shouldn't require a major change in our behavior, although the increase in freedom these changes bring might encourage us to do even better.

I agree that the population problem is with us still, and will be for at least the next couple of centuries, which makes it all the more important that we move as quickly as possible on energy efficiency, so that all the gains made in how we produce our energy won't be erased by uncontrollable population growth. But the solution to that problem has less to do with how we fix the climate change problem than with the education, freedom and empowerment of women world-wide. It is well established that in those regions where women have control of their own reproductive systems, and have access to family planning information, birth rates decline. I see the largest problem in the population arena is in figuring out how to successfully manage a world whose population is stable. For too long we have based our economic system on an ever-increasing population, to the point where governments faced with a stable or even declining population don't have a clue about how to deal with it, and often panic--either importing labor or enacting policies to encourage increased birth rates.

You also wrote "I don't see that as happening quickly unless there is a crisis. It would also take tremendous political will to move the country in that direction quickly (10 to 20 years). One or two politicians with vision and knowledge and will is not enough. Look what happened to Gore for example."

Well, there is a crisis, and we need to start moving the country in that direction *now,* not in 10 to 20 years. We need to start a massive PR campaign in support of renewable energy--to convince people that wind turbines are beautiful (which I, personally, think they are) and that, combined solar energy, both PV and concentrated thermal can meet our energy needs if we do it intelligently (with the prospect of geothermal and wave energy in the not-too-distant future). That, of course, starts with a smart national grid, which will enable us to efficiently move electrical energy over large distances (perhaps superconducting?) and to use the grid to control how we use our electricity and to enable feed-in from individual sources (rooftop PV, etc.), as well as to eventually enable plug-in electric and hybrid vehicles to serve as our energy storage system to meet high demand situations, when the penetration of such vehicles into the market is enough to support that.

You also wrote "As for nuclear power, we are in some serious trouble. The power plants that were built in the 60's and 70's were made to last for 30 years. Well, that "warranty" has expired. The metals are getting brittle, the containment buildings are getting weaker, and on and on. Those are also old designs with fewer safety features. Yet, we cannot afford to turn them off as Hugh has pointed out."

There is considerable pressure now to re-license many of those aging plants, which are facing deterioration problem that you mention, not to mention the aging of the nuclear engineering and plant operator populations, most of whom will be retired within the next decade or two. And the designs for the new generation of reactors is still very fluid. None has yet been finally approved by the NRC (the Westinghouse AP-1000 has just been sent back to the drawing board for rework, putting the plans for most of the 35 new reactors planned for this country on hold). We cannot afford to turn them off all at once, but relicensing should be done very carefully, and it is likely that an aggressive efficiency

program, including building retrofits as well as new construction, and encouraging the use of solar thermal and solar PV units on homes as well as solar PV on commercial rooftops and parking lots can obviate the need for any new plants, so that the conversion to renewables can be phased with the retirement of exiting coal and nuclear plants as they come to the end of their design lifetimes.

You also wrote “I visited the Idaho National Laboratory a few years ago and was quite impressed with the technology of newer designs for nuclear power plants. (The name of this lab is a curious example of public pressure and fear in its own right. The name has changed several times to make it sound more cuddly. Swapping the word "nuclear" for "environmental" and then dropping that all together.) https://inlportal.inl.gov/portal/server.pt?open=512&objID=255&mode=2

They have developed a system that results in glassified nuclear waste that they claim is very hard to reprocess into weapons material or to leak into the ground water. That said, the technology is new and experience with it is limited.”

And of course that is a problem in itself. We need a storage technique that will be reliable for millennia, and we're talking about techniques with which we have "limited experience." It's clear that, even if by some political accident Yucca Mountain comes back into the picture, we have a long way to go in figuring out how to handle the nuclear waste. Another good reason for not creating any more of it than we are now doing.

You also wrote “ I'd love to see the shift straight to renewables, but I just don't see that happening. I agree with the closing quote that Hugh uses from Chip Giller. But I just don't see the USA heading in that direction because it requires personal change and thinking long term. (I just saw the movie "Idiocracy" which is crude and vulgar in many ways but is disappointingly accurate in even more ways. Maybe that is coloring my thinking right now...)”

There is a lot of inertia in the system. Power companies don't like to get away from the old technologies that they are familiar with, but this is an emergency, and I think that if the government takes the lead in emphasizing the critical nature of the problem that we can start moving in the right direction, but it has to be well planned. We can't build a bunch of wind parks or solar farms without having a robust means of getting that energy to market, and we can't afford to turn the problem over to people who don't have sufficient appreciation of the situation. We need to make sure that we have the capability to provide the base power needs until we can get the renewables well-enough designed and distributed to that they can pick up at least part of the base load requirements as well phase out the coal and nuclear plants and phase in the smart grid technologies that can provide the base load capabilities that will be needed for the long term.

You also wrote “ Even so, we would still be left with issues like uranium mine tailings. I come from a state (Utah) that has one of the worst mine tailings problem on the planet with the old Atlas mine tailings next to the Colorado River near Moab, Utah. A legacy of our 1950's rush to all things nuclear. So even new technology nuclear plants is at best a stop gap measure. But, as Hugh points out, there are loads of problems with coal too.”

Cleaning up the uranium tailings mess is easily comparable but not as dramatic as cleaning up the mess left over from building weapons. And the cost in lives to the miners, mostly Native Americans, on whose lands these predations were committed, is still going on. Cancer death rates among miners and other living near the mines (including children who played in the tailings piles without realizing the danger they placed themselves in) remain elevated and the life expectancy among those people has been measurably reduced by their exposure to the uranium ore that had lain safely underground for eons.

You also wrote “ Short of a national, in your face, crisis that directly impacts the ‘average Joe’ in obvious and direct ways, I just don't see a direct conversion to renewables.”

What the "average Joe" is concerned about, and rightly so, is his or her job and this or her family's future. By any ethical principle, we need to make sure that our efforts in environmental cleanup and GHG reduction end up being an opportunity for those people to better their own and their families' lots. Proceeds from such things as carbon cap and trade sales or carbon taxes or any other forms of revenue raising that goes on in the name of converting our energy sources to renewables, must be used to provide the opportunities to those whose present jobs will be impacted by such

things as closing coal or uranium mines, or operating power plants, or other jobs that have kept them at least existing for decades if not generations. If they can see a future for themselves in what we are trying to do, they will not oppose the efforts and can be enlisted to help in them. A 21st Century "WPA," especially in the current economic downturn, will provide those who are facing a bleak future as our energy economy shifts from coal, uranium and petroleum to cleaner renewable sources with some hope that they will be a part of the new prosperity as it develops.

There are a dozen or more books on the market now that provide prescriptions for achieving a transition to renewable energy within the next 40 years, but my favorite is Arjun Makhijani's "Carbon-Free and Nuclear-Free: A Roadmap for U. S. Energy Policy," published by RDR books. It is available at Amazon, or can be downloaded for free from <http://www.ieer.org/carbonfree/CarbonFreeNuclearFree.pdf>

Much of what I have said in my two posts on this thread is lifted from the pages of that book.

Contribution 6
It's amusing that the "renewable" people are just as "all or nothing" as the "fossil" people. That's why NOTHING is done.

Contribution 7
You wrote “One of the biggest asset of nuclear power during the transition period from fossil to renewable is HIGH DENSITY. The current energy infrastructure relies on siting power plants in high population/land use areas. Coal/gas/nuclear power plants can be sited on a couple square miles of land and produce 2000 MW of power.”

And that has meant that we have not built the smart power grid that we need for the 21st century, whether we do any conversion to renewables or not, and have subjected untold numbers of people to the radiation and pollution inherent in coal and nuclear plants, to say nothing of the dangers in storing nuclear waste on plant sites and coal ash in lakes like the one in TN that collapsed recently.

You also wrote “ It would take 4000 1.5MW wind generators to AVERAGE that much (with 33% operational efficiencies--with are typical) and you'd still have periods of no wind in the region. It will take decades to build up an infrastructure where HUGE wind/solar farms can produce, STORE, and TRANSPORT our total energy needs. The North-East (Boston to DC) is always going to be a problem area.”

I could point out that we once had hundreds of thousands of square miles under cultivation to produce hay for the horses that were our primary means of transportation, and 19th century environmentalists were afraid that cities like New York would be buried under and avalanche of horse manure.

Yes, wind parks and solar farms occupy large chunks of land, but they don't have to be dedicated to that use. Farming and cattle grazing can take place on the same land (under wind turbines at least--among solar panels is a bit more problematic). The wind farms east of San Francisco mix power generation and cattle grazing quite nicely, and have for nearly 40 years. And there is enough open parking area in this country to provide a good chunk of our electricity needs by covering them with solar panels (the parking lot surrounding the Pentagon in Washington, could by conservative estimate produce about 3300 MWh/month on a year-round average). In this country, we have between 10 and 13 parking spaces per car. It's time we used them for something more that leaf catchers during the fall. Offshore wind farms are better looking than offshore oil rigs, and can rely on much more predictable and constant wind sources. And while it is true that the wind doesn't blow all the time, so a windmill can typically produce only about 30% of its rated power on average (I note that both coal plants and nuclear plants operate at only about 30% thermal efficiency, and provide between 60% and 90% of rated power, on average), The wind is blowing *somewhere* all the time, and widely separated wind parks can, when interconnected, produce a combined output that is never below about 25% of rated power. (see: Louis Bergeron and Stephanie Kenitzer, "Study finds that Linked Wind Farms can Result in Reliable Power" <http://news-service.stanford.edu/news/2007/december5/windfarm-120507.html>; also Cristina L. Archer and Mark Z. Jacobson, "Supplying Base Load Power and Reducing Transmission Requirements by Interconnecting Wind Farms," Journal of Applied Meteorology and Climatology, Vol 46, November, 2007, pp. 1701-1717) There is enough potential wind energy off our coasts and in the Great Lakes to power the nation at present rates, and the central plains contain at least that much again.

Meanwhile, both solar PV and Concentrated Solar Thermal power farms are sprouting all over the Southwest, which contains as much potential solar energy as all the wind sources together. In other words, there is more than enough wind and solar energy to meet our needs, and it will occupy only a rather small fraction of our land area, and need not impact on agricultural land. The northeast (Boston to DC) can be powered by offshore wind as soon as we can convince Ted Kennedy to sell his yacht :-).

You also wrote " When my class does their energy project (supplying U.S. energy 100 years from now without the use of oil or gas) we don't allow any 'deus ex machina' solutions. We work with proven technology. It can be done, for 10s of trillions of dollars, and several hundred thousand square miles of land. But nuclear, 'clean coal', and as much hydro as possible are part of the program along with hydrogen as a storage medium and portable fuel. What can be done in the U.S. can be more difficult elsewhere. Japan for example has land problems. They really need some high density energy sources."

"Clean Coal"??? And you don't use "deus ex machina" solutions? If there was ever an oxymoron, "clean coal" is it. We have no idea if we can even capture a significant fraction of the CO2 emitted by a coal plant, or what the cost would be, and no one has a clue if any practical form of storage is or ever will be available for the CO2. It will need to be at least as long-term secure as nuclear waste, and there will be a lot more of it. Such a process is at least 20 years away from any possible practicality, and doesn't begin to deal with the severe environmental problems with every form of coal mining, especially the "mountaintopping" variety that is turning West Virginia into an extension of the great plains, without the grass.

If we can learn how to ship electric power halfway and more across our country, the rest of the world can learn how to ship power internationally (we can too--sending power to Canada and purchasing power from Mexico). North Africa can provide all of Europe's needed electricity, and China could supply Japan. I have seen a computer simulation developed by a team of German engineers that shows how Japan could power itself with renewables successfully. The simulation takes into account time of day outputs and local weather conditions. They show that Japan has the potential to produce at least enough to power its current needs, without taking into account any possible efficiency improvements.

The point here, of course, is that if we keep thinking up reasons why something won't work, we will never solve the climate problem. Creative, but level-headed thinking and planning is needed, here and abroad. My sense right now is that much of the rest of the world is well ahead of us in both.

Contribution 8
You wrote: " President Obama's Secretary of the Interior announced today that the use of wind energy on the east coast could replace all the coal powered electrical power plants in the US. When asked how many windmills would be required he said "I haven't done the calculation yet". Good grief!

Obviously that answer depends on what size wind turbines will be used, how much space is available and how close to shore they can be placed. His statement obviously spoke to the wind potential in that area, and it is certainly true that there is more than enough wind power potential to provide the electrical needs of New England, but how it is to be done is a complex issue with scientific, engineering, aesthetic and political ramifications, as you pointed out, although I think Ted Kennedy can be brought around, and I thought I'd heard that a judge had already overruled Ted's objections and the plans for the Cape Cod wind farm were going forward.

As with everywhere, there are potential problems with offshore wind farms in that area, primarily because of the weather. I don't have a good feel for how large wind turbines (5 MW and up) handle gale force winds or higher, but if they are going to have to be replaced too often due to wind damage, that makes New England offshore electricity less attractive. The same problem exists on the mid-Atlantic coasts due to hurricanes. I doubt anyone has done the calculations yet.

Contribution 9
You wrote: "It's amusing that the "renewable" people are just as "all or nothing" as the "fossil" people. That's why

NOTHING is done."

If my only choice was coal or nuclear, I'd take nuclear. Coal is worse, except for the proliferation problem and the fact that nuclear waste lasts so bloody long and is so dangerous. But the damage coal is doing right now is definitely worse and in the immediate future, nuclear could be tolerated if it was the only choice.

Fortunately, we don't have to make that choice. The renewables are ready now, can be done incrementally so the effects can be seen almost immediately. I don't need all 1000 MW of my wind park installed before I can get the first watt out of it. Same with Solar PV and even some types of CST. Nuclear plants are going to take upwards of 10 years to get anything, and that is just too late. But the renewables do need to be accelerated even more. The sooner the better. If GM wants something to do between trips to Washington to beg for more handouts they could convert some of their idle auto plants to building wind turbines (the engineering is similar--a wind turbine is just a big transmission). Or maybe the folks at Chrysler could get a handout or two if they agreed that that would be a better investment than more cars that won't sell. Also wind turbines don't require specialized training to meet the special safety requirements that nuclear plants do, so the labor force is there essentially now.

Also fortunately, the debate over nuclear is mainly ideological. There will be few if any new nuclear plants built in this country--they're just too expensive. $10-$12B per reactor are the numbers that we are talking about here in the Southeast, where compliant legislatures and utilities commissions are falling all over themselves to approve whatever the local power companies want. But once the bills start coming in, I rather think that most of them will be cancelled, leaving the rate payers holding the bag, while the power company execs take the money and run.

But NOTHING is not what is being done. Wind and solar are building apace, and coal plants are being cancelled all over the place. As soon as the power company folks realize that nuclear isn't sexy any more, they'll quit driving for them, too.

I certainly agree that there is a group of anti-nuclear types who are ready to go back to ox-driven grist mills to avoid the possibility of a nuclear plant. But they are a small, if noisy, minority. I'm sure that there will be a few new nuclear plants started. Whether any of them is ever finished remains to be seen.

Contribution 10
Calculating the "wind resistance" of current ones, I think is an easy engineering exercise. The blades are made to be completely feathered already?

Contribution 11
You also wrote " The point here, of course, is that if we keep thinking up reasons why something won't work, we will never solve the climate problem. Creative, but level-headed thinking and planning is needed, here and abroad. My sense right now is that much of the rest of the world is well ahead of us in both."

It is not a case of thinking up reasons 'why it won't work', but rather trying to be realistic about what it is going to take TO make it work.

OK--'cleaner' coal, if you wish, but with one of the world's largest supplies, coal (as clean as we can make it) is very likely to be part of our near future (next century) energy supplies. With the inevitable phasing out of oil and natural gas, the net environmental problems of coal can be minimized. Together with some nuclear, coal can provide the high-density power source that will be needed in _some_ locations. It too can be phased out, but to do so that big IF about shipping power across country (say North Dakota to New York) has to be solved, a national (international if you wish) grid has to be designed and implemented--(that cost is almost never included in 'renewables' estimates)--or we really would need to develop something like Fusion power.

There are several things to include in discussing using wind and solar for the major fraction of energy needs:

1) As you phase out fossil fuels, you then move many energy demands from 'chemical' to electrical. Heating and transportation energy must now come from the renewables. Biomass could only handle a fraction of the transportation

fuel needs--we just calculated (for our project) that 3% of the energy needs in 2100 in the form of biodiessel (from soybeans) and ethanol (from switchgrass) would require 150,000 square miles of land use. If we can back off of oil soon enough, then perhaps some specialized needs--big rig trucks and aviation might still draw from remaining petroleum reserves. The big point here is that the electrical demand could triple without oil and natural gas, and then if you want to eliminate coal, the numbers become daunting.

2) The population (U.S.) is going to continue to increase. Can we hold the population down to say 450 million by 2100? That will take some aggressive work in immigration policy. If the country keeps adding a million or more immigrants a year, immigrants with traditionally higher fertility rates than the 'native' population, and generally more religious attitudes against birth control, 450 million would be a very low estimate. So lets assume at least a 50% increase in population.

3) Efficiency and conservation can certainly lower energy needs. 25% proves difficult (for my classes) to fully quantify, but that should be possible and maybe a bit better. However, with the population growth it means the overall energy demand will increase and with the reduction or elimination of most 'chemical' energy sources, the demand for electricity rises sharply.

4) So what's a 'reasonable' estimate of yearly energy demand in 2100? We work with 20,000 TWh or a power demand of 2.3 TW. What do such huge numbers really mean? IF--you wanted to run the country on wind (assuming you had a grid and had generators spread so that you could guarantee the 25% availability at all times (according the Hugh), then using 1.5MW generators (pretty much the standard although bigger ones are available) you need over 6 MILLION wind generators. In a more realistic system, without any fossil fuel, you might split up the demand, but you can't get much more than 3% from Hydro (and the environmentalists want to dynamite all the dams anyway), maybe 3% from geothermal, might push 10-12% from biomass, but then you have to split the rest--over 80% between wind and solar. Without coal and nuclear--this is huge.

5) Effective use of solar (and to a lesser extent wind) will most likely require storage techniques--maybe electrolysis to hydrogen--to assure an 'energy on demand' network. Whatever the storage and distribution system, it will cost some big bucks. We've estimated about $5 trillion for a hydrogen capable pipeline distribution system.

6) Cost estimates have to account for the likely shorter lifetimes of wind generators and some forms of solar (PV panels) compared to fossil/nuclear plants (about 75 years) and dams (100 years or more). We don't have enough experience to know the replacement rate for large wind generators, but it is likely to be at least twice that of current plants--this increases the cost above those normally estimated for the switch to renewables. Again, such estimates are just to be somewhat realistic about the task--not to dismiss it.

****

To repeat what we do in my energy class--a MODEL of energy distribution for 100 years in the future (one that still uses coal and nuclear but is heavy on wind and solar) costs out at $30-50 trillion--capital costs-- and uses about half a million square miles (much for biomass) of land. What these numbers say, to me, is that this is not a 10 year, 20 year, or barely a 50 year project. To be affordable, the transition must be stretched over a century time frame. However, clearly we need to start now (we are starting now) and will have to ramp up the transitions, but thinking we can eliminate the fossil fuels in a couple decades is, IMO, delusional.

Contribution 12

You wrote “I disagree with your analysis. By not charging the rate-payers for the external costs, you reduce the incentive to conserve. Thereby driving the cost up for everyone. Here in southern California we have tiered rates for residential electric consumption to encourage conservation.”

US energy policies have led to profligate consumption of energy. We have about 5% of the world's population, yet we consume 25% of the world's energy resources.

I get really tired of this one as well--(and the percentage is falling quickly as China rapidly moving to become king of the energy use hill). Our energy use per person is about the same as Canada and Australia. Not too far above

Germany. Big, developed nations, use energy. Its why they are developed. The larger the physical size of the country, the more energy necessary to move people and goods. The more industry that resides within the country, and the more that raw materials are mined, processed, and used within a country, the higher the energy use. Switzerland seems to use no energy--but it lives off the energy burned in France, Germany and Italy. You also have population density and (more to your point) life-style differences. If all Americans would put their family of four into a 1000 square foot apartment, with that apartment stacked on top of and surrounded on all sides by other such apartments--sure the energy usage would drop. Yes, we can use less energy--but I repeat that reducing by more than 25% is tough. As a country of 300+ million people, stretching 3000 miles coast to coast and 1000 miles border to border, with (still) the biggest economy in the world and a 21st century technology, the U.S. does not do all that bad. The problem is really not that the U.S. uses too much energy (OK, a little too much), it is that the rest of the world uses too little to provide a 21st century living standard to their people. The comparison to be made is between the developed world and the 'third world'--average out the variations for population, area, population density, percentage of 'home grown' economy versus imported resources and then do your comparisons. Spare us, please, from the 5%--25% mantra. It really is not useful.

Contribution 13
Here in the U.S. we use 67% more energy per person than the average of the top 18 developed countries.

Canada comes close, but most developed countries use much less energy per person than we do.

http://www.nationmaster.com/graph/ene_usa_per_per-energy-usage-per-person

China and India are using more energy as they develop, but don't come close to any of the developed countries in energy use per person.

Contribution 14
You wrote: “Calculating the "wind resistance" of current ones, I think is an easy engineering exercise. The blades are made to be completely feathered already?”

It isn't the steady winds that I worry about. A feathered blade can handle a substantial wind speed. I've flown around in airplanes with a propeller or two feathered at speeds up to 250 knots with not problems. What I don't know is how well a turbine blade that may be as much as 30 meters long would handle gust loading that could easily be non-constant over that dimension, if the hub structure could be damaged by violent slewing as the wind gusts changed direction quickly.

I also worry about how well the foundation structure would withstand the storm surge. I heard of massive oil rigs being destroyed during some of the really bad storms in the North Sea, and I don't think a hurricane would be any easier on a wind turbine tower.

I'm sure these can be handled by competent engineers, but at some point the additional cost of making them strong enough to withstand a Category 4 or 5 hurricane may run the cost up to the "not worth the effort" level.

Offshore wind turbines are already significantly more expensive than on-shore ones, and having to replace them before their design lifetime due to wind damage doesn't make them any easier a sell.

Contribution 15
It's nice to see a reasonable approach championed. Alternate energy sources are "alternate" because they are not quite ready for prime time. We have an absurdly large supply of ridiculously cheap coal (sorry - I'm not swayed by arguments of "true" cost). It is national economic suicide not to use this supply. Clean it up - do whatever will lessen its environmental impact - but use it. Many "alternate" sources can be refined to the point where they will eventually make economic sense. Wind power NEVER will. No one wants wind farms near them. They may look wonderful to an environmental activist, but to most sane people they are just plain ugly. When even the East coast liberals won't live next to them you know you have a problem. When I fly to California every couple of years and look at the windmills outside of Vacaville blighting those beautiful California hills I get angry enough to almost start shaking. What idiots

would do that to such magnificent countryside?

Centralized power from nuclear and coal feeding in to grids leaves the rest of the land available for our use and enjoyment. Solar and wind sources in diffuse arrays that are everywhere in sight are too big a price to pay for a supposed couple of degree warming from models that can't even hindcast.

Contribution 16
I haven't read every post on this thread, but there are two potential energy sources that seem to always be overlooked. One is OTEC (Ocean Thermal Energy Conversion); energy produced by using the temperature differential in the deep oceans, and the other is tidal (think underwater "windmills"). One of the biggest problems with energy generation/usage is transmission and storage, and these impact greatly on OTEC.

Contribution 17
You wrote “The problem is really not that the U.S. uses too much energy (OK, a little too much), it is that the rest of the world uses too little to provide a 21st century living standard to their people.“ That, of course, begs the question "What is the right amount of energy use?" and the related question "Where will we get that energy?"

I would propose that the answer to the first question is "As much as we can sustainably (100+ yr time-scales) produce." The goal SHOULD be to raise up the per capita use for those who do not enjoy the benefits of energy use, not to cut back those who benefit from the advantages of energy use.

Of course, "sustainable" must also include the ecological effects - pollution, global warming, destruction of habitat, etc. It could even include aesthetic factors (like power lines or pristine wilderness or skylines) or political factors (like handling of nuclear waste or concerns over weapon-grade nuclear fuels).

Unfortunately, I don't see any real answers that don't involve some rather drastic choices - most of which come down to population! From what I can figure out at current rates:

* We do not have 100+ yr reserves of fossil fuels (and there are global warming concerns) * We do not have 100+ yr reserves of uranium (and there are disposal concerns) * We do not have 100+ yr reserves of copper (to expand distribution and to build several 100,000 generators for wind turbines) * We do not have enough land to grow food AND biofuels to replace petroleum. (And even current agricultural practices are not sustainable in many areas).

Solar holds promise it seems (it requires vast land, but the sun should keep shining for well beyond 100 years!), as do geothermal and energy from the oceans.

It looks like we need to (or will be forced to). * cut back on energy use * expand the few truly sustainable sources that can deliver huge quantities of energy * find completely new sources (fusion???) * decrease the world population. Am I missing something?

Contribution 18
You asked “Am I missing something?” Yes, choice (e) all of the above!

Contribution 19
You wrote “ Wind power NEVER will. No one wants wind farms near them. They may look wonderful to an environmental activist, but to most sane people they are just plain ugly.”

For what it's worth, I actually think that windmills look incredibly cool. That said, it will take several states worth of land to get enough solar and wind energy to start replacing many coal, natural gas, and nuclear power plants.

However, we already blot the views of several states with farms. The Central Valley of California should be a lovely desert but it is filled with ugly canals and hideous fields of food, looking totally unnatural. Don't think I'm crazy that

most farms look terrible. Most do not look like calendar pictures or gardens, especially after harvest. They smell bad too, not even counting the livestock.

Why do people put up with it? Well, we like to eat what we like to eat.

And I love my computer and the electricity that runs it.

Contribution 20
Wassa matta? You think the California hill sides are somehow better or more deserving than the W Virginia mountains? Or... maybe you just think the California *people* are better or more deserving.

Quite aside from environmental concerns or what is done to "magnificent countryside," I seriously doubt, for example, just for starters, that any California family's cemetery has been dug up, moved, and then lost, by a stupid windmill company.

Don't get me wrong, I'm all for using the coal as well, but... gimme a break. At least find a different point to argue.

Contribution 21
You wrote “What we can do is find ways for people around the world to generate enough energy to improve their standard of living ...” Can we indeed do this??? I certainly hope so, but it will take some MAJOR changes.

Planetary-scale energy needs will only be met by "harvesting" energy
from planetary-scale sources:
* energy from the earth (geothermal)
* energy from the sun (including wind and biofuels)
* energy from the moon (tides).
* energy from atoms (fusion - not fission because we don't seem to have
enough U)

Until we start thinking on these scales, we are thinking too small! Furthermore, these are mostly diffuse sources, so storage & transportation on a global scale become an issue too. If we do not figure out how to (or develop the will to) harvest these sources on these scales, civilization will not continue as it is.

Contribution 22
Just because people have had to suffer because of property rights abuses in one region is no reason to continue the practice and spread the abuse to other areas. Whenever people justify stomping on individual rights because of the "common good" (read mineral rights) there will be wholesale abuse.

I don't want to look at windmills while enjoying the beauty of Martha's Vineyard, and I doubt if West Virginians enjoy seeing the tops of their mountains sliced off to expose coal. I totally agree with your point that coal production has produced much greater ugliness than windmills have so far. We have the technology to stop these desecrations. Oil companies have figured out ways to let one platform gather oil from many sources miles away.

The remedy to the coal abuses is to have West Virginians and the state of West Virginia sue those companies that lower people's quality of life - and to keep suing until until it becomes more profitable for coal companies to take more responsible approaches. Courts need to review the whole concept of mineral rights in a country that is no longer predominantly wilderness. Northeastern states have taken such an approach with Midwestern power plants that spewed pollutants that were carried to them by the wind.

Environmentally friendly coal production will cost more - but we can't turn our back on such an abundant source of energy. Neither can we just ignore the abundant oil off our coasts. Coal and oil make more sense than seeing windmills everywhere one looks.

Contribution 23

Question 1 -- what percentage of energy supply is domestic?

Question 2 -- what percentage of our GDP is production and what percentage is consumption?

Contribution 24
For answers and more data, please see my PowerPoint I use in my energy course...
http://www.phy.ilstu.edu/~marx/phy207/High_Energy_Society.ppt

Contribution 25
Here's a sad but interesting story. A few years ago we came pretty close to getting a 3MW Vestas wind turbine for Bluffton University. I was one of the persons pushing for this, and I was appointed to the planning committee. We did a preliminary study and found we had a good site with reasonable wind. We found a group of investors willing to loan the whole amount as a capital loan at a reasonable interest rate.

Our regular source of electricity is American Electric Power (AEP), which in our area is 90% coal and 10% nuclear, and our rate is about $0.07/kWhr. We had two options for using the electricity from the turbine...

(Option 1) We could sell it to AEP for their generation cost of about ($0.02/kWhr) and then buy it back at $0.07/kWhr, thus saving $0.02/kWhr. We estimated a 10-year payback period doing it this way. This would be easiest to implement because we wouldn't need a substation/switch to use AEP as campus backup when the turbine isn't enough.

(Option 2) Install a substation/switch that would allow us to use the electricity directly (saving $0.07/kWhr on what we use, and selling any excess to AEP at $0.02/kWhr), and also be able to supplement the turbine from AEP (at $0.07/kWhr) when the wind was too low or the turbine was down. This was more difficult for determining the payback period because it's difficult to determine how often we would have electricity to sell to AEP as opposed to needing to supplement the turbine by purchasing electricity from AEP. Our estimate for this was about a 3 to 6-year payback.

Either option seemed like a no-brainer, we had a lot of community support, and I thought we were going to do it. But the best site on campus was west-southwest of the intercollegiate soccer field and baseball field. The athletic department reasoned that late afternoon sun coming through the turbine blades would cast flickering shadows on the playing fields during games. That killed the program. The fear that an athletic event would occasionally get flicking shadows during a game killed what would have been an excellent investment in alternative electric energy for the university.

Since that time we have had a change in the administration, and I am trying to rekindle interest in a turbine, but movement is slow.

This is just one example that shows how difficult it can be to use "alternative energy" even in situations for which the economics looks quite favorable.

372) Useful references for users of CR-39 chips

Ludwik Kowalski
Montclair State University, Montclair, NJ, 07055
April 13, 2009

1) g) Energy distributions of alpha particles from Am-241, after they traverse mylar filters of several thicknesses, are reported (by Jan Jakubek) in

http://aladdin.utef.cvut.cz/ofat/Methods/HeavyParticles/index.htm

Figure 1, extracted from this reference, shows, for example, that after traversing 24 microns of mylar the mean energy is still 2.2 MeV. The distribution of energy is nearly gaussian. Jakubek's Figure 2 should also be very useful.

= = = = = = = = = = = = = = =

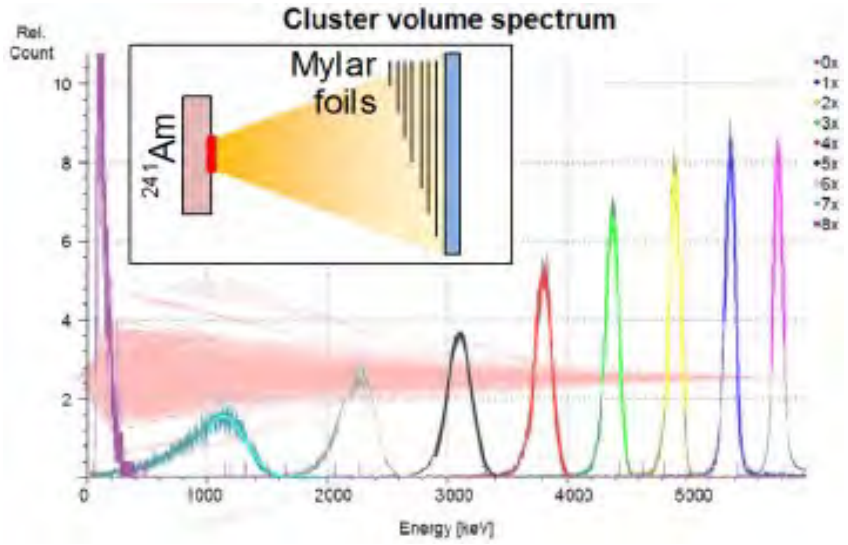

Figure 1

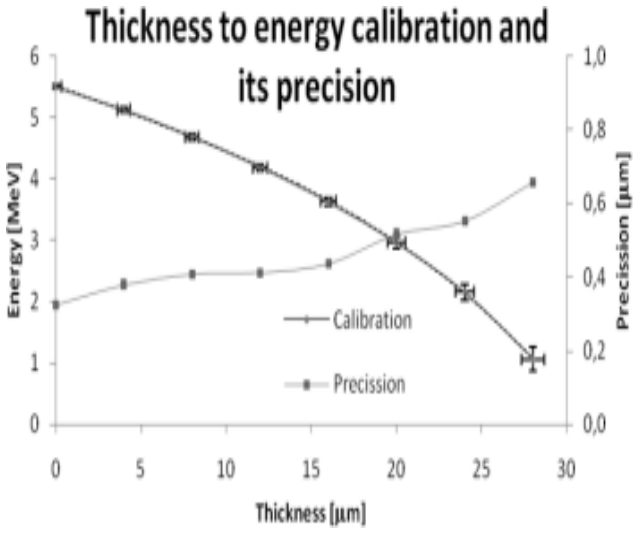

Figure 2

******* Mylar films can be purchased at a company called "spi supplies" *******

P.O. Box 656
West Chester, PA 19381-0656
USA

tel: (800)-2424-SPI or (610)-436-5400
email: spi3spi@2spi.com

It is called XFR Thin Mylar Support Films (for X-ray spectroscopy)

A spool of 6 microns (3 “ wide and 92 meters long) costs $73

********** They also have 3.6 and 2.5 micron mylar **********

2) Those of us who work with CR-39 detectors should not forget about a powerful particle identification toll developed by Russian researchers. SPAWAR team is using this tool by observing how diameters of pits grow when the etching time is increased. A detail description is in two papers that A. Lipson et al. published, in the proceedings of our Catania conference (pages 163 and 182). I used their data to construct turves in Figure 3. Hopefully, this will be useful to some researchers.

= = = = = = = = = = = = = = =

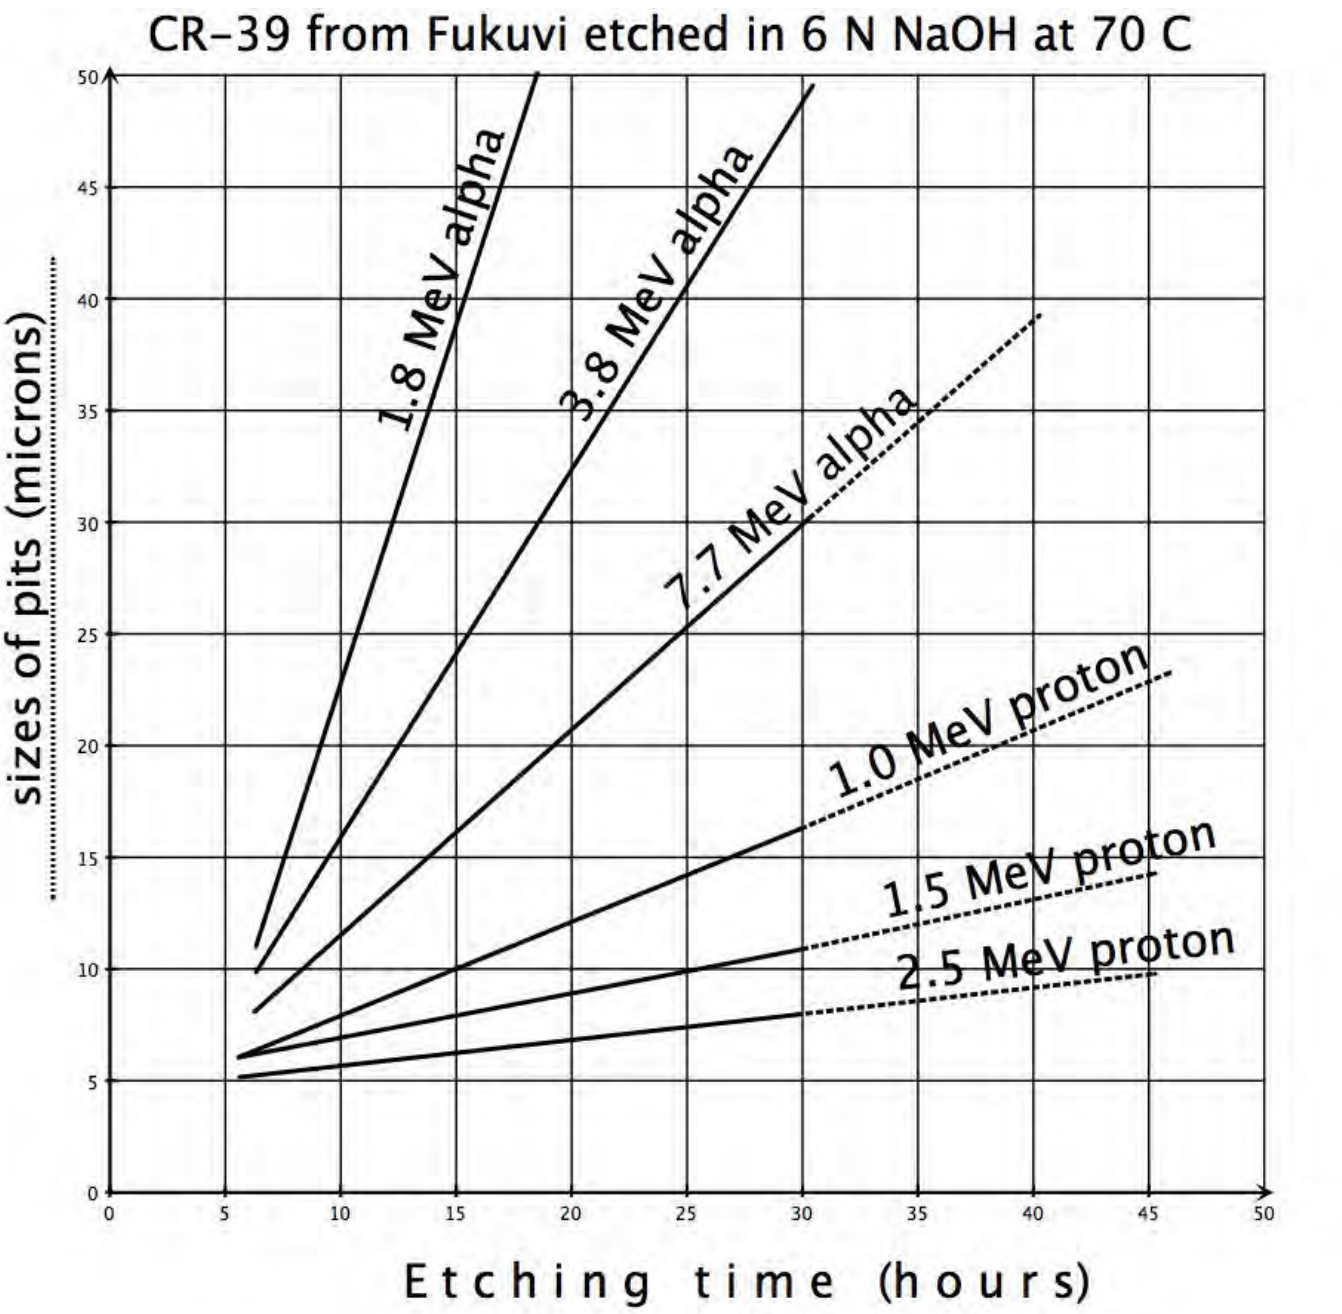

Figure 3

3) Someone wrote that alpha particle pits might have different sizes on CR-39 chips from different manufactirers. I have no experience with chips from manufactures other than Fukuvi. A little corner of each of my chip is always irradiated with alpha particles. And I always look at this corner, to make sure etching was succesful. A big change in size, for example by a factor of 1.5 would probably be noticed. I do not recall any big changes in sizes. Replying to the posted message I wrote:

“One thing that might produce Am-241 pits of different sizes on CR-39 from the same manufacturer (and from the same batch) are different average etching temperatures. I also suspect that an etching solution looses "potency" in time. My etching solutions are always stirred, to make sure the temperature is uniformly distributed within the beaker on the hot plate. I am sure you do the same , or something equivalent. ..... By the way, I suspect that an etching solution looses "potency" in time. My etching solutions are always stirred, to make sure the temperature is uniformly distributed within the beaker on the hot plate.”

4) Another CMNS researcher responded: “ It is correct that an etching solution can lose potency over time [especially if kept in an open beaker] many days. When NaOH etchant is exposed to air, carbon dioxide from the air reacts with NaOH to make sodium bicarbonate NaHCO3. As this reaction proceeds the concentration of NaOH falls and the etchant becomes weaker. Holding other parameters such as time, temperature, and stirring constant the pit size that is reached in an experimental measurement becomes smaller. If one wishes to establish a reproducible correlation between particle energy and pit size, full strength etchant must be used for each measurement.”

5) Range energy curves,for example for alpha particles, seem to be very different for different materials, such as air, polyethylene, aluminum, or iron. But this is true only when ranges are expressed in units of distance. Express ranges in terms of mg/cm^2 and curves become very similar, especially when atomic numbers (Z) are not very different. This is illustrated below.

```
10 MeV alphas in gold: R=45.5 mg/cm^2
6 MeV alphas in gold: R=22.8
5 MeV alphas in gold: R=18.0
4 MeV alphas in gold: R=13.6
3 MeV alphas in gold: R=9.6

10 MeV alpha in nickel: R=22.6 mg/cm^2
6 MeV alphas in nickel: R=10.9
5 MeV alphas in nickel: R=8.5
4 MeV alphas in nickel: R=6.4
3 MeV alphas in nickel: R=4.5

10 MeV alphas in aluminum: R=16.5 mg/cm^2
6 MeV alphas in aluminum: R=7.5
5 MeV alphas in aluminum: R=5.8
4 MeV alphas in aluminum: R=4.2
3 MeV alphas in aluminum: R=2.9

10 MeV alphas in carbon: R=12.4 mg/cm^2
6 MeV alphas in carbon: R=5.4
5 MeV alphas in carbon: R=4.1
4 MeV alphas in carbon: R=2.9
3 MeV alphas in carbon: R=1.9

10 MeV alphas in hydrogen: R=4.19 mg/cm^2
6 MeV alphas in hydrogen: R=1.70
5 MeV alphas in hydrogen: R=1.24
4 MeV alphas in hydrogen: R=0.85
3 MeV alphas in hydrogen: R=0.53
```

A range-energy distance for aluminum, for example, can be used to predict how the energy changes as a function distance in mylar or iron, provided high accuracy is not needed.

To covert cm into mg/cm^2 one must know the density of the material. The density of aluminum is 2.7 g/cm^3. That means that 1 cm of aluminum translates into one gram per square centimeter, or 1000 mg/cm^2. The density of mylar is 1.39 g/cm^3. That means that 6 microns of mylar translates into 0.83 mg/cm^2. A thickness of a thin foil (actually it is its surface density) can be calculated my dividing its measured mass by its measured area. This is often more

accurate than using a mechanical micrometer.

6) How does the size of a pit, due to an alpha particle, depends on the etching temperature of the 6.5 N NaOH electrolyte? My alpha particles were from an Am-241 source removed from a smoke detector. I do not know what the energy was, after particles traversed a layer of something that prevents contamination. It is probably 3 MeV or 4 MeV. To make my data useful at any energy (between ~3 MeV and ~ 8 MeV), diameters of pits are expressed in arbitrary units. The diameter at 60 C is 1 unit, be definition, after 12 hours of etching.

temp=60 C ---> diameter=1.0 units after 12 hours
temp=65 C ---> diameter=1.8 units after 12 hours
temp=70 C ---> diameter=3.1 units after 12 hours
temp=75 C ---> diameter=4.3 units after 12 hours

7) It would be interesting to know (in light of what was stated in point 4 above) what the effect of potency (concentration) of the etching solution is. Perhaps I will investigate this, if necessary. But here is a bit of useful information. One of the researchers who replicated a SPAWAR-type co-deposition experiment, under The Galileo Project, was Winthrop Williams. His CR-39 calibration chip, exposed to alpha particles of 5.45 MeV, was examined by Russian Scientists: A. Lipson, A. Roussetski and E. Saunin. I am reading their 2007 report, in Proceedings of our Catania workshop (page 163).

Williams' chip was etched in NaOH solution of 6.5 N (for 3 hours at 68 C). Russian scientists also irradiated their CR-39 chip with alpha particles of 5.45 MeV. But their etching conditions were different (6 N NaOH, for 7 hours, at 70 C). In both cases CR-39 was from Fukuvi. The pits on the Russian chip were found to be larger than pits on the American chip. That is not surprizing, considering a large etching times difference. What is surprizing is that less than 2 hours was needed to compensate the etching times difference of 4 hours. By the way, Russian scientists did not study the effect of concentration of the NaOH sulution; additional etching for 1.75 hours was necessary to start sequential etching when mean sizes of pits, on chips to be compared, were identical.

To study the effect of the NaOH concentration, one can perform the following experiment. Two Fukuvi chips are exposed to alpha particles of the same energy. Then they are etched in the same oven, for example at 70C, for exactly the same time, in two freshly-made etching solutions, 6.0 N and 6.5 N. I have no doubt that pits etched in the more concentrated solution will be larger. But I have no idea by how much.

8) Referring to 4, one CMNS researcher wrote: "You should be using fresh NaOH solution for each etch. We found close-fitting test tubes that enabled us to use only a few mL of fresh etchant for each CR-39 chip." They probably have an oven with a thermostat, or perhaps tubes containing the etching solution are immersed into a beaker with water, which is standing on a hot plate.

9) I wrote: "Another possibility is to accumulate several CR-39 chips (keeping them in salty water, rather than in air) between the end of electrolysis and etching. That what I am going to do this summer. Following Oriani's protocol, I always drill a little hole in each chip and suspend chips in the stirred etching solution. That would really be essential if the goal were to compare sizes of pits on different chips.

In order to compare experimental results from different labs (I am still hoping for phase 2 of The Galileo Project), the etching temperatures must be specified to within 1 degree or so. The hot plate I am using does not allow me to do this. How precise are typical ovens in chemistry labs? Etching for 12 hours at 70 C would produce much larger alpha pits than etching at 65 C (see unit 6 above).

373) The Curie Project

Ludwik Kowalski

Montclair State University, New Jersey, USA
June 22 , 2009

1) Introduction

History of my CR-39 cooperation with Richard Oriani is summarized in unit 369. The beginning of The Curie Project is described in unit 368. At the end of this unit I plan to show results from that cooperative project; I hope they will be available in September, before ICCF15 (15th International Conference on Cold Fusion in Rome, Italy).

INSERTED ON JULY 17, 2009

As indicated in the title, this unit was created for reporting anticipated experimental results. But I changed my mind; results will be shown in a later unit. What follows are selected messages posted on the private Internet list for CMNS researchers.

= =

2) Another appeal to CMNS researchers

Here is a message I posted (6/24/2009):

‘1) As I wrote earlier, The Curie Project is in progress. But it has only three participants (from the Phys-L list for physics teachers), plus myself. We are using Oriani's protocol; it is described in his ICCF14 contribution.

http://pages.csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

The only two departures from the protocol are:

a) Keeping chips in salty water, when they are waiting for electrolysis and when they are waiting to be etched. Richard wrapped them in Al and kept them is air.

b) The rear side of a chip, during electrolysis, is protected from being in contact with air (by a ~0.5 mm layer of polyethylene). Richard did not protect the rear surface from air. The project desperately needs more participants; it is not too late to join us.

2) Here is a summary of Oriani's results; this does not include nine recent experiments. These experiments will be counted as his contribution to The Curie Project. Richard is using the same CR-39 I am using (we bought one Fukuvi sheet together, two years ago). Not surprisingly, his mean background, measured 13 times, is nearly the same as my background, measured 6 times (so far). His mean background was 13.6 tr/cm^2; his standard deviation was 6.8 tr/cm^2 (as shown in Table I). My mean background was 13 and my standard deviation was 5.

a) Richard’s post-electrolysis chips had tracks on both surfaces. His Table II shows results from 22 experiments (#4, #5, #6, ...#25). As you can see, results differ very significantly from one experiment to another. But 40 out of 44 surfaces had track densities higher than 16 tr/cm^2. In other words the number of post-electrolysis tracks exceeded the

number of background tracks in 90% of cases. That is remarkable.

b) Let me summarize Oriani's results in terms of mean values and standard deviations.

Front surface (facing the electrolyte) mean=142; st. dev.=146
Rear surface (facing away from the electrolyte) mean=132; st.dev.=148

The lowest density was 9 and the highest density was 498 tr/cm^2. In one case the number of tracks was too high to count; I tentatively turned this into 498. The two distributions are very wide. But the mean track density on each side of the post-electrolysis chip, is about ten times higher than the mean density on control chips. This includes the four cases in which the densities were only 9, 9, 11 and 16. The distribution of track densities, on 44 surfaces of post-electrolysis CR-39 chips, is shown in Figure 1 below.

Figure 1 (373histogr.png)

Why is the histogram so strongly skewed? I am not at all comfortable with the fact that the overall mean, 147, and the same as the standard deviation. Yes, 147 exceeds the background by one order of magnitude. But the level of confidence that this would be confirmed in another set of 22 experiments is very low. I was trained to believe that, in order to be taken seriously, a difference between a signal and a background should be at least as large as the sum of standard deviations (of the signal and the noise), preferably two or three times larger. On the other hand the above curve shows that densities exceeding the background are not at all rare. Is there a better way to evaluate a level of confidence than standard deviations? '

3) Categorical data

Suppose Richard's data are used to answer simple "yes" or "no" questions. The questions would be:

Is it true that track densities are higher than mean background?
Is it true that track densities are higher than 69 tracks/cm^2?
Is it true that track densities are higher than 140 tracks/cm^2?

Richard asked the first question 44 times and the answer was "yes, it is true" was obtained 40 times. On that basis one would be able to say that f=40/44=0.91 represents the expected probability that the statement is valid. In other words, 91% of CR-39 surfaces, in another sequence of identical 22 experiments, are expected to validate the statement (that the signal is higher than the background).

This kind of predictions is common. Here is a typical illustration. Suppose a random sample of n=10 people was selected in a town. Six of them speak Spanish. In this case the answer is either "yes" or "no." A fraction f=6/10=0.6 is calculated on the basis of this small sample. How reliable is the statement that "about 60% of people, in this town, speak Spanish? " The answer depends on the value of f, and on the size of the sample. The distribution of f, from many samples of size n, is expected to be nearly Gaussian, when n>20 (actually, a it is already nearly Gaussian at n=10). The width of the distribution of fractions (actually the standard deviation of f) is expected to be equal to sqrt [f*(1-f) / n].

The uncertainty about the expected 91% reproducibility, in subsequent sets of similar 22 experiments, the standard deviation s=sqrt [f*(1-f) / n] = sqrt [0.91*0.09/44]=0.043. Subsequent sets of experiments are expected to produce values of f that are between 0.91-0.043=0.877 and 0.91+0.043=0.953 (two standard deviations). The theoretical reproducibility of nearly 91%, based on real experimental results from one set of 22 experiments, is a rather convincing argument for the claim. That "more than background" claim, however, is not very strong.

So let us make a stronger claim, for example "more than 69 tr/cm^2, as above." Richard reported 25 such outcomes out of 44 measurements (f=25/44=0.57). Thus only 57% of sets of replications are expected to support this new claim. The predicted reproducibility for evan stronger claim, "more than 140 tr/cm^2" is considerably lower than 57%. All this is intuitively obvious; stronger statements, based on the original set, are less likely to be supported (by results from

subsequent sets of 44 measurements) than weaker statements. But thinking in terms of standard deviations of fractions might be helpful. I am learning this from an elementary statistics textbook. According to the "central limit theorem," the distribution of mean values, from several sets of experiments, is Gaussian, even when distributions from individual sets are not bell-shaped.'

4) Ludwik's message posted on CMNS list (6/28/2009)

"The attached histogram [see Figure 1 above] is based on Richard's Table II in

http://pages.csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

It has 11 bins and bins are populated with the following numbers of observations:

14, 10,, 6, 3, 3, 1, 1, 1, 1, 1, 1

The purpose of The Curie Project is to verify Richard's results. He examined 42 surfaces and measured track densities on them. Suppose several people also measure track densities on 42 surfaces, from their own sets of experiments. The histograms would be quite different. This is intuitively obvious, considering small numbers of observations (see above). I verified this by simulating replications with the Monte Carlo method. To accomplish this I simply assumed that the true distribution (one that would be obtained if thousands of surfaces were examined) is the same as Richard's distribution. Below are results from my first five simulations. Each line is a set of numbers to plot one histogram (and to calculate its mean value). The last numbers, after the asterisk, are mean track densities for the five histograms.

19, 7, 8, 8, 0, 0, 0, 0, 0, 0, 0 * 106
14, 16, 2, 3, 4, 3, 0, 0, 0, 0, 0 * 121
9, 11, 7, 7, 4, 0, 0, 0, 3, 0, 1 * 164
21, 7, 0, 8, 3, 0, 0, 3, 0, 0, 0 * 126
11, 8, 6, 0, 2, 0, 4, 0, 0, 1, 3 * 187

The distribution of mean density, from 1000 simulated histograms turned out to be bell-shaped; the mean of means was 154.5 tr/cm^2; the standard deviation was 18 tr/cm^2. Individual histograms are strongly skewed but, according to the Central Limit Theorem, the distribution of the mean of means should be Gaussian. My Monte Carlo simulations confirmed this. And they provided a qualitative definition of "success," for The Curie Project.

The purpose of that project is NOT to replicate the shape of Richard's histogram; it IS to show that the mean track density, on post- electrolysis chips, is not very different from his value of ~140 tr/ cm^2. What does it mean "not very different" ? The difference should not be larger than two standard deviations (2*18=36). In other words, any mean density, between 140-36=104 tr/cm^2 and 140+36=176 tr/cm^2, would be consistent with Richard's result, provided tracks on many surfaces are counted in The Curie Project. That is why additional participants are needed. It is not too late to become a participant. Comments and suggestions will be appreciated."

5) How to mount electrodes

The attached figure shows (very schematically) how to make a cell without a titanium rod in a guiding glass tube (see Oriani's illustration). My cell is open and the rigid column slides into it.

Figure 2 373column.png

6) My CR-39 Chips for measuring background

Each of my post-electrolysis chips has a matching control chip--it is kept in the unused electrolyte during electrolysis. In additions to this, one control chip will be mounted inside the electrolytic cell in exactly the same way as it is during electrolysis, including the position of electrodes. But electrodes will not be connected to the power supply, as Richard did. This test will be much longer than three days; it will show me what is the total contribution of radioactivity, if any,

from the polyethylene, Mylar, o-rings, the electrolyte and the cathode.

7) Another message posted on CMNS list (7/2/2009)

"As I specified before, there are only two departures from Richard's protocol,

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

in the ongoing project. They are:

(a) Keeping chips in distilled salty water, when they are waiting for electrolysis and when they are waiting to be etched. Richard wrapped them in aluminum and kept them in air. During each electrolysis his control chip is kept in the unused electrolyte. We am doing the same thing; in the past (see my Catania report) I kept control chips in air.

(b) The rear side of a chip, during electrolysis, is protected from air (by a ~0.5 mm layer of polyethylene).

Why am I trying to minimize exposure to air? Because I suspect that electrostatic charges somehow appear on CR-39 surfaces kept in air. Some areas become positive and others become negative. The reason for suspecting this is based on the fact that distributions of tracks on control chips, left in air for long time, are often very nonuniform. That could be explained by assuming that some areas attract positive radon ions from air while other areas repel them. Keeping chips in distilled salty water, and using a polyethylene protection, reduces exposure of CR-39 to air (from many days to no more than about 20 minutes). How can this hurt? Following Richard protocol, our control CR-39 chips are kept in a bottle with unused electrolyte, during electrolysis. This also protects chips from air.

P.S.
Only three people joined me in The Curie Project (all three are from Phys-L, an Internet list for physics teachers). Do you agree that the result would be treated more seriously if there were at least one or two electrochemists, with impressive credentials, among us?

The goal of the project is modest; it is to verify Oriani's results--nothing more at this stage. Suppose we confirm that excessive tracks are reproducible on demand. Then we might have a good chance of obtaining financial support, from NSF or DOE, for more sophisticated investigations, for example, with electronic detectors. The goal would be to identify particles responsible for observed tracks, to find parameters influencing the rate of emission, and to test specific predictions based on theoretical models.

IT IS NOT TOO LATE TO BECOME A PARTICIPANT IN THE CURIE PROJECT. "

8) CMNS researchers did not reply to my appeals.

Why not a single CMNS researcher joined me in The Curie Project? Most of them probably agree that participation of Ph.D. electrochemists would be very helpful, as far are credibility of results is concerned. But they prefer to work individually, on their own projects, rather than to work together to verify already-published results. That is why progress is so slow in this area.

9) A message sent to three cooperating teachers

Practical details are usually not described in published papers. But details might help three teachers who will perform experiments in The Curie Project. I assume they read Oriani's paper. Here is what I wrote: "I just started Experiment #7. All goes smoothly. Here is a description of details. Perhaps this will be useful.

1) Performing experiments at home is convenient. This allows me to record the current avery several hours, without any effort. Each experiment now takes three days. But etching will be done at school; in the chemistry lab, under the hood. This is because etching solution, if spilled, is much more dangerous than the electrolyte.

2) I have several well labeled containers. They are:

a) Unused electrolyte (a plastic bottle)
b) Used electrolyte (a plastic bottle)
c) Unused electrolyte for control chips (a plastic bottle with a wide opening)
d) Salty water for unused chips (a beaker)
e) Salty water for used chips (another beaker)
f) Distilled water (also a beaker)

2) Initially all CR-39 chips are in (d). To perform an experiment I remove two chips from (d), rinse them in (f) and set up an experiment.

3) Here is a very important detail. I make a pencil contour of each chip. Control chip is at once placed into (c); the chip is totally immersed.
Each experimental chip has a label, scratched on its surface. My convention is to position the chip in such a way that the scratched label is facing down (away from the electrolyte). Using Richard's terminology, I can say that my front surfaces are unlabeled while my rear surfaces are labeled. By careful; you must know which side is facing what, during the electrolysis. It is easy to make a mistake. I double-check the chip orientation after each experiment. Recognizing the side where the label is might be difficult. But it becomes easy after a right kind of illumination, and the angle of observation, are found. In case of doubt; one can always do this under the microscope.

4) My cell is not as tall as Richard's. But I have enough of electrolyte above the anode to last three days. At the end of day 3 the level of electrolyte is about 8 mm above the anode. I would certainly add a little of water if I noticed a possibility that the level might become much lower during the night, or during a prolonged absence. During the electrolysis, the current increases slowly from the initial value of 65 mA to about 90 mA. Following Richard's advice, I am not trying to keep the current constant (which can be done by changing the voltage or by adding distilled water to the cell).

5) I am using very light cables between the power supply and electrodes. Each cable is scotch-taped to a supporting stand, near the cell. In that way the weight of electric cables does not contribute much to the weight of the column inserted into the cell. I practiced this with during the first experiment (when a layer of polyethylene was used instead of CR-39 and when distilled water was used instead of the electrolyte).

6) At the end of the third day, I reduce the voltage to zero and turn the power supply off. The cable clips are disconnected from the Pt and Ni wires and electrodes are slowly removed from the cell. Then the used electrolyte is placed into (b) and the cell is carefully dismounted. I examine the Mylar and write down what I see (one time I had a hole in Mylar). I also examine the CR-39 surface and write down what I see. (Is it dry or is it wet? It is always dry, but this should be checked.) During that examination I always see where the 0-ring was, because it makes a visible imprint on the chip surface. This allows me to draw a circle on the contour I made in the logbook (see item 3 above). This circle defines the area in which tracks will be counted, after etching. It is important to be organized, and to have a logbook. After drawing the circle, I rinse the post-electrolysis chip in (f) and place it into (e). The control chip is then removed from (c), rinsed in (f), and also placed into (e). Contours of chips, and scratched labels, will allow me to identify chips later.

7) Then I proceed toward the next experiment, etc., etc. Etching will be performed after all experiments are performed. Meanwhile all used chips are in salty water. I add some water to this beaker occasionally, to compensate for evaporation.

8) Let me know when you are ready (after observing tracks on the little chip that was irradiated with alpha particles, and after building a cell). I will send you enough chips for three experiments (two chips per experiment). I suggest we share the results on the same day; probably before the end of September. In this way we will not influence each other."

10) Another message posted on CMNS list (7/4/2009)

I do not know why no one replies to messages I keep posting about The Curie Project. Perhaps no one reads them;

perhaps CMNS researchers think that the topic is not worth discussing. Below is another message; will it generate some interest? This remains to be seen.

'What does the adjective "reproducible-on-demand" mean? Strictly speaking, reproducibility is not possible because every measurement is associated with a random error. The same can be asked about the "highly reproducible," about "reproducible," and about "more or less reproducible." This question, particularly important in our field, is prompted by Richard's ICCF14 report

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

The abstract of that paper contains the following: "However, not every electrolysis experiment produced nuclear particles so that total reproducibility was not achieved. Therefore another experimental technique has been developed which has shown the generation of nuclear particles in each of twenty five consecutive electrolysis experiments using heavy or light water solutions of lithium salts." Does this statement mean that Oriani-type experiments are "reproducible on demand" ?

The purpose of The Curie Project is to verify that consecutive experiments demonstrate emission of nuclear particles due to electrolysis. Note that results from the first eleven experiments, in Richard's Table II, were performed with the older CR-39 in which the mean density, on 16 control chips, was 26.4 tr/cm^2 (st.dev. 12.1). The remaining 14 experiments were performed with the newer CR-39 in which the mean density, on 13 control chips, was 13.6 tr/cm^2 (st.dev.=6.8).

Please help me to decide what kind of minimum results would be needed to conclude that The Curie Project validated reproducible generation of nuclear particles due to electrolysis. I will probably perform at least ten experiments. Three other participants will probably perform at least three experiments each. Richard's contribution will be in the form of results from experiments performed after ICCF14. Do you agree that a definition of "success" should be made before the results are known?

P.S.

IT IS NOT TOO LATE TO BECOME A PARTICIPANT IN THE CURIE PROJECT. '

11) Comments etc.

a) Ed Storms, the author of a recently publish CMNS book

http://www.lenr-canr.org/Introduction.html#StormsBook

posted this message on the CMNS list: "I would like to extend the discussion that Ludwik has started. Two different types of experiments are possible. The first tries to demonstrate that a phenomenon is real. Reproducibility is important when the reality of a phenomenon is in question. This the issue Ludwik has raised with respect to the Curie project, i.e. how big must the result be before it can be considered real? The other kind of experiment accepts the reality of the effect, no matter how difficult it is to reproduce or how big it might be, and tries to understand how and why the phenomenon occurs. I think this is the kind of experiment we now need because the phenomenon has already been shown to be real by a huge data set.

We now need to understand the variables and conditions that affect the phenomenon. This means that people need to explore different conditions, not simply duplicate conditions that have been successful in the past. A very large parameter space awaits exploration, which requires trying many conditions, most of which will give nothing. However, the conditions that give a positive result become important because they provide a boundary to the active parameter space. Experiments that attempt to exactly duplicate previously successful conditions provide very little new information other than to show that the collection of conditions created at the time, most of which are unknown and unmeasured, happen to combine to give a positive result. The only way to determine which of these conditions is

important is to change them and see what happens. For example, suppose the radiation is very sensitive to the concentration of $PdCl_2$ and the chosen value happens to be on the edge of the critical value. One person happens to be on the high side of the designated value and gets a positive result and another person happens to be on the low side and gets no radiation. Without knowing the true effect of the $PdCl_2$ concentration, the result will provide no useful information other than to give one more positive result to show skeptics. This is only one example of hundreds of possible variables that might have an effect. We need to start the long and boring exploration of these possibilities rather than trying to simply reproduce the effect. Without a useful theory (perhaps too many theories) to guide this search, the work needs to be done mainly by trial and error methods until some of the important variables have been identified.

On the other hand, I agree that discovery of a reproducible method would make such an exploration of variables easier. For example, it is easier to find first base if the location of the ball field is known in advance. However, we don't even know the city in which the ball field is located. We need to send out explorers to every city we can think of to locate the ball field before we start asking the location of first base. We have shown by chance that the ball field actually exists, but the map was never properly drawn by the successful explorers. We don't need to once again prove the ball field exists. We only need to locate it in a way that results in a useful map.

This means the variables we have available in the experiments need to be changed by amounts that are easy to measure in order to be sure that the variables are not affecting the result by small chance variations. This takes time so, I suggest, the sooner we get started the better."

Hmm, "people need to explore different conditions, not simply duplicate conditions that have been successful in the past." That might be a good explanation CMNS researchers do not want to participate in The Curie Project. But shortly then I received a message from a after young researcher wrote does want to collaborate. Announcing that event, I wrote:

"1) I am happy to report that one researcher from our list is also going to participate in The Curie Project. That is very welcome; the more the better.

2) That person wrote: "My goal of working on the Curie Project is so that I can give simple reproducible experiment to scientists who have venture capitalist connections and let them run it and get them excited about it. The key is that I need something relatively simple and highly reproducible.

I have some CR-39 and I'm gathering the equipment over the next few weeks. Do you have any useful components that I can buy from you? In particular, where to buy the Mylar?"

3) We have practically no 6-micron Mylar left. Can someone send me some, to be sent to project participants? Each Oriani-type experiment uses about one square inch of Mylar. Five participants, performing 5 experiments each, would use about 30 square inches. I would be happy to pay for about 300 square inches, in anticipation of future experiments.

4) Will the "reproducibility on demand" be confirmed in The Curie Project? We will probably have a clear answer in September.

5) Please help me to decide what kind of minimum results would be needed to conclude that generation of nuclear particles due to electrolysis is "reproducible on demand." I agree with Ed that a lot of investigations will be needed, after reproducibility on demand is accepted. Each sequence of several experiments would begin with an experiment that always produces excessive tracks. Other experiments in that series will be conducted to answer a simple question--what effect a change in one parameter has on the mean track density? A change in one parameter could be:

a) Replacing Ni cathode by a Pd or Pt cathode.
b) Placing the cell into a magnetic field.
c) Replacing one kind of electrolyte by another.

6) I also agree with Ed that this kind of investigations would benefit enormously from specific theoretical (computational) predictions. Something like this:

a) My theory predicts that replacing Ni by Pd would increase the mean track density by at least one order of magnitude.
b) My theory predicts that magnetic field will reduce the mean track density by a factor of about two or three
c) My theory is that using $PdCL_2$, instead of $Li2SO_4$ will increase the mean track density by two orders of magnitude.

Theoretical predictions should be specific; the more specific they are the more useful they are likely to be."

In a private message one CMNS researcher wrote:

" 1) In my opinion, in addition to reproducibility one might test for additivity (number of tracks of particles due to electrolysis should be proportional to duration of electrolysis). And it should be proportional to excess heat. Naturally, this should be true when other conditions are strictly identical. My prediction is that there will be no proportionality; there will be some kind of saturation.

2) In applying magnetic field, one must not forget about the terrestrial field. Do not be disturbed by its small size. In the final analysis, we do not know what is the nature of terrestrial magnetic field, no matter what the experts say. By the way, terrestrial field has two components. That is why it would be useful to apply magnetic field in both directions. My prediction is that the form of tracks might change radically when the vertical field (exceeding 20 Gs) is applied.

3) S-based electrolytes might produce stronger effects than Cl-based electrolytes.

Ludwik, I am aware that these comments are useless. There is no need to answer, or to pay attention to them. "

This is not what a useful theoretical prediction; the author is aware of this. Why is S more desirable than Cl? Why should vertical magnetic field produce the described effect? What is the cause of the described saturation? Predictions without justifications are not likely to be productive. Cooperation between theoretical and experimental scientists is necessary. Theoretically inclined people should be informed about essential experimental details; experimentalists should be informed about assumptions on which theoretical calculations are based, and, if possible, with mathematical equations as well.

12) More comments

In a message posted on CMNS list, another scientist wrote that 100% reproducibility is not a necessary requirement for the existence of a phenomenon. Some CMNS effects are not reproducible on demand because we do not know how to control them.
Responding to this I wrote: "That is true. But, according to Table II in

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

each of the 25 consecutive experiments "has shown the generation of nuclear
particles." That is why the initial goal of The Curie Project is to verify the high level of reproducibility. Suppose we confirm that Richard's protocol yields highly reproducible evidence of chemically-induced emission of nuclear projectiles. Suppose that a paper, coauthored by all project participants, is submitted to Physical Review, or to another journal that rejected Richard's original manuscript. Suppose that this fact is widely publicized (with help of honest TV journalists, etc.). I suspect that this might produce at least one desirable result--publication of our paper. That would be an important step toward the end of unfair discrimination.

At the other extreme we might find the opposite situation--no one but Richard observed a clear signature of a nuclear process due to electrolysis. That would be the end of the story, as far as high level of reproducibility is concerned, at least for me. And what if some of us, excluding Richard, observed the clear signature while others fail to observe it?

That would be a situation described by Brian. We would say that Oriani effect is not very different from many other CMNS effects--it seems to be real but not yet reproducible on demand. Of course, we hope that the exceptionally high level of reproducibility will be confirmed. That would be our "success." But we should be prepared for different outcomes--a "failure" or a "partial success."

Another message posted by Ed Storms
Responding to an interesting observation made by another CMNS researcher (also about importance of reproducibility) Storms wrote: "I agree with what you say and with the logic behind Ludwik's approach. However, I do not agree that a reproducible way to make pits in CR-39 will convince skeptics that LENR is real. First of all, the measured flux is very small and is not clearly related to the other kinds of evidence for a LENR effect. Second, the method is not well understood by the scientific establishment, which would be necessary for the effect to be considered proof. The neutrons claimed by Pam et al. get deserved attention for reasons that Ludwik and other successful studies cannot duplicate. The SPAWAR results were examined at a respected laboratory using high level professional equipment. Even if a procedure is found allowing anyone to make the required pits, the results will not prove that important heat can result from such a reaction. Such a procedure will show only that low level radiation can be produced, which I agree is important but not important enough to interest serious founders, especially ones who want to make energy. Cold fusion is important because it might make useful energy and it implies a nuclear reaction rate far in excess of the SPAWAR results, which is in excess of what can be explained by any theory.

Instead of trying to simply reproduce one small part of the effect this way, I suggest the best approach is to focus on trying to understand the effect, either what is required to make it happen at a higher rate or the nature of the radiation. Granted, getting the effect to work is essential before it can be explored. Nevertheless, I'm suggesting the emphases be placed not on reproduction but on understanding, with reproduction being only the first and not even the most important step. The stated goal would not be to provide a method people could use in their own lab to prove to themselves that the effect is real. Instead, the goal would be to use the reproducible procedure to discover something important about the effect. While this would happen automatically when a reproducible procedure is found, stating it up front with emphasis gives the effort more importance than simply trying to achieve reproducibility."

And here is the message posted by me: "Brian, Ed and Tom clearly identified two distinct aspects of our dilemma: we need to understand what is going on, and we need protocols yielding reproducible CMNS signatures.

Why do I think that focusing on reproducibility is now more important than focusing on understanding? Because, as stated above, we do not have an "accepted baseline case from which controlled explorations can be made." Suppose I want to learn about the effect of X on excess heat, or on the rate of a transmutation. I perform ten experiments and results scatter from nothing to a lot. What only thing I learn is that experiments do not yield information about the effect of X on the selected effect. This can be contrasted with a situation in which results from consecutive experiments are more or less similar. I obtain the mean value of the result and start another sequence, for example, after increasing or decreasing X. This would tell me something definitive about the effect of parameter X. Focusing on understanding is not possible without a reproducible baseline."

On July 7, 2009 I wrote:
How can one objectively distinguish real excess tracks from apparent excess tracks? I had a plan for this. Unfortunately, the number of participants in The Curie Project is too small to implement it. (Not counting Richard, whose results we will be verifying, there are five of us: two high school teachers, two engineers--who are on this CMNS list--and myself.) Suppose the number of participants is 25, instead of 5. Suppose that each of us performs 6 experiments. This would produce 25*6=150 measurements of track densities. Let me ignore two trivial outcomes-- (1) every measurement is positive (confirming that track densities due to electrolysis are significantly higher than on control chips), or (2) every measurement is negative.

The third possible outcome is that some measurements yield positive results while others yield negative results. I have a plan for this difficult scenario (see below). Do I explain it clearly? Would it be acceptable to most scientists? What is wrong in this plan? What is a better alternative?

a) Each participant has a series of six results. This gives us 25 mean track densities, one from each participant.

b) A histogram of mean values is constructed. Suppose the first bin is for means between 0 and 30, the next is for means between 30 and 60, etc.

c) Yes, 25 is not a large number. But it might be sufficient to answer a simple question--is the distribution consistent with the bell- shaped curve?

d) Reasonable consistency would then be interpreted as an indication that excess tracks are real (the mean of means becomes our estimate of the "true" excess track density). Clear inconsistency, on the other hand, would prevent us from making this assertion. Yes, I would also prefer 250 participants, instead of 25. But this is totally unrealistic, in our situation. Suppose 12 means are in the first bin, 6 means are in the second, and the remaining means are nearly randomly distributed (a tail) among bin 3, bin 4, bin 5, etc. That would certainly not be consistent with the expected bell-shaped distribution.

The rational for depending on the histogram of mean values is based on the so-called "central limit theorem" of statistics. If occasionally- observed excess tracks are real then the distribution of mean values must be Gaussian, provided the number of mean values is very large. Existence of a "true value" is equivalent to the existence of a large unchangeable population from which individual samples (yielding mean values) are randomly selected."

Ed Storms responded:
"Ludwik, I think you are making this problem too difficult. If you do not see significantly more tracks on the CR-39 that is near the cathode compared to locations more distant, then you have failed to demonstrate reproducibility. The exact number of pits does not matter. Your object is to demonstrate the reality of the effect, if the reality cannot be recognized by eye without complicated mathematical analysis, it has failed. The Spawar results were easy to recognize as localized radiation simply by visual inspection of the CR-39. You need a similar result if you intend to claim to reproduce this result. Of course, complicated analysis is required to identify the nature of the radiation. However, this is a secondary result that does not appear to be part of your procedure. On the other hand, if your object is to study the effect and show which variables are important, as I suggested, then you need to make qualitative measurements including when pit density is low, because you need to relate pit density to the different conditions being explored. However, this does not appear to be part of your procedure either."

My reply:
"1) Yes, situations in which statistical analysis is not necessary are preferable.
2) Particles producing "tracks due to electrolysis" might be produced in the electrolyte, as reported at ICCF10. The first thing I will do, if reality of excess tracks is confirmed, will be to change the distance between the cathode and the chip from nearly nothing to ~2 mm (which is more than sufficient to stop alpha particles emitted from the cathode). The purpose of The Curie Project is nothing more than to get a clear yes-or-no answer about reality of excess tracks via Oriani's protocol. Investigations of parameters is tempting; but we should not be distracted. This would be the next step."

On July 8 I posted this message:
" 1) I hope some of those who are not able to perform The Curie Project experiments will be able to participate in the analysis of results. Our data will probably be available in September. But this should not prevent us from discussing strategies. Please save this message; it might be useful later.

2) As you know, row data are summarized in Table II of Richard's ICCF14 paper

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

In table I of this paper he tells us that the first 11 experiments were performed using CR-39 where mean background was 26.4 tr/cm^2 (stdev=12.1 tr/cm^2). Better CR-39 was used in the remaining experiments (mean=13.6, stdev=6.8)

2) What do we want to accomplish? We want to answer two questions: (a) are our results statistically consistent with Richard's results? (b) Do our results (and Richard results, summarized below) support the claim that his protocol yields

a highly reproducible signature of a nuclear effect due to electrolysis?

3) The most interesting Richar'd result comes from his experiment 9 (too many tracks to measure). But I am excluding it; I am going to use only what was actually measured. The first two experiments (SPAWAR-type electrolysis) are also excluded. In other words, we have 21 experiments in which track densities were measured. Each experiment provided two numbers (after first etching)--track density on the front surface and track density on the rear surface. For the time being I am place all measured densities into one set of 21*2=42 results. What follows are measured track densities, listed in ascending order; ignore the number in parentheses; it identifies the experiment, not the number of tracks per square centimeter (like the first number in each line).

4) The mean value is 122 tr/cm^2; the standard deviation is 124 tr/cm^2, and the median is 73 tr/cm^2 (in other words, one

half of the results produced 73 tr/cm^2 or more). A large difference between the mean and the median indicates that the distribution is strongly skewed. This is confirmed by following histogram:

bin 1 (0-30 tr/cm^2) < ---------- 6 results
bin 2 (30-60 tr/cm^2) < ---------- 10 results
bin 3 (60-90 tr/cm^2) < ---------- 9 results
bin 4 (90-120 tr/cm^2) <-------- 4 results
bin 5 (120-150 tr/cm^2) <--- 2 results
bin 6 (150-180 tr/cm^2) <--1 results
bin 7 (180-210 tr/cm^2) <------3 results
bin 8 (210-240 tr/cm^2) <--1 results
bin 9 (240-270 tr/cm^2) <0 results
bin 10 (270-300 tr/cm^2) <--1 results
bin 11 (300-330 tr/cm^2) <0 results
bin 12 (330-360 tr/cm^2) < ---2 results
bin 13 (360-390 tr/cm^2) <0 results
bin 14 (390-420 tr/cm^2) <--1 results
bin 15 (420-450 tr/cm^2) <--1 results
bin 16 (450-480 tr/cm^2) <0 results
bin 17 (480-510 tr/cm^2) <--1 results

5) How to deal with a situation in which the distribution is not Gaussian, and when the standard deviation is about the same as the mean value? These are real experimental data. Knowing that the standard deviation is 124, what is the level of confidence in the following statement "The mean=122 tr/cm^2 is significantly larger than the background." The level of confidence would higher than 90% if the distribution was roughly bell-shaped and if the standard deviation were something like 40 tr/cm^2, or less. ”

Ed Storms responded:
‘If the standard deviation is as large as the value, my suggestion is to ignore the results and work to improve the signal rather than applying math. No one will believe the results no matter how you "skew" the data.’

My reply July 9, 2009
“I have no doubt, at the intuitive level, that Oriani's results provide a very strong evidence that a difference between the mean track density--on his 42 post-electrolysis CR-39 surfaces (122) and the mean track density on his control chips (26)--is highly significant. But I do not know how to calculate the level of confidence for this statement. That is not a good reason for ignoring the results.

Yes, a significant difference does not guarantee that others will report similar results; that is what the Curie Project is about. The more participants we have the better. IT IS NOT TOO LATE TO BECOME A PARTICIPANT.

P.S.
Intuitive evidence is not a guess; it must also be justified. Here is the justification for my use of the term "intuitive level" above:

Richard tells us that experiments from #4 to #11 were made with CR-39 where mean background control density was 26 tr/cm^2. This amounts to 8 experiments, or 16 measurements of track densities. Among these I see only one result where the density was less than 26. All other track densities, including the four from the very impressive experiments #5 and #11, are larger than 39. Please let me know why an honest skeptic would reject this argument.

The last 14 experiments were made with CR-39 where the mean background control density was 14 tr/cm^2. This amounts to 28 measurements of densities. Among these I see only three results where the density was less than 14. All other densities are larger than 25 tr/cm^2, including ten densities higher than 100 tr/cm^2. Please let me know why an honest skeptic would reject this second argument.

How can anybody doubt that the difference between Richard's control chips results and his results from electrolysis experiments are dramatically different?

Is it not true that Richard's evidence (that post-electrolysis densities are higher than control densities) is very satisfactory? "

My message posted on July 10, 2009
"Some phenomena are reproducible but rare. In other words, one does not always observe them. How to test for reproducibility of such results? By comparing what happens with what should happen if results are reproducible (reproducible results are expected to to satisfy the Poisson distribution should). The shape of that discrete distribution depends on only one parameter L (lamda). Both the mean value and the standard deviation are equal to L. Calculations are no longer tedious and error prone; use the online calculator at:

http://rockem.stat.sc.edu/prototype/calculators/index.php3?dist=Poisson

Suppose a reproducible event is claimed to occur only twice per day (on the average). I attempted to detect it in ten consecutive days nothing was found. One does not need to be very sophisticated to conclude that the claim was not validated by me. But this can also be demonstrated by using the Poisson distribution. What is the expected (most probably) number of observations in 10 days? it is 10*2=20. What is the probability to observe 5 observations in ten days? I make L=20 (most probable result) and x=5. According to the Poisson distribution (use the calculator above) the probability for X=5 is 0.000005. And the probability that X=0 is practically zero.

But in some cases intuitive predictions are not obvious. Suppose 16 observations were made. Is this consistent with the expected value of 20? For X=14, the probability is 0.039. This is not much smaller than 0.089, the probability for X=20. In other words observing something only 14 times in ten days, instead of 20, is not very unlikely.

Let me apply this approach to Richard's observations. According to my summary (posted two days ago) based on Table II in

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

Richard examined 42 CR-39 surfaces and found 15 cases in which densities exceeded 100 tr/cm^2. According to Poisson's distribution (L=15 and X=15), the probability of observing exactly the same result as Richard is 0.102. Another researcher also measures track densities on 42 surfaces and finds that track densities exceeding 100 are on only 12 surfaces. Is this consistent with Richard's observations? The probability of that outcome (L=15, X=12) is 0.083. That is not much smaller than 0.102, the probability of the most likely result. I would say that 12 is in good agreement with Richard's result, 15. But what about X=5? In that case the probability would be 0.002. I would say that Richard's result, 15, is not reproducible.

Is there anything wrong with this approach? It is highly desirable to have an agreed upon test for reproducibility before The Curie Project results are known. The same approach, by the way, can probably be used for other skewed CMNS distributions. Excess heat, for example, as summarized in Ed's book, was more often observed at low powers than at high powers. That is also a very skewed distribution."

Ed Storm responded:
"You have two questions to address, Ludwik. Do the pits result from a random process or are they the result of rare special conditions? Your approach assumes the former, which is not very interesting. You are trying to show that a rare process is initiated under certain conditions. This is not a random process, hence the math you use does not apply. You need to show that the effect is larger than would be expected from a prosaic process. You need to identify the likely prosaic processes and show that they do not occur at the observed level. This requires changing the conditions in a known way and seeing the effect of these changes. Simple duplication to which math is applied based on a random process means nothing."

My posted question (after quoting the first question above):
"What kind of random process would produce many more tracks on experimental chips than on control chips? Richard's control chips are treated in exactly the same way as experimental chips, except for one thing. Control chips are in the bottle with unused electrolyte when experimental chips are exposed to a thin Mylar film supporting the cathode."

P.S. (after several hours of silence from the list). What preoccupies me does not preoccupy others. Each researcher has his own priorities. But researchers do not share their experimental problems with each other very often, except at formal meetings. That is rather unfortunate. :-)

I am deliberately trying to separate two questions: (a) How to decide, that The Curie Project results (when available) are consistent with Richard's results, and (b) whether or not a given set of results provides evidence of a nuclear process due to electrolysis. The second question is more interesting and more important. But, for the time being, I am focusing on the first question. This should not prevent us from addressing the second question, in view of what was reported by Richard in

http://csam.montclair.edu/~kowalski/cf/368TGP_oriani.pdf

Our sets of results might be consistent with each other without providing evidence for a new nuclear process due to electrolysis. Another possibility is that our sets of results are not consistent with each other but each provides evidence of the desired CMNS process. What is wrong with trying to answer the first question before addressing the second one?

Please help me to find an agreed-upon method for objectively answering the first question. Richard results were presented at ICCF14; The Curie Project results will probably be available in September. It would be useful to agree on the method before the results are known. Should we count cases where the mean density exceeds 100 or should we count cases where it exceeds 60 tr/cm^2 ? How to objectively justify the choice?

In principle, our two sets of results should be consistent (or inconsistent) no matter what lower limit is chosen. But our sets suffer from small numbers of measurements. What is true for a large set of measurements, such as 400, is not necessarily true for a set of only 40 measurements. Here is one possible choice (upper limit 60 tr/cm^2) and its justification:
a) 16 control chips (older CR-39) showed the mean of 26.4 tr/cm^2 (stdev=12.1).
b) 13 control chips (newer CR-39) showed the mean of 13.6 tr/cm^2 (stdev=6.8).
c) The weighted average is very close to 17 tr/cm^2. We chose 60 because it is more than three times larger than 17. (Also note that 26+12+14+7=59)."

On July 11, 2009, at 9:33 AM, Edmund Storms wrote:

"Ludwik, although the electrolyte does not attack CR-39 before electrolysis, the situation can change when electrolysis starts. Many very reactive molecules are made during electrolysis and I expect some will pit CR-39. This pitting will be tricky to separate from radiation because pitting, like radiation, will be less the further the distance from the cathode. In addition, a protective covering designed to stop chemical attack will also partially stop radiation. Of course, a careful study can separate these effects. Consequently, some of the pits could be caused by chemical attack and their number will appear to be random depending on a combination of many uncontrolled conditions. Since chemical attack is the most likely source of pits, the experiment needs to explore conditions that can clearly separate this possibility from the effect of particles. When very few pits are seen, this becomes a difficult problem. Because CR-39 accumulates any effect, the rate can be very small, hence might be caused by any number of prosaic processes, some of which might be hard to predict without careful study. In contrast, the Spawar study produced so many pits that many of these effects could be eliminated. The Curie Project needs to see a similar large number of pits."
justify the

My reply: “Thanks Ed,
1) I am neither a chemist nor a material scientist. But I will be very interested in what other electrochemists are going to say. In some Oriani's experiments control chips were actually in the cell with the Mylar, the cathode and the electrolyte above. The only difference was that the current was zero, rather than many milliamps. In other words, the effect is due to the electric current. You are probably thinking about chemical reactions caused by the current. Right? The electric wattage is very low (about 0.6 W in my case) and the cathode is in thermal contact with the cold electrolyte.

2) Are you aware that according to the most recent article, published by the SPAWAR team, about 90% of pits disappear when the chip is protected from the electrolyte by a thin layer of Mylar? Yes, the remaining 10% is still a lot of pits; probably "too many to count."

3) The codeposition procedure (covering chip #7 with Mylar), used by F. Tranzella, on the other hand, yielded a very different result, as reported in Catania (Lipson et al., page 182 of our proceedings). The track density became comparable to what is typically observed by Oriani. Furthermore, Tanzella's tracks were identified as protons of several MeV. What should we think about this apparent controversy? Would you agree that your suspicion of chemical effects is also applicable to Tanzella's results? If not then why not?

4) Two days ago you asked for the tiny bubbles in my cell. The electrolyte becomes "milky" about two or three seconds after the current is turned on. But it remains "milky" for about six to eight seconds, after the current is turned off.”

Ed’s reply:

“1) The current creates many unstable chemical species that can react with relatively inert material during their short lifetime. For example, stainless steel is stable in H_2O+LiOH but is not stable when the fluid is electrolyzed. These unstable, reactive compounds are made at the electrodes which result in a concentration that is greatest near the electrodes. Therefore, the drop off in pit density away from the cathode can be caused by how far the reactive material can diffuse before it decomposes rather than by absorption of particles in a greater length of fluid.

2) Thanks, this is important information. The question is whether the Mylar is fully protective or whether some of the reactive species can eat through the Mylar. However, the pits on the opposite side that is not exposed to the electrolyte would seem to be caused by real energetic particles. Also the pits that show clear characteristics of particle effects also provide good evidence for particle emission. As long as a large number of such pits are present, I would accept the conclusions.

3) I agree, possible chemical effects become more important when the pit density is low.

4) Interesting. You are obviously making many very small bubbles that seem to be related to the nature of the cathode surface.”

A message posted by Scott Little (7/12/2009)

“Ludwik, One of the problems you face in interpreting results from your Curie project is this: Do the pits look right? IMHO, this subjectivity is one of the greatest shortcomings of CR-39. Please look at some of the photos we posted in our SPAWAR report here:

http://www.earthtech.org/CR39/index.html

Alpha particle pits are fairly uniform in size and have a random spatial distribution over the surface of the CR-39. As a result of this distribution, overlaps are relatively rare. Compare this with what we called the "soap bubble" appearance which we are virtually certain is the result of chemical attack on the CR-39.

Note also the appearance of pits caused by various mechanical damage means. Again there is a high number of

contiguous groups of pits, which is not expected from energetic particles. Yes, I understand that there is a hypothesis for multiple tracks from energetic particles but surely the overall cross-section (nuclear cross-section multiplied by a geometric cross-section expressing the probability that the event is properly located/oriented so that it develops during etching) for that interaction is very small compared to the prevailing interaction that produces a single pit.

If you find lots of pits in your Curie experiments, please post lots of good microscope photos so that all of us can help you judge whether or not they look right.....)"

Ludwik's reply:
"Thanks Scott,
1) Pictures of our pits will be shown at my website. And I will be happy to send etched chips to those who might be interested. The goal of The Curie Project is to verify Richard's results. His pits are very similar to those produced by alpha particles. That is why only such pits will be counted. Will we also observe pits (on both sides of CR-39), at densities exceeding what is typical for his control chips (mean about 20 and st.dev. of about 10 tr/cm^2)? That remains to be seen.

2) Referring to Oriani-type experiments, you wrote: "We performed background counts on both sides of 8 chips. The average was approximately 100 pits/cm^2." That amounts to 16 surfaces. I suppose your four-years-old CR-39 chips were from the sheet whose part you sent me four years ago. Please confirm this. My recent measurements show that the mean background, for that sheet, is 26 tr/cm^2. I plan to verify this. If confirmed then your average of 100 tr/cm^2 would be consistent with Oriani's measurements, at least qualitatively."

Ludwik (replying to Ed's message; 7/13/2009)

"Dear all,
1) My suggestion is to start using electronic detectors instead of CR-39, as mentioned in an earlier message. Placed in air, next to a Mylar window, they would not be sensitive to "unstable chemical species." The same, by the way, would be true for a CR-39 detector placed about 1 mm away from the Mylar window. Furthermore, as many of you know, silicon-surface-barrier detectors do much more than to accumulate signals produced by nuclear projectiles; they provide information about their energies and about times of emission (does it occur in bursts? does it change when the electric current is increased? What happens when the current is turned off? What happens when the magnetic field is applied? What happens when the electric current is redirected to another cathode, when several drops of something is added to the electrolyte, when .....? etc. etc.).

2) Why should several hundred tr/cm^2 be called "very few pits" when Oriani's mean control chips density is about 20 tr/cm^2 (and the stdev is about 12 tr/cm^2)?

3) The problem with artifacts is more general. Three kinds of CMNS phenomena: "excess heat," transmutation," and "emission of radiation" were already named in 1989/1990. I am thinking about Bockris, Fleischmann, Jones, and Pons. Two objections were immediately raised by skeptics: (a) results are not reproducible. (b) results might be due to artifacts. How do you know that your excess heat is due to a nuclear process, and not to another (known or unknown) phenomenon? How do you know that the so-called "new elements" were not already present in your materials (or introduced during manipulations)? How do you know that CR-39 pits are not due to "reactive molecules," as suspected by Ed?

4) The immediate goal of The Curie Project is to verify that Oriani effect is reproducible. This is much easier than to provide convincing evidence against artifacts. Why is it so? Because the number of conceivable artifacts is practically unlimited. Knowledgeable people can always invent reasonable artifact scenarios. A claim for a discovery should be tentatively accepted after satisfactory arguments were presented against two or three most obvious artifacts. That is what usually happens in most areas of science, as far as I know. It is practically impossible to answer all conceivable objections when a discovery is first announced. We do not except a newborn baby to walk or run; this comes later. Tentative acceptance is a beginning of more refined investigations. Some initial benefit of doubt is usually given to qualified researchers. Why shouldn't we tentatively accept Oriani's effect as real? Convincing evidence

against obvious artifacts has already been presented by both Richard and the SPAWAR team.

5) Yes, I know that reproducibility is a precondition for all debates about experimental data. A negative result is not convincing unless experiments are known to be reproducible. Reproducibility is mother of science.

6) SPAWAR results, as far as I know, are reproducible when CR-39 chips are exposed to electrolyte, as in The Galileo Project protocol. But they are not reproducible when Mylar is used. This observation is based on what was known two years ago (Catania workshop) and what was published last April (by the SPAWAR team). Why was the controversy not mentioned in their last paper? What is the present status of reproducibility of SPAWAR results? ”

Appended on July 17, 2009
I do not know why numerous attempts to obtain information about the status of the Tanzella-SPAWAR discrepancy did not produce any new information on our CMNS list. Authors of papers to which I was referring are the list subscribers. Something important is probably behind this strange situation; what is it? Giving up on this, I posted another message. Last night I wrote:

“Theoretical topics, such as HUP, QM, QCD, standard model, existence of energy states below the ground state, etc., are certainly interesting to those who are qualified. But where should serious debates on such topics take place? Michal Gryzinski, for example, debated his ideas at gatherings of theoretical physicists well equipped to understand him, to criticize him, to help him, to explain his ideas to others, etc. Is the CMNS field appropriate for debating such issues? If I had something to contribute in the field of "quantum chromo-dynamics," for example, I would address those who know this theory well, and who use it routinely. I would not address a conference (or list) for geologists or chemists. Yes, QCD might eventually help them; but that would not be my excuse for addressing them, instead of addressing theoretical physicists. I am afraid that only a small fraction of us is equipped to discuss advanced theories.

Our field is already very controversial. We were not able to convince mainstream scientists that our claims (excess heat, transmutations, and nuclear projectiles) are valid. In order to succeed, we should stay away from additional controversies, at least for the time being. I am afraid that embracing other controversies could hurt us at this time. Do you agree?

P.S.
The interview with Fleischmann, published today, reminded me of another case where a premature attempt to explain experimental facts backfired. Suppose the claim made by Fleischmann and Pons were limited to "we discovered unexplained heat." This would lead to arguments about experimental techniques, the field in which Martin was a recognized first class international authority. But he said "therefore it must be nuclear," as quoted in the interview. Undesirable consequences of this premature statement are still with us. It would be better if they waited for independent confirmation of excess heat before speculating about its origin. Linking an interesting experimental fact with a controversial theoretical topic is an open invitation for troubles, with referees and with other scientists. Do you agree?”

A nearly-immediate reply, from Ed Storms, was about importance of understanding. How can I disagree with this? Science is not only a collection of experimental results; it is also a set of explanations. According to American] “National Science Teachers Association”

http://www.nsta.org/about/positions/natureofscience.aspx

“A primary goal of science is the formation of theories and laws, which are terms with very specific meanings.

*) Laws are generalizations or universal relationships related to the way that some aspect of the natural world behaves under certain conditions.

*) Theories are inferred explanations of some aspect of the natural world. Theories do not become laws even with additional evidence; they explain laws. However, not all scientific laws have accompanying explanatory theories.

*) Well-established laws and theories must be internally consistent and compatible with the best available evidence; be successfully tested against a wide range of applicable phenomena and evidence; possess appropriately broad and demonstrable effectiveness in further research..... While science and technology do impact each other, basic scientific research is not directly concerned with practical outcomes, but rather with gaining an understanding of the natural world for its own sake."

That answer to "what is science?" has not changed substantially since the times of Gallileo and Lavoisier. Science was, and continues to be, the basis for our technological civilization.

A discovery can be made experimentally or it can be made theoretically. Here is one well-known example. A Danish astronomer Tycho Brahe studied motion of planets and recorded their positions. His assistant, a German scientist Johanes Kepler, analyzed the result and formulated lows of planetary motion. His first law stated that trajectories of all planets are elliptical. His second and third laws were about the dependence of velocities of planets on their distances from the sun. Results of Brahe's investigations were raw experimental facts about individual planets; Kepler's law were generalization based on these facts.

Knowing about Kepler's laws, Isaac Newton discovered a theoretical explanation of planetary motion. He showed that Kepler's laws can be mathematically derived from only one assumption. That assumption is the existence of an attractive force between all objects in the universe. To be consistent with Kepler's laws, this gravitational force must be directly proportional to masses and inversely proportional to distances between the objects. Newton's theory was an important contribution to our understanding of nature; it is now used to design man-made satellites. Progress of science is based on experimental and theoretical investigations; they go hand and hand with each other, in a long run.

But neither Ed, nor other who responded, addressed the issue of negative effects of premature explanations. Instead of focusing on replications, readers (and referees) are likely to focus on explanations. Experimental data and theories go hand in hand but, in the final analysis, theories which disagree with facts are rejected, not the other way around. Ed Storms wrote:

"The issues involving QED, QM, and the Mills approach are basic to understanding LENR. Any theory must be consistent with what has been observed outside of CF, which includes phenomenon related to and explained by QM and the other models. Once a nuclear reaction takes placed in a CF environment, the consequence must be consistent with what has been observed to happen when similar nuclear reactions occur in other environments. In short, we need to see a link between CF and other observations. This means the theories used to explain these observations need to be understood before they can be applied to CF in order to show a relationship to other phenomenon.

Clearly QM is not fully understood by conventional science even when it is applied to accepted observations, hence the debates. In the process of understanding CF, I expect an understanding of the basic ideas behind QM will increase. I'm sorry to say we need to understand these ideas whether we like it or not. Also, we should not compromise our discussion just because some scientists are closed minded even about subjects that do not involve CF. These narrow minded people are clearly not able to evaluate reality even in normal science much less when it comes to the challenge of CF. We should not let their deficiencies influence our approach."

Two people wrote that they enjoy theoretical discussions on the CMNS list. Responding to them, I wrote:
" Me too. Yes, we do need theories to guide us. In the long run, experimental data and theories go hand and hand. Keep in mind, however, that a scientific theory conflicting with experimental data must be rejected, not the other way around (as some skeptics do). My main point was that readers and referees should not be distracted from experimental procedures by controversial theories.

Let me bring another illustration. It is the ICCF11 paper of G. Lochak and L.Uretskoev. They described a procedure by which the isotopic composition of a Ti wire was changed. What was the purpose of trying to explain a reproducible laboratory result with magnetic monopoles? This was not a good strategy. My articles would have a different title, for example, "A distorted isotopic ratio in Ti: how can it be explained?" I would keep my theory on the back burner, waiting for additional replications, and for the acceptance of my experimental claim. Why? Because the topic of magnetic monopoles is known to be controversial. An explanation based on a non-controversial theory, on the other

hand, would be worth mentioning. That would probably be helpful.

Linking an interesting experimental fact with a controversial theoretical topic is an open invitation for troubles, with referees and with other scientists. That was the main point of my message."

Ed Storm responded: "I agree with you, Ludwik. Experimental papers should not attempt an explanation unless the experiment was designed to answer a question theory raised. Speculation about an experimental result should be reserved for a paper devoted solely to that effort. Mixing theory and experiment invites trouble as you say. Unfortunately, people seem to be unable to restrain themselves in trying to explain rather than simply reporting."

This prompted me to post a short observation: "Why are people unable to restrain themselves? Because we were trained to think that science is much more than factology. And this is true." Elaborating on this Ed Storms wrote:

"The problem is in our genes. The human species has a need to explain. We can't help it. This allows great progress but also creates the conflict in all subjects because we take our explanations too seriously as the truth. In fact, the explanations are very seldom correct much less being the truth. Unfortunately, our species was also given an ego that has no humility. Consequently, most people will defend their chosen explanation to the death no matter how simple-minded the explanation might be. You can see this process operate most clearly in religion and politics. Science tries to overcome this problem with limited success."

Appended on July 29, 2009
A CMNS researcher posted a message about hypothesizing. Responding to this message I wrote: " (1) What is a scientific HYPOTHESIS ? It is neither a theory nor an experiment. It is a preliminary ASSUMPTION made by a scientist. Some call it intuitive thinking, others refer to it as a speculation, educated guess, hand-waving, etc. (2) I think that linking our field with controversial assumptions, such as hydrinos, is likely to result in more harm than good (at this stage)."

Scientific method in physics consists of techniques to investigate natural phenomena. Does a particular reported phenomenon exist? What is known about that phenomenon? How to explain it in terms of truth already accepted by scientists? The first two questions are addressed by experimentalists; the third is addressed by theoreticians. Experimental data are validated in terms of reproducibility. Theories are validated not only on the basis of logical (mathematical) correctness but also on the basis of specific predictions verified in reproducible experiments. Some theories are closer to reality than others.

376) Arata type experiments

Ludwik Kowalski

Montclair State University, New Jersey, USA
September 17, 2009

Introduction
Arata and Zhang persentation, described in (1), took place in May 2008. A recent paper by Kitamura et al (2) describes attempts to replicate experiments of Arata and Zhang. Actually, their paper is more than a replication. Arata's experiment did demonstrate simultaneous generation of excess heat and helium. But no quantitative results were produced (how much thermal energy and how much helium). Kitamura's paper does provide information about the amount of thermal energy but no information about helium. Hopefully amount of helium produced inside the Pd powder will be measured and results will be reported at the upcoming CMNS conference. If helium is the "nuclear ash" from "cold fusion" then the amount of excess energy per atom of created helium should be close to 24 MeV. Quantitative correlation between excess heat and helium has been reported by several investigators, for example, by Mike McKubre et al (3).

Arata's Experiments
As mentioned in my item #23 (at this website) Arata used the powdered palladium. Initially the powder was placed into a cavity of a palladium cathode. The deuterium atoms, released during electrolysis, migrated into the cavity through the thin wall of that double-structured cathode. This project was summarized in (4). In more recent experiments (1) the powder (mixture of Pd and ZrO_2, an alloy of Zr+Ni+Pd, or pure Pd) was placed into a large cell. The cell was first evacuated and then exposed to pressurized gas. Excess heat and helium were produced when the gas was pure deuterim; these byproducts were not produced when the gas was common hydrogen.

Presence of excess heat was inferred from a small difference of temperature (about 0.5 C) between the inside and outside the cell. That difference of temperature remained constant for about 2500 minutes (after the powder was saturated with deuterium). Presence of ^4He--most of it in the powder and not in the gas--was demonstrated by using a high-resolution mass spectrometer. The current due to ionized ^4He was about 25 pA. This number, unfortunately, cannot be used to calculate the number of helium atoms. To accomplish this one must know the R ratio (the number ions reaching the mass spectrometer's collector divided by the number of helium atoms produced during electrolysis.) Suppose R=1.0, which is highly unrealistic. In that case the charge collected in 2500 minutes would be $25*10^{-12}*2500*60=3.75*10^{-6}$ coulombs, corresponding to $3.75*10^{-6}/1.6*10^{-19}=2.34*10^{13}$ produced atoms. The $1.6*10^{-19}$ is the net charge of a single helium ion in the spectrometer.

How much excess heat would be produced if 23.8 MeV were released with each helium atom? The answer is 89 joules. The corresponding power would be 0.00059 watts. In reality R was probably much smaller than unity, corresponding to more atoms and to higher power.

Kitamura's Experiment
This experiment (2) was similar to that of Arata and Zhang. But the heat generated in the cell was measured by using a flow calorimeter. Three kinds of powder were used: pure Pd (0.1 micron grains), Pd-black and a mixed oxide of Zr and Pd. The highest heating power, close to 0.1 watts, during about 800 minutes, was for the mixture of Pd and Zr oxides. It is significant that excess heat was produced when deuterium was used; it was not produced when ordinary hydrogen was used.

How many atoms of helium would be produced during that time if all excess heat was due to D+D nuclear fusion? The answer is $1.3*10^{15}$, or about as little as in one cubic centimeter of normal air. Is this detectable? Probably not. But I am only guessing. I agree with authors that "it is crucial to confirm the phenomenon of heat and He generation with fully quantitative reliability." But is this possible when excess heat is generated for less than 1000 minutes, at the rate of about 0.1 W? The answer depends on the limit of sensitivity of the helium detection method.

Nuclear or not nuclear?

Absence of a nuclear signature, such as "helium ash," suggests that a chemical fuel of some kind might be responsible for the measured excess heat--thermal energy released in 800 minutes was close to 0.1*800*60=4800 joules. This is about the same as the amount of heat released when 0.1 grams of gasoline is burned. But absence of a chemical fuel in 99.5%-pure gas is not the only argument against chemical origin of excess heat. All possible artifacts, except deuteron-specific, can be ruled out; excess heat was not generated when ordinary hydrogen, rather than deuterium, was introduced into the cell.

An attempt to detect neutrons and gamma rays was made, but as stated in (2), results were negative. What other nuclear reaction, besideds cold fusion, could have produced excess heat without emitting detectable neutrons or gamma rays? I am pleased that the article was published in a very prestigeous mainstream journal.

Added on 11/21/2009

Commenting on the above, Ed Storms wrote: "Your comments about the heat having two possible sources is correct, but incomplete. All heat that is generated by a CF reaction can have 5 sources.

1. Heat from fusion,
2. Heat from other exothermic nuclear reactions,
3. Heat released when the NAE is created, (This creation process must be exothermic.)
4. Chemical heat not related to CF.
5. Error

The measured relationship between energy and amount of He shows that source #1 can be a major source of heat. However, the other sources can operate when conditions do not cause fusion. As we understand the process better, we need to more carefully determine the amount of energy caused by each of these sources. Such values will go a long way to determine which theories are correct and which are only imagination."

The term NAE, invented by Ed, stands for Nuclear Active Environment. Yes, to make a new kind of nuclear energy commercially useful the cost of released energy must be lower than the cost of required NAE. But scientific understanding can be made when this condition is not satisfied. Consider the NAE in a tokamak; it is extremely costly. The break-even point, for a sustained tokamak operation, has not bean achieved. But hot fusion scientists continue to believe that a lot can still be learned from very expensive experiments. That is a healthy attitude. Decisions about how

much money to spend on research are not made by scientists; each individual scientist wants as much money as possible, for his or her project. Decisions on what fraction of GNP should be spent on research, and how much money should be allocated on different projects, should be make collectively.

Added on 11/23/2009

It is interesting that the CMNS list is sometimes quiet for weeks, and sometimes intensive. It did become intensive in the last last week. The topic was p+p fusion. Due to the energy and momentum conservation, this two-body reaction In stars is extremely slow; it must be proceeded by the slow p+e conversion of p-into-n. But it can be direct in the deuterium lattice; where surrounding atoms act as a large third body. One researcher reminded us of claim (made by Mills in 1991) that measurable excess heat was produced in a cell whose electrolyte was based on ordinary water. The cathode of that cell was nickel, as in Oriani-type cell I am using. That is what caught my attention. In a subsequent message I wrote:

The amount of energy released per D atom would be:

[(2*1.007852-2.0141022)]*931.5 = 1.49 MeV.

I am using the $E=m*c^2$ formula with $c^2 = 931.5$ MeV/amu. Suppose excess heat from the CMNS p+p reaction is generated for 1000 hours at the rate of 0.1 W (or 100 hours at 1 W, or 10 hours at 10 W, etc). Then the total amount of produced energy would be

$0.1*1000*60 = 6000$ joules $= 6000*6.24*10^{15} = 3.74*10^{19}$ MeV

The corresponding number of D atoms (the cold fusion ash) would be $3.74*10^{19} / 1.49 = 2.5*10^{19}$. Suppose the "ash" is dissolved in 100 cc of ordinary water (in the used electrolyte). That water contains $3.3*10^{25}$ molecules of H_2O. Concentration of heavy water (mostly DHO_2) is about 5 molecules per million molecules of H_2O. In other words 100 cc of ordinary water would contain $3.3*10^{20}$ atoms of D. This is much more than $2.5*10^{19}$ atoms in the nuclear ash. The task of identifying nuclear ash would thus be very difficult if the excess heat were only 6000 joules. But suppose the excess heat is 600000 J (10 W and 1000 hours, or 100 W and 100 hrs, etc.). In that case detection of nuclear ash would be easier because its relative concentration would be more favorable.

378) Cavitational effect on radioactivity

Ludwik Kowalski

Montclair State University, New Jersey, USA
September 30, 2009

What follows was part of the previous unit #377. But the unit became too long and I decided to split it into two. This is the second half; the first half is still in unit 377

1) Fission versus fusion

Responding to a solicitation, I wrote a short essay (about 800 words) entitled "Nuclear fission, discovery of" for Salem Press. They will probably publish the essay in the book entitled "The Thirties in America." Unfortunately, I am not allowed to share the draft at this time. What I would like to do instead is to compose a longer essay entitled "Fission versus fusion," or something like this. Here are some observations; ; they were also posted at the private Internet list for CMNS researchers.

A) Nuclear fission, discovered in 1938, was quickly confirmed in several laboratories. Hahn and Strassmann's paper was published in January of 1939; the mechanism of the reaction was understood weeks later (by Lise Meitner, who coined the name "fission" and predicted about 200 MeV by event). This was at once confirmed experimentally (by Frish in Denmark, by Joloit Curie in France, and by Fermi in the US). The preexisting-accepted theory of Niels Bohr (the liquid drop model) was at once used to explain why fission is possible in the most massive nuclei, such as uranium (high values of Z^2/A). The discoveries of secondary neutrons, first by Joliot Curie and then by Fermi, were also made in January of 1939. The discovery that fission induced by slow neutrons takes place only in U-235 was also made in 1939 (Fermi and his collaborators). That opened the path to well-known applications, first military and then civilian. Spontaneous fission was discovered in 1940 (by Petrzhak in USSR). Note that these discoveries were made at universities, years before government-sponsored programs were created.

B) Basic nuclear physics facts behind hot fusion (exothermic nature of reactions, their cross sections etc.) have also been known for very long time, mostly from research conducted with low energy accelerators. The preexisting-accepted theory was able to explain the energy dependence of cross sections. Progress from knowing and understanding to the first practical application (hydrogen bomb) took about five years. But progress toward civilian practical applications (hot fusion reactors) continues to be very slow.

C) Discovery of excess heat, attributed to a nuclear reaction, took place twenty years ago. A large number of other CMNR discoveries, such as emission of nuclear particles and transmutation, were announced since that time. But the world is still waiting for a protocol yielding a "reproducible on demand" demonstration of a strong nuclear effect due to a chemical effect. The word "strong" is important because two kinds of nuclear forces are “strong” and “weak.” Strong forces are associated with nuclear reactions while weak forces are associated with beta decays. One kind of beta decay, capture of electrons from an atomic K orbit, does depend, to some extent, on the chemical composition.

D) What used to be called "cold fusion" is now called "condensed matter nuclear science" (CMNS). Other widely known names are “low energy nuclear reaction” (LENR) and “chemically assisted nuclear reaction” (CANR). New names specifically refer to “nuclear reactions,” such as emission of neutrons, protons, and alpha particles.

2) Importance of reproducibility: chicken-and-egg dilemma

Reproducibility on demand is essential in all scientific fields, especially in fields expected to influence technological applications. How can a proposed CMNR theory be validated? A theory is expected to make specific verifiable

predictions. How can predictions be verified without phenomena being reproducible?

The CMNS field has been controversial since the discovery of "cold fusion" was announced; it is still waiting for a generally accepted theory. There are many interesting CMNR reports, as described in numerous postings at this website, and in papers posted at www.lenr-canr.org. Some discoveries are spectacular. What the field needs, however is at least one experimental protocol yielding reproducible-on-demand results. This is essential. The discovery of "cold fusion" was announced two decades ago but experimentalists are still waiting for an accepted theory to guide them. Theoreticians, on the other hand, are still waiting for reproducible (reliable) experimental results to validate logical conclusions. CMNR investigators are fully aware of this chicken-and-egg dilemma. How can this vicious circle be broken? How can it be explained?

Responding to what I posted at the CMNS list, Dennis Cravens reminded us that theories do not have to have reproducible on demand effects. He wrote: ". . . For example, there are theoretical models of super nova and sun spots that do not require 'on demand' effects to be verified or established. All that is required is that the observations obey predictions whenever they happen..... " Another CMNS researcher gave the cancer treatments as an example. These are valid observations. But most technological applications, especially those used in generation of electricity, and in transportation, are based on reproducible phenomena. Cancer treatments would probably produce nearly the same results if all patients were nearly identical.

3) Speeding up the radiactive decay of thorium?

Another CMNS researcher informed the list about a recent claim (1) that the rate of decay of alpha-radioactive ^{228}Th was speeded up "by a whopping factor of 10,000." This claim was not independently confirmed in other laboratories. But shortcomings of the report were described in (2). The authors of (1) wrote, in the abstract:

"We show that cavitation of a solution of thorium-228 in water induces its transformation at a rate 10^4 times faster than the natural radioactive decay would do. This result agrees with the alteration of the secular equilibrium of thorium-234 obtained by a Russian team via explosion of titanium foils in water and solutions." They refer to Urutskoev and other researchers who reported "nuclear reactions induced by pressure waves."

I agree with (2) that a better experiment can now be designed. Here is my message about this, posted on the CMNS list: *"I just finished reading additional two papers (Cardone responding to Ericsson's criticism, and Ericsson responding to Cordone's response). Valid points are presented by both sides. The time seems to be perfect for designing a better experiment to verify validity of the initial claim of Cardone (and those who conducted similar experiments before). I would be happy to collaborate with someone who has experience with cavitation processing. My experience in working with nuclear detectors, most recently with CR-39, might be useful. Let me know."*

In an earlier message I wrote: *"Authors of the critical paper (Ericsson et al.) are probably not aware of many puzzling CMNS results. By the way, they did not try to replicate the Cardone's results; they described the shortcomings of the procedure, etc. Replication experiments conducted in different laboratories would tell us how reproducible the result of Cordone et al. are. Most people do not like to replicate experiments performed by others; they prefer to test their own ideas. This is one of the reasons that progress toward recognition of CMNR is very slow. Do you agree?"*

I read two additional papers (Cardone responding to Ericsson and Ericsson responding to the response). The fact that all four papers were published in Physics Letters, a prestigous mainstream journal, is significant. They also published the Kitamura et al. article this year. Does it mean the end of discrimination is approaching? I hope so.

4) More about speeding up the radioactive decay of thorium.

At first I thought that CR-39 played an essential role in backing the claim made in (1). But I changed my mind, after reading the paper again. I have a bunch of comments and questions about this.

a) Sizes of photographed areas (in their Figure 1) are not specified and track densities are not given. Why is it so?

b) The authors wrote that radiation from Th-228 was recognized on the basis " unmistakable 'star-shaped' look of

some tracks." This would indeed be the case if Th-228 was in a solid. But thorium dissolved in a liquid should not produce such stars.

c) The explanation has to do with the fact that emission of an alpha particle from Th-228 is followed by delayed emission of additional four alpha particles (from Ra-224, Rn-220, Po-216, and, most often Po-212) separated in time. The second alpha particle, from Ra-224, can be emitted five or ten days after the first particle. In a liquid source (thorium salt dissolved in water) separation in time also implies separation in space. That is why no "star-shaped" tracks are expected in a CR-39 kept in the liquid. Ra-224 atom will usually decay far away from where it was produced. But this is not true for a solid source. In a solid source sequentially emitted particles most often originate from the same point. That is why alpha particle tracks often form multi-prong star-like patterns in nuclear emuslsions. Why was at least one star-like pattern not shown in (1)? Circles in Figure 1 are not at all informative. Are they more informative in the printed article than on my screen? I do not know. In any case, referees should have asked for at least one better resolution photo.

d) The authors write that "the ratio of the number of traces and the number of solutions is therefore 3/4 for the reference solutions and 3/8 for the cavitated ones." This is not clear to me. What is clear, however, is that three tools available to support the claim--only one half of thorium remains in the vessel after 90 minutes of cavitation--were highly appropriate. The first tool was the magnetic spectrometer, the second tool was the NaI gamma spectrometer, and the third tool was CR-39. The magnetic spectrometer results were presented clearly. The gamma ray spectrometer results (showing that cavitation reduces the radioactivity of the solution by the factor of two) were not shown at all. The CR-39 results were not presented clearly, as far as I am concerned. A clear presentation would consist of track densities (or the total numbers of tracks) on all photos shown in Figure 1.

e) My recollection is that seven strong peaks are clearly identifiable in the gamma decay of natural thorium in equilibrium with its daughters. A change in the shape of the spectrum could provide information about which daughter, if any, is destroyed more efficiently by cavitation.

f) According to my rough estimate (see point 5 below), the pit density, due to Th-228 dissolved in water (at the 0.03 ppb concentration), would be between 12500 and 2500 tracks per square centimeter, after the exposure lasting 90 minutes. This is much higher than what is usually found on unexposed chips; typical radon and cosmic rays densities are close to 10 tr/cm^2.

g) The authors wrote that the ratio between the half-life of Th-228 (1.9 years) and duration of cavitation (90 minutes) is 10^4. This is correct. In the next sentence they conclude: "this means that cavitation brought about the reduction of Th-228 at a rate 10^4 times faster than the natural radioactive decay would do." I am puzzled; what additional information was used to justify the conclusion? Was the answer obvious to referees? Note that the factor 10000 is the ratio of rates at which Th-228 disappers (via natural versus artificially induced decay). It is deduced from the fact that one half of the initially present Th-228 is destroyed during 90 minutes of cavitation.

5) Appendix (Estimation of a blank chip track density)

Consider 1 cm^3 of the 0.03 ppb water solution (of Th-228 atoms) on top of the 1 cm^2 surface of CR-39. How many tracks to expect, after 90 hours ? The exact answer can be obtained by a Monte-Carlo code. A simple estimate, see below, is also possible. I will assume, to simplify calculations, that only Th-228 is able to form track. In other words, I will ignore alpha particles emitted from daughters of this isotope.

a) 1 cm^3 of water contains 3.3*10^22 molecules; the number of Th-228 atoms in it is:

(0.03/10^9)*(3.3*10^22)=10^12 atoms.

b) The range of alpha particles in water is about 40 microns, or 4*10^-3 cm. Only some alpha particles emitted from the 40-micron layer of solution will be able to create pits on the CR-39 surface. Others will be either absorbed in water or be intercepted at a too large angle.

c) How many Th-228 atoms are in the 40 micron layer? The answer is

N=(10^12)*(4^10^-3)=4*10^9

d) The activity A (alpha particles per minutes), of the layer is N*L, where L is the probability of decay per unit time.

L is given by ln(2)/T=0.69/T, where T is the half-life. For Th-228 T=1.9 years, or 10^6 minutes. The probability of decay per unit time is thus

L=0.69/10^6=6.9 *10^-7 per minute

e) The activity A of the layer (alphas per minute) is

A=N*L=(4*10^9)*(6.9*10^-7)=2760 alphas per minute

The number of alpha emitted in 90 minutes is close to 250000. Suppose that only 5% of these particles are able to produce tracks. This is probably a reasonable assumption. In that case the pit density would be 12500 tracks/cm^2. The density would be 2500 tracks/cm^2 if only 1% of alpha particles emitted from the 40 micron layer were able to produce tracks. And it would be 250 tr/cm^2 if the fraction were only 0.1%. [P.S. reflecting about this again, I think that 0.1% is more realistic than 1%. Fortunately, even 0.1 % would be OK, from the point of view of feasibility.

6) Reading the first criticism of Cardone (1) by Ericsson (2)

a) The following observation of Ericsson et al. is worth thinking about. They wrote: "if the decay of ^{228}Th is actually accelerated as (possibly) claimed during the cavitation, and such decay can be registered by the CR39 detectors, then the detectors monitoring the cavitated solutions should not show fewer but four orders of magnitude more events." That would not be true if detectors were placed into the vessel before cavitation or after cavitation (not during cavitation). Track densities after cavitation would be two times lower than before cavitation, for the same exposure time. I agree with (2) that the reported ability to identify decays taking place during cavitation is highly questionable.

7) Reading the first reply of Cardone (3) to Ericsson et al.

a) Cardone et al. think that "the main shortcomings of the criticism by the Swedish authors are due to their omitting of inserting our experiment in the wider research stream of piezonuclear reactions, and to the statistical analysis they used, which does not comply with the rules generally accepted for samples with small numbers." Relevance of earlier studies, in particular to investigations of Russian scientists, was well described in (1). That is why I would also not discuss it in an article written to criticize the methodology used in (1). That would only be important if the same mistakes were made by other authors.

b) Referring to their gamma counter results, Cordane et al. conclude that they are dealing with processes in which transformations of elements take place "without significant emission of gamma radiation." That is a very important clarification. It means that absence of gamma rays is not a valid argument against absence of nuclear reactions. But it has nothing to do gamma rays emitted from the solution, either before or after cavitation. A gamma spectometer would show what fraction of radioactive isotopes is destroyed, and which gamma emitter are destroyed more effectively. The authors of (1) are correct that they are not the first to claim reality of nuclear processes without emission of gamma rays.

c) Photos in reference (3), unlike those in reference (1), show readable scale lines near the corners. Now I know that photographed areas were 2.9 by 2.2 mm. The left photo shows that white dots, presumably tracks of alpha particles, are localized in a nearly circular area whose diameter is about 2 mm. That is not what I would expect to see on the surface of a CR-39 immersed in an alpha-radioactive liquid. Why is the distribution of tracks not uniform? I wish the etching conditions of CR-39 were specified (solution, its molarity, its temperature, and the duration of etching). This would help me to decide whether or not white dots are tracks due to alpha particles. My experience in working with CR-39 detectors suggests that thin and long lines are not tracks of alpha particles. I have no idea how to explain chain-like clusters shown in the left side photo. The right side photo (the chip was outside the vessel) does not exhibit such

clusters.

d) A little later the authors refer to the "inhomogeneity of the initial concentrations of all used (both cavitated and reference) samples." Why a thorium salt dissolved in water would not be distributed uniformly in the solution? Unfortunately, no information about non-uniformity is provided. Does it have anything to do with the nature of the thorium salt? If so then what was its main composition? What was its purity? Where was it obtained?

8) After reading the second reply of Ericsson (4) to Cardone (3)

a) It is clear to me now that the question about non uniformity of the thorium distribution is related to the first comment in reference (4)--how do the authors of (1) know that samples of the same initial volume contain the same initial amount of thorium? A large systematic error can indeed be made when the distribution of thorium is not uniform, for example, then the liquid is not stirred. My impression was that cavitation is like stirring.

b) The authors of (4) also feel that not enough information was presented about CR-39 methodology.

c) My impression, in looking at the two pictures in (3), was that the left one is in the water containing thorium while the right one is in the air, outside the chamber. But I was apparently wrong; the caption is clear that the left one is in water. All the questions I asked were about the left picture (see point 7 above). Now the situation is even more obscured. Why so many tracks were found in CR-39 immersed in the ultra-pure water?

d) I agree with (4) that arguments presented in (1) and (3) are not very convincing, and the experimental procedure can be improved. Only one of three available tools, the magnetic mass spectrometer, was used to directly support the extraordinary claim? Why was the gamma rays spectrometer not used at all to compare levels of radioactivity before and after cavitation? Why so little information was presented the CR-39 results?

e) A better experiment is worth performing, to obtain a definite yes-or-no answer about the claim made by Cardone et al., and by Russian investigators who they quote. The important point is that Ericsson et al. did not perform any experiments; they only stated that results could possibly be due to trivial mistakes. Possible mistakes are not demonstrated mistakes. The topic is too important to declare the article be worthless. Yes, it would be better if Cardone et all were more experienced, and if referees were more demanding. But that does not exclude a possibility that the claim is valid.

f) Let me share a trivial mistake suspected by Fabrice David, a French CMNR researcher. In a message posted at our private Internet list he wrote about a possibility that Th-228, in the experiment of Cardone et al., is redistributed rather than destroyed. He wrote: "sonication induces cavitation, and cavitation induces reactive chemical species like ozone or hydrogen peroxide. Thus, thorium can change its oxidation state, and (perhaps) stick to the glass surface." That would indeed produce the results reported in (1). Fortunately, CR-39 chips can be used to verify whether or not thorium that is no longer in the solution is on the glass, or in another suspected region, such the cavitaror.

g) The following statement from (1) puzzled me. "We measured the ionizing radiation in the empty Duran vessel both before and after cavitation. The radiation measurements were carried out by means of two Geiger counters with mica windows (one of which equipped with an aluminum filter 3 mm thick), and of a thallium activated, sodium iodine gamma-spectrometer. The results turned out always compatible with the background level." Why did they measure radiation inside an empty vessel; I would measure it in the vessel with the solution, first before and then after cavitational treatment (in order to show that the level radioactivity was significately reduced by cavitation). Is it possible that they were thinking about a possibility mentioned by Fabrice? Nothing of that kind is mentioned in (1) and (3).

h) The authors of (1) do not provide information about what mass was selected to measure the decrease in the concentration of thorium. Were the measurements based on the mass 228 peak only or were they based on several peaks? My guess is that only one peak was selected. The gamma spectrometer should display several energy peaks, some due to Th-228, others due its daughters. It is very unfortunate, that no gamma radiation spectra were shown in (1). Such spectra, as indicated above, could provide very valuable information about changes resulting from cavitation.

The CR-39 will record alpha particles from both Th-228 and its daughters (assuming Th-232 does not contribute to what is observed.) For that reason the measured reduction of radioactivity, resulting from cavitation, might depend on which of the three methods is used. All three methods, however, should produce the the same result if transmutations induced by cavitation are not isotope-specific.

i) There is a lot to learn about the claimed effect, after it is shown to be reproducible on demand. Unfortunately, I have zero experience with cavitators. Otherwise, I would have used all three instruments described in (1), actually a much older version of a mass spectrometer (not with a laser beam). Assuming cavitators are not too expensive, I am suggesting that reproducibility on demand is tested by using CR-39 detectors only. In that way many researchers, even students, could participate in gathering information about reproducibility.

379) A rejected manuscript.

Ludwik Kowalski

Montclair State University, New Jersey, USA
October 2, 2009

1) My manuscript with comments on new SPAWAR results, submitted last spring, has been rejected today. The pdf version of the manuscript can be downloaded from

http://csam.montclair.edu/~kowalski/cf/379spawar2.pdf

I hope it will be useful to those who are studying tracks observed in codeposition experiments.

2) Here is my general observation:

Conclusion
SPAWAR experimental CR-39 results are reproducible, as demonstrated in The Galileo Project [10]. Participants disagreed about interpretation of results [11,4] but everyone who used the SPAWAR protocol observed the same kind of pits as reported in [1]. That is very significant. It means that an acceptable explanation of reported facts will be found, sooner or later. Experimental data, presented by competent scientists, must be taken seriously, even when they seem to conflict with generally accepted ideas. The accepted idea, in this situation, is that a nuclear process cannot be triggered by a chemical process, such as electrolysis. The author of this note believes that rejections of claims, made by Ph.D. scientists, who publish regularly in refereed journals, should not be made only on the basis of conflicts with currently accepted ideas. They should be made on the basis of hard evidence. Experiments supporting rejections should be examined as critically as those validating unexpected claims. What is needed is an organized attempt, similar to The Galileo Project, to replicate the protocol in which the detector is located outside the electrolytic cell.

3) The letter of rejection (see below) contains extracts from comments made by three referees.

Dear Dr Kowalski,

Your manuscript: “Chemically-induced Nuclear Activity or an Illusion ?” has been carefully considered by the referees of The European Physical Journal-AP. As you can see on the enclosed reports, the referees have raised serious concerns regarding its suitability for publication.

I therefore regret to inform you that your manuscript has not been accepted for publication. Thank you very much for having submitted your article to our journal and I hope that you will nevertheless consider EPJ-AP for the publication of your future articles.

****
Referee 1:
This paper criticizes a work done by P.A. Mosier-Boss, S. Szpak, F.E. Gordon, and L.P.G. Forsley showing the presence of pits in CR39 foils during electrolysis. The point raised by the author is the interpretation of the pits diameter. According to the original work, they estimate that they are due to alpha particles, whereas the author of this paper shows that they are due to heavier particles.

This paper does not object the nuclear origin of the pits, but only the origin of.

Referee 2:
The paper represents a criticism on the works of SPAWAR group on in-situ charged particle detection with the CR-39track detectors during electrodeposition of Pd, published in EPJAP earlier {see ref. [1-3]). Desipte the fact that, in my opinion, these works are really deserve to be critisized, the manuscript AP09225 is not suitable for publication in EPJAP in its present form. Indeed, the presented paper brings nothing new either from theoretical, or in terms of experimental point of view. No new experimental data are presented. So, the graph in Fig.1 is representing a rebuilding of the experimental data obtained with Van DeGraaf accelerator for protons and already published by A.G.Lipson, A.S. Roussetski, and E.I. Saunin. ? Analysis of #2 Winthrop Williams' CR-39 detector after SPAWAR/Galileo type electrolysis experiment?. Proc. of 8th International Workshop on Anomalies in Hydrogen / Deuterium Loaded Metals. 2007. Sicily, Italy. (in the same book as ref. [9], cited by author).

Thus, this paper cannot be considered as original one. Moreover, the paper is written in the style of popular article (not acceptable for serious publication in scientific journal). In a much shorter version this paper could be considered for submission as a Comment on the works [1,2,3] by P. Moseir-Boss et al, recently published in EPJAP. However, Kowalski has already published his similar comment on some of those papers in EPJAP {see ref. [5] of this reviewed paper). Therefore, it is clear that presented paper does not correspond to the EPJ standards. This is why, the presented manuscript cannot be published in EPJAP.

Referee 3:
In fact I spend some time trying to find out what are the arguments and real conclusions. They speak about nuclear effects, but the observation looks like a simple electrolyses. I showed the image to a chemist: he said all our bathes look like that. I just suggest to submit the article to a chemist journal.

380) ICCF15 will start tomorrow in Rome

Ludwik Kowalski

Montclair State University, New Jersey, USA
October 4, 2009

1) The 15th International Conference on Cold Fusion, ICCF15, will start tomorrow in Italy. The conference website is

http://iccf15.frascati.enea.it/

Going there I just downloaded the abstracts. I have no idea when the proceedings (with full articles) will be published. Proceedings from the ICCF14, which I attended (Washington DC, October 2008), have not yet been published. What follows are the notes I made by browsing throug selected ICCF15 abstracts, quickly.

2) I. Dardik et al. referred to their already-known spectacular excess heat result (experiment 64). The electric input power was "less than 1 watt," the thermal energy output power was "up to 30 W." The total energy gain was "approximately 25." That record result was obtained in the open electrolytic cell. New experiments are performed in close cells, containing recombiners. New results "re-confirm the validity of the Energetics open cell results."

3). Letts et al., are studying low power excess heat influenced by the laser illumination of the cathode. Two laser beams (of different frequency) are used. Theoretical aspect of this approach was presented by Peter Hagelstein. This was at the University of Missouri LENR Seminar in May 2009. All presentations at this seminar are very interesting. Link to them are at

4) Y. Iwamura et al.: " Transmutation reactions of Sc into Pr has been confirmed" by using X-ray fluorescent spectroscopy. The item below shows that results are not always reproducible.

5) Bazhutov et al. calibrated CR-39 detectors with hydrogen and nitrogen ions with energies up to 5 MeV. This was done in connection with new investigations of the erzion model.

6) K. Grabowski et al.: "Thus, we concluded that the transmutation of Cs to Pr when deuterium permeated MHI's multilayer structure could not be firmly established, as contamination during the foil production or during the foil analysis could not be ruled-out."

7) A. Lipson: "The presented data on observation of real nuclear signatures accompanying deuterium loading/deloading in metals, open the way to convince physicists in nuclear origin of excess heat effect."

8) Y. Toriyabe et al. bombarded Li with deuteron beams (energies 10 to 80 keV). Preliminary experiments show that acoustical cavitation affects emission of alpha particles. "The reaction rate varies in cycles which synchronize with the frequency of the ultra sonic wave, although the enhancement of the reaction rate is not so large."

9) A. Frumkin et al. observed nuclear projectiles (3 MeV protons, 1 MeV tritons and alpha particles of higher energies.

10) A Roussetski et al. describe a new low-energy (up to 0.05 MeV) ion beam installation HELIS, in Moscow. This accelerator of ions of light elements (with atomic number in the range Z=1-54) is likely to play an important role in CMNS investigations. The deuteron current density can be as high as 2 A/cm^2.

11) S Tsvetkov et al., detected emission of neutrons (at the rate of 10^5 per second) correlated with excess heat. Neutrons were emitted when deuterium was loaded into titanium.

12) A. Takahashi discusses nuclear reactions which result in emission of neutrons.

13) V. Kirkinskii, also reports emission of neutrons from titanium loaded with deuterium. The counting rate (57 +/- 13) exceeded the background by the factor of about 1.8. The emission rate is estimated to be between 100 and 1000 per second.

14) 14) A. Roussetski et al. referring to a SPAWAR type experiment performed at SRI, presented "evidence for fast neutron emission (En ~ 2.0-2.5 MeV) during SRI's SPAWAR-type PdDx electrolytic co-deposition experiment." Their experimental findings, already reported in Catania, show that dominant CR-39 tracks were due to protons (presumably recoiling protons from collisions with neutrons) and not to alpha particles of very low energy.

At the May 2009 seminar (see point 3 above) Pamela Boss said that majority of tracks they observe are due low energy alpha particles. Larry Forseley, also from SPAWAR team, thinks that tracks observed, especially on the back sides of CR-39 chips, are due to neutrons. No SPAWAR talks or posters appear on the list of ICCF15 presentations. Frank Gordon, the leader of SPAWAR team, made an excellent review of two decades of their research. How can anyone disagree with their experimental evidence (published in 23 pier review papers) that signatues of nuclear processes do occur when their codeposition protocol is used? Or how can anyone disagree with his last last remark, that progress toward understanding of CMNS phenomena would be much faster if research were coordinated (all researchers performing the same experiments at the same time)?

381) Free ICCF4 proceedings

Ludwik Kowalski

Montclair State University, New Jersey, USA
October 6, 2009

WHAT FOLLOWS IS THE MESSAGE I POSTED ON THE CMNS LIST TODAY. WILL IT RESULT IN SOME ACTION? THIS REMAINS TO BE SEEN.

1) Jed Rothwell deserves to be appreciated many things, including making proceedings of the 4th International Conference on Cold Fusion freely available at:

http://www.lenr-canr.org/News.htm

2) I wish proceedings from all conferences were available in the same way. Perhaps Google will do this; I read somewhere that they plan to digitize all rare valuable books. I suggest that someone who has all volumes contacts Google and offers the books to be immortalized. That would be a very valuable contribution to history of science.

3) The pdf files (four volumes) are searchable. For example, I opened Volume 3, entitled "Nuclear Measurements," and used the FIND command (from the EDIT menu). In the search box that appeared I typed CR-39 and pressed RETURN at my keyboard. The document scrolled on my screen to the paper of JIN Shag-xian et al. Figure 3 of this paper shows tracks of nuclear projectiles in the CR-39 detector. I did not know that CR-39 were used in CMNS research in 1994. The reported track density was 3*10^5 per square centimeter. Only a small fraction of tracks had the same diameters as those due to alpha particles from americium; most diameters were much smaller.

Here is the abstract: "The experimental studies of YBCO-D system indicated that YBCO high temperature super-conductor (HTSC) was shown to have a similar effect on deuterium absorbability and anomalous nuclear effect like palladium('). We found that Y1Ba2Cu307-6 could absorb deuterium at normal temperature and forms D,Y~Ba&usO.r-s. We also found that the deuterated YBCO could produce high energy charged particles far larger than background. The influence of the absorbed deuterium on the characteristics of YBCO HTSC and the mechanism of the anomalous nuclear effect are not clear and needed to be further studied."

4) This was published 15 years ago. What is the current status of investigations of particles emitted from superconductor's? I haven't seen any recent reports about this phenomenon. Before continuing my search I would like to make another suggestion. We already have Storms' book summarizing scientific aspects of CMNS research

http://www.worldscibooks.com/physics/6425.html

What we also need is a book about CMNS history, preferably written by another high caliber researcher. I am thinking about something that all scientists can read with understanding, about a mixture of semi-popular scientific summaries and sociological aspect of research. For example, how were announcements of different discoveries received by other researchers? Were they confirmed by other CMNS researchers or were they ignored? How can this be explained? Why do people who were very active long time ago stopped contributing? Such questions can probably be answered only by someone who was part of CMNS since the very beginning. Many of these people will not be around in a decade or two.

OCTOBER 7, 2009. NO ONE REPLIED SO FAR. THAT IS NOT SURPRISING; MOST ACTIVE CMNS

RESEARCHERS ARE AT A CONFERENCE IN ROME (ICCF15).

This website contains other cold fusion items.

382) Data, facts, laws and theories

Ludwik Kowalski

Montclair State University, New Jersey, USA
October 17, 2009

The abbreviated version of the text below was posted on the CMNS list yesterday.

What follows was prompted by Nicholas Wade's New York Times Book Review (October 11, 2009). My comment is about scientific DATA, FACTS, LAWS and THEORIES.

Cognitive Structure of Science

a) Any recorded piece of information, about a natural phenomenon, is DATA. It can be the result of an observation or an experiment; it can be qualitative or quantitative.

b) A piece of data recognized as valid, by most practitioners in a given field, becomes a FACT. Laboratory facts are confirmed data; any scientist using the same protocol is expected to obtain the same data; at a specified level of reproducibility. Science is not mathematics; that is why the level of reproducibility, for example 90%, should be reported.

c) A LAW is a generalization of facts. I am thinking about Kepler's Laws (how planets move), about Mendeleyev's Law (how elements are ordered in a chart), Faraday's Law (how changing currents can be induced), etc.

d) A THEORY is an explanation of a law. I am thinking about Newton's gravitational theory, about Maxwell's equations, about quantum mechanics, about Heizenberg's principle, etc. Distinctions between laws and theories (and between facts and theories) are worth recognizing. Unfortunately, this is not always done.

e) Theories are based on assumptions which may or may not be valid. Assumptions can be based on facts, on laws, or on intuition.

f) Scientific theories are validated not only on the basis of their logical (mathematical) correctness but also on the basis of their ability to guide to discoveries of unknown facts. Scientific theories evolve; some theories are more powerful, more general, more useful and more elegant, than others. A theory is not acceptable to scientists unless it is susceptible to refutation. In other words, a scientific theory must be falsifiable.

g) The concept of 'absolute truth,' often used by mathematicians and theologians, does not belong to science. Wade wrote: "A theory, however strongly you believe it, inherently holds a small question mark. The minute you erase the question mark, you've got yourself a dogma."

h) An hypothesis is a tentative idea to be confirmed. It is a common instrument of human thinking. Hypothesizing is used by all those who collect data, who turn data into facts, who generalize from individual facts, and by those who explain facts of nature. Tentative assumptions are made by all thinking people, not only by physical scientists.

i) To avoid confusion, scientists try to define their terminology. The term ‘theory,’ for example, does not mean the same thing as the term ‘hypothesis.’ But non-scientists often confuse these two terms. In common language the words ‘theory’ and ‘speculation’ are often used as if they were synonyms.

j) ‘Force,’ ‘energy,’ and ‘power’ are commonly used interchangeably by non-scientists. Novice physics students often find this confusing.

Several researchers commented at once; the above text contains additions made to accommodate comments. The entire text shown above was posted this morning on the Phys-L list for physics teachers. This generated three interesting replies, as shown below in blue.

Teacher 1:
I also read Wade's article.

I disagree; I don't think a meaningful distinction can be drawn between fact, theory and law. For starters, Newton's laws are wrong but Einstein's theory is correct. Kepler's laws are only approximate. So we don't use these terms consistently (perhaps we should but it is too late, we don't).

Second, facts are contingent on theory in at least two ways. The fact that we observe current flow is contingent on our theories of how ammeters and voltmeters work. There are few observations made today that don't depend on starting with some assumed (theoretical) knowledge. This is ok, we can't test everything at once so we assume some things are true while we test other things. Theories also tell us where to look for facts. We don't just go out and start measuring stuff to see if there is some correlation somewhere. For example the data supporting black holes only makes sense because we have a theory of black holes. We have to know to look for gravitational lensing before we can discover the fact that black holes exist. It doesn't make sense to try to separate facts from theory.

I think Wade in the NYT book review was trying to get at how science can be right at the same time that it can change over time. Here is a better way to think about it. We are perfectly rational to believe (and I mean really believe) that something is true if all the data supports it and, upon trying to find counter evidence we find none (this is important- finding data in support is often easier but one good counter example destroys the theory). It is equally rational to change your mind if you get better information. I really believe my breakfast cereal is nutritious. Then I read in the news about a contamination problem and change my mind. I am not being silly or irrational, rather I am being very rational.

Now, any good scientific concept is fruitful- it suggests new ideas to try. So sure, the testing process is never done but just because you can think of some new test doesn't mean you should abandon the concept. In the history of science we almost never abandon a theory or law until we have something better to replace it. This also is rational; a well established theory is worth keeping, even if it might suggest new ways to test it.

We should believe (I mean really believe it is true) in evolution as the best truth that is available. Until we have evidence to the contrary. And it also makes sense to keep testing it, even while believing it is true.

Oh and hypothesis are a nice idea but I don't think very many scientists actually operate that way. We start with something that looks interesting or puzzling and start playing around with it; our intuition outruns our rational mind at first. Usually after the fact we can come up with a hypothesis but more often we start with a hunch or a dream or an idea. The guy who discovered the benzene ring didn't have a hypothesis initially- he dreamed of a snake rolling down a hill by biting its tail and forming a hoop. But it doesn't matter where we get ideas from (hypothesis or dreams). What matters is if we can back them up with physical data and, after trying hard to knock them down, they are still standing. I have noticed that biology papers tend to state a formal hypothesis but I don't see this done in many physics papers.

Teacher 2
I disagree with almost all of Wade's list and agree with Teacher 1's criticisms.

One more point: According to my understanding of the term, a hypothesis may be made without regard to whether it is true or not. Sometimes a hypothesis is assumed, expected, or hoped to be true but sometimes not. In particular, at the start of a proof by contradiction, we make a hypothesis that we expect to be entirely false.

To repeat: offering a hypothetical statement says *nothing* about the truth, falsity, probability, improbability, etc. of the statement. For more on this, see

http://www.av8n.com/physics/hypothesis.htm

There are other words we can use, such as conjecture or supposition, when we wish to suggest some marginal or provisional belief in a statement. Of course at this point we are dealing in shades of gray, since all scientific laws are to some extent provisional.

Here's my take on truth, belief, and knowledge:

http://www.av8n.com/physics/truth.htm

I agree with KF that real-world day-to-day scientific activity is _not_ well described in terms of hypothesis testing. It is often the case that scientific results can _retrospectively_ be analyzed in terms of hypotheses supported and hypotheses rejected ... but this is usually not necessary or even helpful at the beginning or middle of a project.

It just cracks me up when people who have not ever done science, nor even seen it done, insist that "THE scientific method" equates to hypothesis testing. I wish non-scientists would refrain from telling scientists how to do science.

Teacher 3
Hi all- I've NOT read the NY Times article, but have read the postings. It's my undestanding that the accepted, currently-used term is "model". The take is, that it is too presumptuous to claim that we are seeking truth, as physicists our job is to predict the results of experiments. We do this by formulating models which, if successful, become "standard models." Thus one occasionally hears reviewers say "the standard model appears to be working embarrassingly well" - meaning that we expect that there is "physics beyond the standard model" that should reveal itself in precision tests of the standard model.

We know, of course, that there are observations that don't seem to fit within the framework of our standard models - we characterize these as "unexplained".

Currently, where the support dollars are going, the following are objects of attention:

*) Dark matter - what is it? Supersymmetry is a popular guess.
*) Dark energy - is it just Einstein's constant? Is there a Higgs that can be identified with a mechanism for giving particles mass (I claim that a well-defined particle is not needed for the Higgs mechanism)
*) What are the neutrino mixing parameters?
*) Does supersymmetry exist?
*) Do the weak interactions become strong at high energies?
*) Can accelerator designors find acceleration schemes that will permit the construction of small high-energy colliders.

There are also some questions left over from the 'sixties, but these are no longer popular.

Ludwik's Reply:
I hope that there will be more contributions to this interesting thread. I do not disagree with the above comments. Let me make one thing clear; I did not try to write an essay on the so-called scientific method. It is impossible to write such essay without omitting some aspects of scientific methodology. Furthermore, what one writes depends on the audience. In the CMNS field, which used to called “Cold Fusion,” a distinction between data and facts, as I defined these words, is very important; the amount of data is very impressive we are still waiting for recognized facts. In my

opinion, the most promising data should be identified and all efforts should be concentrated on turning these data into facts. Agreeing on the meaning of essential words is an important preliminary step for discussing scientific methodology of validation.

I hope that my description of four essential concepts, DATA, FACT, LAW and THEORY is clear. But I am not sure that the above four words are the best for the corresponding concepts. Which words would be more appropriate (leading to a minimum number of possible confusions)? .

I also like the term “model;” it is a synonym for “theory.” But I always add the adjective “theoretical,” to avoid confusion with a physical model, for example, of a building, a bridge, or airplane. The term hypothesis is part of common language and scientists are not forbidden to use it. A hypothesis is an assumption that something is either true or not true. Tracing the origin of assumptions might be interesting; but that is a different topic. Validations of scientific assumptions should not be based on their origins.

P.S. (10/18/2009)

M.B. who I encountered on another forum, asked a question about the so-called “sociological science.” I think she is a not-a-very-young journalist. She wrote: “I personally wondered what science is in poli sci.” Then she specified:

I have a Bachelors (1944) and already was skeptical of the "science" aspect. My motive to study such was more for the philosophy of international politics. Regardless, how does one measure? There are hints such as candidate polling (and George Gallup had U of Iowa connections.) Like nowadays, we studied wars and new peace pacts. Hardly a topic to quantify. As I watch what modern students study, it seems they take the courses to engage in jobs with government or the media. There is merit, but I question the science.

Something different might be said for economics. Of all the social sciences, here we have measurable data and I forgive those who call it science--the "dismal science" they say.

Sociology falls in an iffy category for me. It seems that studies on prison recidivism, for example, may use quantifying (therefore conclusion) methods.

I believe social sciences, balanced against physical sciences, have relevance. However, deep study requires more than a few studies which pit two human conditions against each other. Most issues relating to international affairs--war and peace, for example--relate mostly to economics. I guess that's why I was called an economic determinist, even before I was old enough to vote.

This is an interestiing topic. Sociologists, political analysts, historians, psychologists, economists, mathematicians , philosophers, etc. do often call themselves scientists. Many people thing that scientists are all those who use numbers. I am not sure that this is correct; the methodology of validation is probably a better yardstick, to distinguish scientists (as a group) from nonscientists. That topic, by the way, is likely be of great interest to most students.

Teacher 4:
I would assume the article in question is "Evolution All Around" criticizing the book " THE GREATEST SHOW ON EARTH The Evidence for Evolution" By Richard
Dawkins.

1) The review is quite reasonable and actually only differentiates between theories and facts. It says that Dawkins strays into saying evolution is a fact and not a theory or model. This looks like a very reasonable criticism of Dawkins. As far as I can see it makes no general definitions of the other words.

2) As to a law being a generalization of facts, that is not exactly how the term is used. Virtually all laws are equations or relationships which may be either general or specific. If you look at all of the laws they are generally equations such as Boyle's law, Newton's laws... Sometimes the equation is merely implied as a statement of a principle.

3) A theory is a consistent framework for relating various laws and facts so that one can make predictions about unknown situations. Sometimes you can also call a theory a model. But in no sense is it an explanation. The theory itself can often not be explained, but it can be used to generate predictions. If it can be explained that would be in terms of another theory and eventually you get to postulates or assumptions which have no explanations, and are sometimes do not even look reasonable, but they work.

4)

I numbered the paragraphs and eliminated the last one; it has nothing to do with the topic of our thread. The above message is a good illustration of disagreements resulting from imprecise terminology. My terminology of the four basic terms (data, facts, laws and explanations) has been introduced.; let me stick to it.

1) Evolution is a theory explaining many facts recognized by biologists. Dawkins, on the other hand, according to the above, states that evolution is a fact. Yes, I know that the term 'fact' can refer to different things in common language. That is why scientists must first agree on definitions of basic terms.

2) This paragraph is another illustration of the same thing. I suggest that the term "fact" should refer to validated data (accepted by most practitioners), not to anything else. Likewise, I suggest that the term "law" refers to nothing else than a generalizations of facts.

What is wrong with this approach? How else can we deal with imprecise terminology of common language? As I already mentioned, some people use the words "force," "energy," and "power" interchangeably. As physicists we introduced precise definitions of these terms to students, and we try to stick to these definitions. What is wrong with assigning precise meaning to the four concepts needed to discuss scientific validations? Three questions should probably be answered:

a) Do we need precise definitions of basic words used to discuss scientific validations?

b) Are the four concepts I identified (by assigning specific four words to them) indeed essential, as far as scientific validation is concerned?

c) Are the words assigned to these concepts appropriate? If not then what are better words?

P.S.
Note what I am referring specifically to scientific validations. This term does not cover as many topics as the often-rejected term "scientific method." I am not proccupied with generalizations about how discoveries are made (what comes first, etc.).

I believe that the four concepts I defined are essential, as far as scientific validation is concerned. But I suspect that better words can be chosen to name these concepts.

Teacher 5
I will admit that I cringed a bit when I saw a video in which Dawkins used that phrase, but if one looks at "evolution" as a term simply meaning "change over time," then it seems much more reasonable to assert that evolution is a fact. The observed fossil record is clear--by whatever method one can imagine the fact is that species have changed over time. Now when one extends the idea to "evolution by natural selection," then we have moved into the realm of theory (beyond hypothesis, since evolution by natural selection is a synthesis of an overwhelming body of evidence) or model by which we explain how the "fact" of evolution came about.

It isn't clear from Dawkins' comments if he does mean evolution in its more simple sense, or in its more complete and common meaning. I'm sure however, that if questioned about it, he would either modify his comment or clarify his

definition of evolution to conform to the standards we are discussing here.

His insistence on using the word "fact" is, I believe, more of a rhetorical device than a logical one. He is trying to emphasize that, based on the overwhelming evidence and the interlocking methods by which evolution is taken to occur, evolution by natural selection is as close to a "fact" as almost anything scientific can be. The idea is over 150 years old, and all of the evidence so far developed supports it fully. This is a rather long lifetime for a theory to stand in the modern world, where challenging a prevalent idea is a widely accepted scientific activity. After all, few scientists are going to go down in history for confirming Darwin's work, it is the ones who successfully upset that apple cart who will be remembered.

Teacher 4 again:
While the definition proposed for a fact aligns with common usage in science, the proposed usage of law does not. Just look at all of things called laws and in general they are relationships between variables. Everyone may propose a definition, but to be used it must be accepted by the community that uses it.

Historically the definition of a law has been taught as something at variance with the way in which it is actually used. The old definition of law as a verified theory still appears in many texts, but it is going away as it is completely out of alignment with actual usage. Come up with a list of laws, so we can find out how often it is not a relationship between variables. If there are no counter examples or they are few, then the definition that I have proposed is the common usage and should stand.

Language is not definable by logical rules, but relies on common agreed on definitions. Many arguments about "what is" are often just people insisting their definition is correct and the other person is using it wrong. Dictionaries now recognize that and are no longer purely prescriptive.

As to imprecise terminology there is no use telling students definitions that are at odds with how people in the field of study actually use the terms. What about the historians of science? How do they define the terms in question, or what definitions have they found tend to be prevalent now?

Ludwik's reply:
1) Each Kepler's law is an example in which the term "law'" means "a generalization based on facts."

2) What would be a better term for "a generalization based on facts." Should we say "Kepler's generalizations?"

3) Newton's law of gravitation, on the other hand, is not "a generalization based on facts." That is why I think it is better to say "Newton's theory of gravitation." It explains Kepler's Laws in terms of postulated F=G*M*m/r^2 .

4) Yes, what I am trying to do is full of traps. But is it worth trying? Please help me to choose better words, to make definitions more acceptable. I believe the four selected concepts are essential, as far as scientific validations are concerned. What names are better than DATA, FACT, LAW, and THEORY?

Teacher 6:

Not to take away from Teacher 5's point, which I agree with, but I wince a little bit whenever I hear appeals to the amount of "supporting evidence" for a theory without an accompanying assessment of the degree to which the theory may be *vulnerable* to evidence. After all, proponents of intelligent design can also point to overwhelming supporting evidence. The difference is that it is entirely inconceivable that any evidence could ever be found that is inconsistent with ID.

Teacher 5 again:
Valid point. I was thinking about the possibility of evidence against evolution that could be conclusive (e.g., finding fossils from widely different time periods co-located in the same rock layer), but decided to leave it out to keep my response short. It is certainly true that, even as a "fact" evolution is still subject to refutation by evidence, although, so

far, all the evidence found supports the evolutionary model we presently have constructed. ID [Intelligent Design], on the other hand, as John points out, is not susceptible to refutation and therefore cannot be considered a scientific theory in any sense. And furthermore, not only can it not be refuted in principle, it can also make no useful predictions about what we should expect to find, while the evolution model makes many of them.

Ludwik's comment:
According to point (f) in:

http://csam.montclair.edu/~kowalski/cf/382terms.html

"Scientific theories are validated not only on the basis of their logical (mathematical) correctness but also on the basis of their ability to guide to discoveries of unknown facts. Scientific theories evolve; some theories are more powerful, more general, more useful and more elegant, than others."

I will add another sentence "A theory is not acceptable to scientists unless it is susceptible to refutation. In other words, a scientific theory must be falsifiable.

The attribute of usefulness was suggested by someone who is not on our list. I am open to constructive suggestions.

Teacher 4 again :
Boyles law, Newton's laws, Kepler's laws, Hooke's law, The law of conservation of energy... have very little in common except for the fact that they are called laws and that they are relationships between variables.

One might call conservation of energy a universal law meaning that there are no known exceptions, while Hooke's law is an empirical law which certainly has exceptions. Why not have E=mc^2 as a law? But for some historical reason it is not. The term law would seem to imply that it is absolute, while many laws are only obeyed under certain conditions.

Hooke's law can be easily discovered by a student in a short lab, while Kepler's laws took years and much struggle to create. The term law seems to be applied to various equations almost by accident. I could just publish an experiment and generalize it and call it a law according to your definition. Is Hooke's law general? Is F=mg also a law? Or how about Ff=mu Fn? Sometimes they may be considered laws, but sometimes not.

I object to the word explanation because ultimately one comes up against the< fact that your explanation is just a statement "that is the way it is". Theories are in a sense complete reasonably consistent models which cover a whole range of phenomena. As such they are merely what we use to make predictions. They explain thing in terms of other things, but ultimately they are not complete explanations. The term explanation leads students and the public to think that they are final complete explanations rather than tentative models.

Part of the problem in the past has been the rigid definitions of these things promoted by textbook authors. These are not strictly scientific terms, but partially social and historical. Making rigid narrow definitions will be confusing because each scientist has a slightly or greatly different view of these terms. So I propose that law is a historical term applied to a relationship between variables. It is very difficult to say much beyond that. It is easier to say why one is Sir Soandso than to say why something is called a law. He was knighted by the queen or king, but laws are decided by convoluted accidents of history.

Teacher 7 :
One of the main problems involved in discussing whether evolution is a fact or theory is the context. There are two which tend to be commingle.

One issue is the evolution of life forms. There are many robust lines of evidence that life forms have evolved from common ancestors. Unfortunately, some have shortened the idea of the evolution of life forms to the single word, evolution. So in this context, evolution is a fact.

The other issue is the means by which evolution has occurred. Darwin's theory is that of evolution by natural selection. Unfortunately, some have shortened the theory of evolution by natural selection to the single word, evolution. So in this context, evolution is a theory.

This was most eloquently stated by Stephen Jay Gould who wrote: "Well, evolution is a theory. It is also a fact. And facts and theories are different things, not rungs in a hierarchy of increasing certainty. Facts are the world's data. Theories are structures of ideas that explain and interpret facts. Facts do not go away when scientists debate rival theories to explain them. Einstein's theory of gravitation replaced Newton's, but apples did not suspend themselves in mid-air, pending the outcome. And humans evolved from apelike ancestors whether they did so by Darwin's proposed mechanism or by some other, yet to be discovered." [Stephen Jay Gould, "Evolution as Fact and Theory," May 1981; from Hen's Teeth and Horse's Toes, New York: W. W. Norton & Company, 1994, pp. 253-262.]

Teacher 8 :
Teacher 4 wrote: “Boyles law, Newton's laws, Kepler's laws, Hooke's law, The law of conservation of energy... have very little in common except for the fact that they are called laws and that they are relationships between variables.” And that they are all generalizations of facts. In physics, we tend to generalize by making equations with variables.

“However, given that the genesis of this discussion was evolution, one might like to choose definitions that apply in biology. How do biologists use the term law? A little googling reveals that although there is some disagreement about whether biology can have laws (see

<http://www.springerlink.com/content/g0gj47u3q5716250/>),

the term is used for generalizations that cannot be expressed in terms of variables
(see

<http://en.wikipedia.org/wiki/Dollo%27s_law>).

Teacher 4 also wrote: “Why not have E=mc^2 as a law? But for some historical reason it is not. I could just publish an experiment and generalize it and call it a law according to your definition. Is Hooke's law general? Is F=mg also a law? Or how about Ff=mu Fn? “ I think it is clear that Ludwik is using 'generalize' in the sense of 'summarize,' not in the sense of 'extrapolate.' Perhaps there is a wording that is less open to misinterpretation.

Nevertheless, I would have no trouble calling E=mc^2 and F_f= mu F_N 'laws.' They are not traditionally associated with someone's name, but I can easily imagine using the word 'law' while describing them to a student.

Teacher 4 also wrote: “Sometimes they may be considered laws, but sometimes not.” Taking this in context, I believe what is intended by this sentence is "Sometimes they may be considered accurate, but sometimes not." The usage of "law" here would then be consistent with “The term law would seem to imply that it is absolute, “ But of course Hooke's law famously demonstrates that this is not consistent with normal usage -- as John explicitly states. Whether some generalization is 'sufficiently accurate' in any _specific_ situation is not pertinent to whether it can appropriately be called a law.

Ludwik’s new suggestion”
Thank you for these illustrations and observations, John and James.

1) I wrote:

DATA = what is reported
FACTS = validated data
LAWS = generalized facts
THEORIES = explanations of laws and facts

I am glad that we are not arguing about the concepts appearing on the right of the equations. They are essential and

obvious. I am certainly not the first to identify them. We are arguing about the words appearing on the left.

2) And yes, we have to deal with "social and historical" factors. Different people assign different meaning to words. This does create confusion. How can the situation be improved? One possibility is to invent totally new words, such as:

AADO=what is reported
BADO=validated AADO
CADO=generalized BADO
DADO=explanations of BADO and CADO

Yes, this is terribly artificial and probably impossible to impose.

3). Another approach would be to use existing words which are not likely to generate confusion. Here is one such possibility.

FIND=what is found and reported
CONFIRMATION=validated FIND
GENERALIZATION=generalized CONFIRMATIONS
MODEL=explanations of GENERALIZATIONS and CONFIRMATIONS

For example:

John's find and Mary's confirmation.
Kepler's generalizations and Newton's model.

That is probably better than artificial words. Perhaps someone will suggest better words; I am not a native English speaker. The third option is to accept the existing chaos and suffer the consequences.

Teacher 4 again :
No matter what we decide to do, there is no way to impose a specific set of terminology on physicists, let alone chemists and biologists. The only thing we can do is to try to communicate to students a fairly rational view. We don't have a prescriptive language academy as the French do. Despite that the French still do not follow the orders from above.

So there is no sense getting upset about some variant terminology as long as it is not too far from the mark. It is fun to argue about it! And our discussions have very little effect on the larger community who is oblivious of them.

However, it would be good to get the outrageous mistakes out of the textbooks in regards to this terminology. While the texts are very poor at teaching students, they are used as a resource by teachers and the teachers often slavishly follow them. When the latter is done science ends up being a hash.

It is sort of like dancing. One can accept some mistakes as long as the person does not go in a totally wrong direction and mess up everyone. So whether they do a proper hay, or just a circle is not disastrous.

Teacher 7 :
The Clausius statement of the 2nd Law of Thermodynamics? Or the Kelvin-Planck statement?

Teacher 4 again :
I did say that a law can be an equation, and the 2nd law of thermo can be an inequality equation. But laws are sometimes stated in such a way as to obscure the equation such as NTN1 or NTN3. One can play the game all day with looking for exceptions, but can anyone make a fairly good list of the known things that are all called laws and see if there are any rules that govern the preponderance of them. Then a better definition might be found. We don't make

the rules for what is called a law, common usage is the true deciding factor, and there are always exceptions. It the alternately proposed definition of a law seems more reasonable where do laws stop and theories begin? Another thing one can say about laws is that they are very specific, and that a theory often encompasses a number of laws. But we are dealing with classification which is somewhat alien to physicists, but not to biologists.

So can someone come up with a comprehensive list? The majority of examples prove the rule, not the exceptions because the definition of a law is not a physics definition.

Teacher 8 :
How are the Law of Conservation of Momentum or the Law of Conservation of Energy a relationship between two variables? The two take very different forms depending on what types of energy are being converted or what type of collision is being discussed. Newton's First Law of Motion? Newton's Third Law of Motion? Lenz's Law?

Wow, speaking of Lenz's Law, I came across this very cool video:
http://www.youtube.com/watch?v=fxC-AEC0ROk

Teacher 9 :
I think I know what "Data" is. And I'll even accept "Confirmed Data" I suppose as a comment that the experimental results are reproducible.

I don't know what "generalized data" is.

I don't know the difference between a theory, a law, a model, a framework, a [insert name]. How does this affect the way I teach or learn physics? It just seems to me that it is an accident of the historical development as to which term is associated with which development in physics -- maybe a measure of the term in vogue at the time of the development. Is the standard model of particle physics a theory? A model? Is there some semantic arithmetic law: 2 theories + 1 law = 1 model? (And if that's true and no one has claimed it, can it be Keller's Law? No wait, Keller's Theory? No wait, arg!)

No one who does physics or who teaches physics should be up at night worrying about these distinctions. So I wonder about the biologists. Is evolution a theory, a law, a model? I question the motivation of those who would have us ponder this, with a line from the movie 1776: "Whatever it is, I'm against it!"

Teacher 10 :
I was taught to use "The Energy Principal" by Peter Redmond whenever possible, as it is easier. This was some time ago -- have laws been substituted for principles?

I instinctively used law for the relationship of extension and force in my hardening magnetic repulsion oscillator. Not a generalization; is this wrong?

Ludwik Kowalski:
1) In a private message B.K. wrote:
Jules Henri Poincare (1854-1912) observed that “Science is built with facts as a house is with stones, but a collection of facts is no more a science than a heap of stones is a house.”

2) Let me paraphrase this : Laws of physics are relation between variables, but a relation between variables is not necessarily a law of physics.

3) And here is something similar. Each medieval stonecutter, working on a cathedral, was asked "what are you doing?" The first said: "I am chipping stones," the second said: "I am supporting my family;" and the third said: "I am glorifying God."

Teacher 11:
. . . The word "believe" often has a semi-religious overtone. To many people "believe" is equivalent to "faith in something that will never change" or even "my strongly held opinion that I have no intention of changing no matter what".

But most often scientists have something slightly different in mind. If I say I believe in something, for example evolution or the theory of relativity, what I really mean is that I think there is good evidence supporting it and no credible evidence against it. So it is reasonable to believe in it, at least until there was credible evidence to the contrary.

The idea that we can (and ought to) change our beliefs when we get new, better evidence seems to be a foreign idea to most people. Yet most people do this all the time, at least for beliefs that aren't so central. We believe our neighbor is honest and then we find his name in the paper as a crook so we change our belief.

I have no problem if someone uses the word believe in the above sense, either for belief in god or belief in evolution or even belief that evolution doesn't occur. Once we understand "belief" as something open to change based on evidence we can start talking about evidence.

Ludwik:
The word ‘believe’ does belong to common language. But it is not used in scientific validations of facts and theories.

383) Two older sets of experimental results

Ludwik Kowalski

Montclair State University, New Jersey, USA
October 23, 2009

Unit 368 described a still ongoing CMNS project. The purpose is to validate experimental results that Richard Oriani presented at ICCF14. More recently, Oriani shared older results from experiments in a U-shaped electrolytic cell. These results are also waiting for independent validations. What follows was posted at a private list for CMNS researchers, (on 10/12/2009):

The tabulation below is a summary of my past experiments on the generation of charged nuclear particles in the anode compartment of electrolysis cells of U configuration. CR39 detectors suspended in the vapor above the electrolyte in the anode compartment (the anolyte) are enveloped by the oxygen generated at the anode. The fact that charged particles can be produced in an environment devoid of hydrogen and far from the electrode is something that theorists in the LENR field should be aware
of.
The electrolyses were carried out with H_2O/Li_2SO_4 as the electrolyte, Pt as the anode metal, and Ni as the cathode material, and lasted two to four days. The listed data are from experiments whose CR39 chips are still available for counting the nuclear tracks. The chips from additional experiments can not now be found for counting, and some of these experiments may in fact have produced no larger numbers of tracks than the controls. Moreover, I know that some of the experiments produced only few tracks. The generation of nuclear tracks on CR39 chips held over the anolyte is not reproducible. Nevertheless, the production of many tracks in an oxygen environment in these ten experiments should persuade theorists to attempt to elucidate the underlying mechanism.

exp #	tracks/cm^2	
	Side A	Side B
1	253	349
2	306	250
3	272	301
4	258	307
5	612	385
6	238	200
7	326	228
8	300	245
9	160	190
10	193	237

Controls:
Mean=5.9 (tracks/cm^2),
Std. deviation= 2.7tracks/cm^2)

These are indeed remarkable data illustrating emission of charged nuclear projectile caused by electrolysis. I hope an attempt to independently validate these results will be made. Equally interesting is Oriani's report that charged nuclear projectiles are emitted from the cathodes after the electric current, flowing through the electrolyte, is turned off. What follows was also posted at a private list for CMNS researchers, (on 10/13/2009):

I report here results of experiments done in 2005 and 2006 that reveal a residual effect, a sort of "life after death" in the words of Professor Fleischmann. This is the production of nuclear tracks by metal sheets that had previously been used as cathodes in electrolyses. I urge theorists in the LENR effort to attempt to formulate a mechanistic interpretation of these data. Even though the generation of nuclear particles during or after electrolysis can not be the agent for the thermal power that has been often measured calorimetrically, this phenomenon is well worthy of study in its own right as well as for a possible connection with the nuclear reactions responsible for excess power production.

Electrolyses were done in two different cells usually with H_2O/Li_2SO_4 as electrolyte and nickel as the cathode material, although a few were done differently, as indicated in the tabulation below. In all cases the cathode was a metal sheet held between the two o-rings of a glass joint (see Fig.1 of Ref.1) and the cathode served as the bottom of the electrolyte pool. A platinum spiral served as the anode positioned about 2 cm above the cathode sheet. The principal purpose of most of the experiments was to observe nuclear track production on CR39 chips held within the electrolyte or suspended in the vapor above the electrolyte. These measurements have already been reported (Ref.1). In many of these experiments the cathode sheet was dried directly after the electrolysis by placing absorbent filter paper upon it. After this, pre-etched and pre-counted CR39 chips were placed on either side of the cathode sheet and the whole assembly was tightly wrapped in aluminum foil for a few days. Etching in caustic and counting of the nuclear tracks followed the duration of the exposure of the chips.

The track number densities here tabulated represent the differences between the tracks before and after the exposure of the detector chips to the used cathode. For simplicity I report only the track densities developed on the chip positioned upon the side of the cathode sheet that during electrolysis had been in contact with the electrolyte (here called the wet side). In all cases the track densities from the wet side were greater than those from the opposite side (here called the dry side), although the dry sides produced track densities much larger than those on the control chips. The controls were of two kinds: pre-counted CR39 chips suspended over electrolyte solution without ongoing electrolysis, and pre-counted CR39 chips placed on fresh nickel sheet and tightly wrapped in aluminum foil. In a few experiments a second exposure of the used cathode to CR39 detectors was carried out immediately after the first exposure was terminated.

NOTES: For the controls: Mean=18 tracks/cm^2 Std. deviation= 10 tracks/cm^2

X means few tracks

* Pd was the cathode material

** Pt-plated copper was the cathode material

*** Pd as cathode and D_2/Li_2SO_4 as electrolyte

S Control chips suspended over electrolyte solution, no electrolysis

N Control chips placed upon virgin Ni sheets, wrapped in Al foil

A) Four experiments in which two exposures were made show that the rate at which particles are emitted after the end of electrolysis remains nearly constant during two or three days.

B) With one exception, labeled as X, track densities on experimental chips are larger than on control chips.

C) Referring to the first set of results (on 10/24/09) John Fisher wrote:

Group,

These experiments support polyneutron theory. According to polyneutron theory the nuclear reaction responsible for LENR in electrolysis experiments occurs in the bubbling region near an electrode where a polyneutron chain reaction is maintained. Bubbles that originate in this region rise and drag along electrolyte and the waste products it contains, and maintain an inflow of fresh electrolyte to replace it. Waste products include double nuclei, in which a large polyneutron and an ordinary nucleus (oxygen-16 or helium-4 in Oriani's experiments) are bound together. Double nuclei are not stable, and undergo alpha decay of the polyneutron component. These energetic alphas are responsible for Oriani's etch pits. It does not matter whether bubbling is driven by evolution of hydrogen atoms near a cathode or by oxygen atoms near an anode. The LENR action occurs in the electrolyte, which has the same composition at both electrodes, leading to double nuclei and alpha decay at both electrodes. The theory also predicts excess heat at both electrodes.

D) Referring to the second set of results (on 10/25/09) John Fisher wrote:

Polyneutron theory offers an explanation for the "life after death" nuclear tracks observed by Oriani and described in his communication of 13 October (I have lost that communication save for a printout, so cannot reproduce it here). In my 24 October communication I suggested that double nuclei, composed of an oxygen-16 nucleus and a large polyneutron bound to each other, are formed in regions of active LENR near electrodes in electrolysis experiments. And I suggested that the polyneutron components are unstable and emit alpha particles as they decay. (Two beta decays are associated with each alpha decay.) Because the oxygen-16 double nuclei are chemically oxygen those that reach a cathode can join an oxide film on the cathode surface, or otherwise chemically attach to the cathode. There from time to time they briefly transmute to fluorine and neon with two beta decays and then back to oxygen when an alpha particle is emitted. These alphas can be recorded on CR39 chips. After each alpha emission the polyneutron is reduced in size and the coulomb barrier for alpha decay (caused by the charge of the oxygen nucleus) grows larger. The alpha decay rate slows. The rate of production of CR39 tracks and of energy declines. These are the late stages of "life after death" for both tracks and heat.

E) Also relevant (?) is a message posted by another CMNS researcher. It listed possible paths for the exothermic p + Li reactiones.

$^2H + {}^6Li \rightarrow n + {}^7Be + 3.381$ MeV

$^2H + {}^6Li \rightarrow {}^1H + {}^7Li + 5.025$ MeV

$^{2}H + {}^{6}Li \rightarrow {}^{3}H + {}^{5}Li + 0.592$ MeV
$^{2}H + {}^{6}Li \rightarrow {}^{3}He + {}^{5}He + 0.901$ MeV
$^{2}H + {}^{6}Li \rightarrow {}^{4}He + {}^{4}He + 22.372$ MeV

Note that 7.5% of lithium (in Oriani's electrolyte) is ^{6}Li and his ordinary water contains a small amount of heavy water, and thus ^{2}H. Naturally, one can think of several other exothermic nuclear reactions able to produce nuclear projectiles, for example, $^{1}H + {}^{6}Li \rightarrow {}^{4}He + {}^{3}He$ (Q=3.7 MeV).

Yes, I am fully aware of Coulomb barriers involved. But this is a problem common to all CMNS reactions. An interesting paper about how to addres the Coulomb barrier issue was presented by E. Storms, at the last international 'cold fusion' conference in Rome (ICCF15).

384) Loose Ends

Ludwik Kowalski

Montclair State University, New Jersey, USA
November 7, 2009

1) I did not participate in ICCF15 which took place in Rome last month. Next International Cold Fusion Conference, ICCF16, will be in India, in February, 2011.

Even the Pope is up to date on our research (photographed by F.D.).

2) A journalist, specializing in history of CMNS, Marianne Macy, published an interesting article about ICCF15:

http://www.infinite-energy.com/images/pdfs/macyiccf15.pdf

I was fascinated by the recovery of Martin Fleischmann, resulting from medical treatment by Irving Dardik. Dardik is an American physician who believes that CMNS phenomena can be induced by super waves (electric current of a complex frequency distribution). I heard him speaking about this at ICCF14. He has been using super waves to treat patients for many years. Suffering from Parkinson's disease, Martin Fleischmann was in rather poor shape recently.

According to Macy, *It took a year for Martin Fleischmann to make the decision to come to the U.S. to work with Irv Dardik. When arrangements were made for the trip, Fleischmann had classic symptoms of Parkinson's disease and could not fly. He and his wife Sheila boarded the Queen Mary in June 2009 to sail to New York. By the time he flew back to England, it was a less than a week until ICCF15 began. In the three months of his stay, he had worked with Irv Dardik and his team faithfully. "I never saw Martin say, 'I can't do it, I'm going back to bed,'" Dardik related.*

Fleischmann's daughter Vanessa, who had "not expected much," was struck by the change when she saw her father this fall. "It's as if we are going back in time some years," she said. Fleischmann committed to having local trainers

and supervisors continue his program from his home in England, working with the Dardik Institute via a computer setup. Martin Fleischmann, exposed to a flu before he left the U.S., was tired when he returned to England on September 29. He went to bed and rested for a few days. But at the end of the week, he got on a plane again, this time to Rome.

3) There was a brief exchange of messages about the so-called zero-point energy, at a private Internet discussion list. A.M. wrote: "I am dubious about getting useful energy from the ZPE (just as I'm not sure that you can get useful energy from the thermal motion that drives Brownian motion - and for the same reasons)." S.L. added: "We've spent a lot of time considering the possibility of extracting energy from the vacuum. It is important to realize that the same physics (QM, QED) that predicts the existence of the zero-point field also forbids the extraction of energy from it. Specifically, the ZPF is the lowest allowable energy state of the vacuum."

4) At the same time I received a private message from Ken Schoulders, the author of numerous articles about tiny clusters of zillions of electrons, named EVs. His most recent manuscript can be downloaded (it might take a minute or so) from
http://pages.csam.montclair.edu/~kowalski/cf/384shoulders.pdf

Ken believes that electric sparks consist of such clusters. This is another topic which does not belong to CMNS. I do not see benefits from explaining one controversy (a nuclear effect due to electrolysis) with another (existence of EVs). I think that each effect should be studied independently, at least at this stage of knowledge. In any case, I am not equipped to study EVs. What keeps zillions of electrons together?"

Responding to this, Ed. Storms wrote:
You advise not involving the unknown EVO in cold fusion because you can't understand how so many electrons can be held together. Cold fusion has a similar problem. No one can understand how the Coulomb barrier is reduced enough to allow such a high reaction rate. I think we should consider that a relationship exists between these two phenomenon, not just that both are unaccepted. Both require a process that offsets or neutralizes an electronic charge. In the case of an EVO, the neutralized charge is negative, while it is positive in the case of CF. In both cases, the charged particles are able to get unnaturally close to each other. In the case of CF, this close approach allows a nuclear reaction to take place, which is not possible in the case of electrons. In addition, It is easy to imagine that the presence of an EVO might help neutralize the charge between nuclei and help cause a nuclear reaction. In fact, Ken's observations suggest such a process.

On another topic, I would like to know how people view such speculations as done above. Is this theory or just BS? Where does BS end and theory begin? Does theory always have to involve math? If so, what is the value of math that is applied to the wrong mechanism and conditions because such ideas as above were ignored?

Ludwik Kowalski responded:
Ed's speculation is interesting. In my opinion speculations, even dreams, etc. are worth sharing. They can be, and probably often are, powerful motivational factors. That is why I do not think the vulgar BS term is an appropriate descriptor. But loose speculations are not part of our acceptable scientific validation process.

Let me refer to a well known example. Calorimetric measurements, in 1930s, revealed that the amount of thermal energy released in beta decay is much lower that what was expected. That prompted Pauli to predict existence of neutrinos. Was his publication only a speculation (motivation for the 1940's experiments in which neutrinos coming from a nuclear reactor were discovered) or was it part of an acceptable validation process? I agree with Ed that this topic is worth discussing.

Andrew Meulenberg wrote:
Ludwik, I partially agree and partially disagree.
(1) Dreams and fantasies can be very powerful motivators; but, they can also be very dangerous to the dreamer who can't cut loose or distinguish them from reality. (2) Sharing dreams is more often negative because most listeners can't see the same picture and thus respond appropriately (3) Remember, BS is good fertilizer. However, it does no good just to sit on it. You have to spread it around (in the proper places).

Another CMNS researcher added:
Why vulgar? Ed was probably referring to Bold Speculations.

Ed clarified:
I was actually referring to Bad Speculations. :-)

Ludwik added:
Bold scientists make bold speculations while bad scientists make bad speculations. But what kind of speculations are made by bogus scientists. How to distinguish bogus speculations from those that are useful? This seems to be the essence of Ed's question.

Ed Storms wrote:
The issue is how to separate loose speculation from usefulspeculation, as your example below describes. I submit that all theory starts with speculation. The speculation shows where to look for the operation of a mechanism or what kind of mechanism is worth exploring with various mathematical tools. I get the impression that speculation is called a theory only after math has been applied even though the math adds nothing but a restatement of the speculation. In fact, most of the math in "theories" applied to CF are simply a restatement of the basic assumption. The fact that such a mathematical restatement is possible is used as "proof" that the initial assumption is correct. People then attempt to calculate reaction rates based on this approach. However, the results are impossible to apply to observation because in the real world, conditions are not uniform or under control. Consequently, it is impossible to test such a theory.

I propose a different approach. Enough is now known about the phenomenon to make logical deductions. These deductions reveal where the nuclear events are occurring, some of the conditions that must exist at these sites, and information about the mechanism. When does such an approach rise to the level of theory?

Akito Takahashi wrote:
Does theory always have to involve math? Who can make quantitative estimates without any mathematics? I have no other ideas than believing that mathematics is indispensable to make a theory "plausible". We have no other tools than mathematics (primitive or elegant does not matter) for quantitative estimates. However, it does not always mean that the usage of mathematics makes up theory so beautiful and complete. We need cross-checking its consistency from many angles. The quantification of a theory makes the cross-checking clear and definitive. . . .

Ed Storms responded:
I agree, Akito, math is necessary to make quantitative estimates. But is it necessary for an idea to be called theory? For example, is it necessary to apply math before plate tectonics or Darwin's Theory of Evolution are called theories? More to the point, must math be applied before a proposed mechanism about where and how cold fusion operates is called a theory? For example, at ICCF-15 I proposed a mechanism for cold fusion but in many minds this does not rise to the level of theory. Why not?

You have raised another question - how does a person judge whether an idea is plausible or not? Math can take two roles: it can be the entire basis for a model or it can be used to compare a proposed mechanism to other measurements. In the first case, the ability to achieve internal mathematical consistency alone is used as a demonstration that the initial assumption is correct. String theory comes to mind as an extreme example. In the latter case, the theory is considered correct only when the math shows quantitative consistency with many independent measurements. The theories of thermodynamics are good examples of this approach.

The problem is that math alone does not make a theory plausible. For example, in the case of cold fusion, most math simply restates the initial assumption without adding anything new. Following the initial assumption, a series of ad hoc assumptions are made to move the math to the next level. I don't think this process adds plausibility even though it is necessary to explore a proposed mechanism. To be clear, I do not object to this process. I'm only objecting to the process being used to add plausibility to a proposed idea. The initial idea is only plausible after it shows a quantitative relationship to many other kinds of measurements or makes exact predictions. In my opinion, no theory in cold fusion has reached this level. I believe the basic reason we have this problem is because the mechanism and where this

mechanism operates in a material have not been correctly identified.

You wrote" We have no other tools than mathematics (primitive or elegant does not matter) for quantitative estimates. However, it does not always mean that the usage of mathematics makes up theory so beautiful and complete. We need cross-checking its consistency from many angles. The quantification of a theory makes the cross-checking clear and definitive." I agree. This process is necessary. The question is, at what point does a proposed model become plausible? When I ask this question, the answer has to apply to a person who has not proposed the initial idea. For a person to go to the considerable effort to develop a mathematical model, they must be certain in their own mind that the basic idea is correct. Therefore, they have an important emotional stake in the idea being correct. This is natural and required for an idea to be fully defended, but it can result in conflict and differences of opinion that can never be resolved. As a result, discussion between advocates of particular models, theoreticians, is seldom productive. . . .

Ludwik wrote:
1) It will probably be useful to separate arithmetic (use of numbers) from the rest of mathematics, such as calculus, etc. Arithmetic is part of common language; it is widely used outside science. That is why a publication in which arithmetic is used is not necessarily scientific.

2) To non-scientists the word "theory," often means "a questionable speculation." It is only a theory, they often say. But we use this word differently. Scientists, for example, are often characterized as either experimentalists or theoreticians, depending on what tools they use to make discoveries, or to explain discoveries. Those whose primary tool is mathematics are called theoreticians; those who use other tools are called experimentalists. (This is not the only case in which a word means a different thing to a scientists and a non-scientist. 'Force,' 'energy,' and 'power' are commonly used interchangeably by non-scientists).

3) In my definition, a law is a generalization of facts (for example, Kepler's Laws). Some laws, as emphasized by Ed, are qualitative while others are quantitative. A theory, in my definition, is an explanation of a law (for example, Newtons law of gravitation) or of a fact. It can also be either qualitative or quantitative. A qualitative theory, as emphasized by Akito, is less useful than a quantitative one.

4a) In the last paragraph Ed asked: "at what point does a proposed model become plausible?" I suppose that the word "plausible" refers to a mathematical model "to be taken seriously." Those who are not able to penetrate details of a model have no other choices than to rely on the authority of the author, or on the authority of those who say that no mathematical mistakes were found.

4b) Note, however, that scientific theories, unlike mathematical models, are validated not only on the basis of their logical correctness but also on the basis of their ability to guide to discoveries of unknown facts. That how I understand Ed's statement that "math alone does not make a theory plausible." Experimentalists look for quantitative predictions of scientific theories and try to validate them with their own tools--laboratory instruments. I agree with what Ed often repeats--the value of a scientific theory depends on the number of verifiable predictions it makes.

Ed responded:
1) I agree we can break math down, but I would not make the break where you place it. The models being applied to CF use a level of math much different from calculus, which I suggest is a form of arithmetic. For example, I would put the Hamiltonians, Eigenfunctions, wavefunctions, and Schrodinger equation separate from calculus and arithmetic. These are based on concepts and assumptions about Nature and are not truly like calculus and arithmetic. In any case, these concepts seem to be an essential feature of anything that is called a theory in CF even though their use requires numerous ad hoc assumptions.

2) A theory only becomes useful and valuable when experimentalists verify it, yet theory seems to hold a higher role than experiment. We saw this approach operate when people rejected CF because they could not explain it.

3) Is being able to calculate a hypothetical reaction rate more valuable than being able to say that if you mix X with Y, the CF reaction will work better?

4a) Very few theories in CF have mathematical mistakes. The issue lies in the assumptions on which the math is based, which keep changing as objections are raised.

4b) That's right. A model is useful only when it guides work successfully. The model might even be incomplete, hence not plausible. My only goal in this discussion is to encourage people to show exactly how their model relates to the real world and to variables that can be modified to have a beneficial effect. Short of that application, a model is only a logical game.

Ludwik wrote (quoting (2) above:
a) History of CMNS would be very different if Fleischmann and Pons announced nothing more that the discovery of unexplained excess heat. In that case only qualified electrochemists would probably perform replication experiments. Confirmation of of the discovery would lead to theoretical speculations, most probably only by qualified theoreticians. In other words, influence of bogus experimentalists and bogus theoreticians, on the outcome of the validation process, would probably be negligible. Premature speculations about nuclear origin of excess heat was a mistake with devastating consequences.

b) Suppose I am clever or lucky to discover a new phenomenon. Suppose I suspect that it belongs to cold fusion field. I would keep the suspicion for myself. In a submitted paper I would describe the procedure and emphasize my inability to explain the results. (If the discovery were excess heat then I would have tried to convince readers that known chemical reactions are not responsible for it.)

c) If I were a theoretician I would not have tried to validate a theory with irreproducible experimental results. I would have only said that such and such assumptions lead to such and such consequences. That would be a mathematical model, not a scientific theory. Yes, I know that the word "theory" means different things to different people. Distinguishing a mathematical model from a scientific theory is probably useful. To turn a mathematical model into a scientific theory I would make verifiable predictions, hoping they will be confirmed by experimentalists. A model becomes a theory when it's predictions are confirmed. This is not the same thing as "predicting" what is already known.

d) P.S. (on another thread):
I wish I were sufficiently knowledgeable to debate the topics mentioned by D.S. The only option I have is to trust high energy physicists. Reliance on authority of experts is much more common than most laymen believe. In fact, that is what makes today's science very different from what it was, for example, in the second half of 19th century.

e) P.P.S. (indirect measurements):
The repulsive force between two atomic nuclei (when their surfaces are separated by at least two fermi of empty space) is proportional to 1/r^2. How do we know this? By performing scattering experiments. Here is one example. Rutherford was observing alpha particles scattered by a thin gold foil. Assuming the Coulomb law is valid he derived a mathematical relation between the probability of scattering, P, and the angle of scattering T. The theoretically calculated P turned out to be inversely proportional to [sin(T/2)]^4). This relation, and other theoretical relations, was confirmed by experimental data.

Measuring one thing and theoretically inferring something else from it, can be called an indirect measurement of that "something else." Another illustration is determination of the radius of an atom, also via the Rutherford scattering formula. What is actually measured is the angle at which the experimentally measured P becomes smaller than that predicted by the theoretical formula (derived under the assumption that the nuclear radius is zero). The "indirectly measured" atomic radius is calculated from that angle. Most measurements in atomic and subatomic physics are indirect. In other words, theoretical and experimental instruments are inter-linked in atomic and subatomic physics. Indirect measurements are also used in classical physics, for example, when radar is used to measure a distance.

John Fisher (who developed a CMNS theory described in units 227 and 364) wrote:
I have been asked several times to comment on LENR theories. Quantum mechanics has been developed and refined in hundreds of thousands of experiments and by tens of thousands of experimenters and theoreticians over a period of a hundred years. It is the most comprehensive and quantitatively accurate description of nature ever achieved. A truly

remarkable accomplishment of humanity. I accept quantum mechanics as the basic and essential framework for understanding the physical world, including LENR. Experiments beginning with Fleischmann and Pons have persuaded me that the LENR phenomena are real, that they indicate nuclear reactions of a previously unappreciated nature, and that they offer promise of potential social benefits. I have been searching for an interpretation of these phenomena that can explain what has been observed, and that will predict what can be observed in future experiments. Quantum mechanics provides the basic methodology, and I do not consider any theory that is in conflict with it.

Ed Storms responded:
1) John, quantum mechanics is a very broad field with many variations and assumptions, some of which are not universally accepted. While I agree, the basic idea needs to be accepted and used, the problem comes in the details. Just how should QM be applied? What if a novel electron energy level or state is required to explain CF, but this has not been considered by QM, hence is rejected. Should this rejection be ignored?

2)QM has been very successful in describing the hydrogen atom. However, it has less success in describing other atoms without using ad hoc assumptions.

3)Which assumptions should be accepted and which should be rejected? On what basis should the choice be made? These are the questions I'm trying to answer.

John Fisher responded (point by point):
1) A state that has previously been considered by QM and rejected should continue to be rejected even if "needed" for LENR. A state that has not previously been considered by QM should be considered. It can be tentatively accepted while its QM implications are explored. Depending on whether the QM implications agree or disagree with observation, its tentative acceptance may be strengthened, or it may be rejected as failing to agree with observation. This is how much of our understanding of nuclear physics has been accumulated.

2) The assumptions behind the theory of the periodic table of elements are not ad hoc. They are the same assumptions as for the hydrogen atom. However the determination of physical parameters has usually been done by experiment rather than by theory because experiment is so much easier. (As an example from nuclear physics one needs to know the masses of the various isotopes in order to calculate the energetics of nuclear reactions. We use measured masses because we do not have the computing power to calculate them.)

3) An assumption should be rejected if its QM implications disagree with observation. Otherwise it can be tentatively accepted until further observations with broader implications may lead to disagreement and rejection. If the proposer is skilled or lucky his assumption may never lead to disagreement with observation and may win enduring acceptance.

Andrew Meulenberg wrote (addressing John Fisher):
. . . Thus QM, is not wrong. It is just not self sufficient. As Ed has stated, it depends on what is put into the model. One extreme is GIGO - garbage in, garbage (or, as Dean would say, Quarks) out. The other extreme, just as bad, is to not allow new ideas in. [Dean is a CMNS researcher who wrote that the idea of quarks is nonsensical.]

Ed Storm wrote: (addressing Tom Barnard.)
I'm trying to think of some way to get through this impasse. I have found trying to critique a theory with some one who has a committed view to be impossible. The logic structure is complete in their mind. Like a builder, each beam and brick has its place and a failure of any part threatens the whole structure. Consequently, no part can be recognized as being in error. The result is an increasingly detailed argument about increasingly small details until the big picture is lost and patience runs out. I have also discovered that QM can be molded to fit almost any notion about reality and to arrive at almost any conclusion. If you examine the many ways other people have used this tool to explain CF, you will see what I mean. To add to the problem, different people have different ways of explaining the same ideas in QM. As a result, a lot of time has to be invested to discover just what is being said. Furthermore, QM is not the only way, or perhaps the best way, to describe CF, at least not in its pure form. So, rather than beat a theory to death, my attention is directed mostly to discover just what is known so that we all have a common reality to which the theories can be compared. . . .

Ludwik:
Attempts to turn a mathematical model into a scientific theory are usually made after at least one experimental result is recognized as reproducible on demand. That is why I would replace the term “a common reality,” in the last sentence above, by “a reproducible on demand experimental result.”

Tom Barnard wrote:
I very much feel your frustration Ed. I respect very much the work you have put in and continue to. I respect everyone's time. I would not persist here for trivial reasons. I have worked very hard to attain a certain intuition based on QM. Many years solving the Schrodinger equation for known phenomena in order to gain basic competence. My ideas are really quite simple QM. Basic phenomena in the QM world, but voodoo in the Newtonian world. I can't help that.

I know it is a matter of trust and frankly, I haven't earned any. That is why an adherence to the basics; to alleviate the trust factor a little. Everything I say can be fairly easily checked in the texts, of course, necessitating trust in the texts. . . .

Andrew Muelenberg wrote:
Ed, Please lighten up a bit. Your questions and challenges are pertinent; but, they are also premature and discussing them in detail at this point detracts from others obtaining the background information that they (and you) may require.

You are too anxious to get to the goal. Your goal is 20 feet up and you refuse to see the ladder as an option because it has a few broken rungs. Please don't block the ladder, because you think it is unsafe. Let others use it if they wish. Once they are there, then you might reconsider using it. . . .

When I first saw [Tom’s approach], everything fell into place. This concept is similar to KP's lochon model to overcome the nuclear Coulomb barrier and, when properly extended, is sufficient to explain all of the other CF data observed. Tom hasn't gotten to that latter point yet, but my ICCF-15 presentation (to be posted here after Tom finishes his model) describes the rest of this story. Please, note your objections (for future discussion); but, let Tom continue unless someone else finds it difficult to continue without more detail.

Andrew also commented on so-called “zero point energy” (ZPE), discussed in another thread. Recognizing reality of ZPE, someone compared proposals for using this energy to attempts to get work or electricity from Brownian motion. Referring to this Andrew wrote: “. ....Brownian motion again: the moving particles can do work; they move other particles. If micro-resonators were put into motion by the thermal activity, then they could generate fixed-freqency AC currents that could be rectified to give useful energy out. Even if all the waste heat were recycled to the thermal bath, the bath would cool unless compensating heat was added. While this can be done in theory, it is not cost effective. ZPE is similar to Brownian motion, but at an even smaller scale....."

Ed responded:
Point noted Andrew. My problem is Tom's inability to explain his idea in a way I can understand or agree with. He knows only the language of QM, which is the only viewpoint he will accept. Reality can be explained many different ways and each is equally valid within its limitations. I find the best description to be a mixture of methods, especially when QM moves too far from easy understanding. As you noted, my patience is thinner than it should be because I have studied all of the various theories and find them filled with unsupported assumptions, therefore a waste of time. I'm especially impatient with claims that a viewpoint based on QM must be accepted just because QM is too complex to understand or because the description is textbook correct. I'm presently writing a paper in an attempt to bring together all of the relevant experimental understanding so that some of the theories can be properly tested against reality. I'm of the belief all math must be related to what can be measured, hence it must be understandable in terms of the variables and conditions we can control and measure. Anything short of that requirement is hand-waving, which is a very common practice in theory.

Meanwhile, I agree with Tom, a special kind of bonding is required to create a structure that can shield the Coulomb barrier. QM might have a role in explaining this bond provided it is applied to the correct conditions and assumptions. Mills proposed a similar bond that has been rejected using QM. It would be great irony if QM could be used to justify

such a bond. Anyway, I will stop critiquing Tom's description as you suggest and wait patiently for him to complete his description.

I might add, I find this discussion very useful because it forces me to consider approaches and understanding I would normally ignore. So, I encourage Tom in his efforts and wish him success.

Andrew added:
Ed, I don't want to discourage your critical and careful analysis. Please continue to comment on areas that you have difficulty accepting. Just don't expect them to be resolved immediately. A brief comment won't slow progress and it will help Tom, and others, to note areas that may require more work.

My understanding is that Tom acquired QM recently - by a lot of hard work. He might appear to have the convert's enthusiasm, but I believe he spoke the classical language previously. (I may be wrong, but I don't believe that his critical revelation came from QM.) However, I think that he also recognizes that if a model, right or wrong, is not couched in QM terms, it will not be considered valid by the rest of the Physics community. So he is doing a triple service:

1) he's teaching some of us, and bringing many of us up to speed on, the language of QM.
2) he's giving us the language that might make CF acceptable to modern physics.
3) he's proposing a model, which may not be completely correct or complete, with aspects of what I consider to be the best chance of breaking the CF-modeling dilemma.

I also look forward to seeing your paper. From some of your comments, I feel that there are areas on which I would like to see more data.

Ed added:
Tom, as Andrew suggests, please go on with your explanation and I will hold my comments until you have provided the entire picture. In the process, please be aware of the assumptions you are making. I agree, a novel electron bond is required. If you can prove, using QM, that such a bond exists, you will beat Mills at his own game. However, as you discovered from my comments, this will not be easy. Also, remember QM is not the only way this bond can be explained if it is real. Anyway, I look forward to your description.

385) Cavitational effect on radioactivity (continuation).

Ludwik Kowalski

Montclair State University, New Jersey, USA
December 7, 2009

1) **This is an update on what I wrote in Unit #378,** about the report of Cardone et al. In addition to the first four publications listed below.

I subsequently discovered a short note (June 8, 2009) on the same subject in CERN Courier . The author, John Swain, wrote: "It is a common belief that radioactive decay rates are unchanged by external conditions, despite many examples of small shifts (particularly involving external pressure and K-capture decays) being well documented and understood. However, Fabio Cardone of the Institute per lo Studio dei Materiali Nanostrutturati in Rome and colleagues have shown a dramatic increase – by a factor of 10,000 – in the decay rate of thorium-228 in water as a result of ultrasonic cavitation. Exactly what the physics is and whether or not this sort of effect can be scaled up into a technology for nuclear waste treatment remain open issues."

2) Unable to attend ICCF15, I submitted my own set of observations (about Cardone cavitational effect) to Physics Letters. This was two days before the conference. The note I published (6) can be downloaded from my website.

http://csam.montclair.edu/~kowalski/cf/ . . . . . .

Comments on what I wrote would be highly appreciated. I plan to update this unit when new information becomes available.

3) APPENDED ON 12/7/2009

Here is the message I posted two days ago on a private Internet list for CMNS researchers:

"According to an ICCF15 report of A. Carpinteri et al. at

http://iccf15.frascati.enea.it/ICCF15-PRESENTATIONS/S6_O5_Carpinteri_Lacidogna.pdf

neutrons are emitted when iron-containing marble is mechanically crashed. [Google found this paper for me because F. Cardone is one of the three authors.] Their detector, located about 10 cm away from the marble block, recorded ten times more neutrons during the crash than during the crash of marber that did not contain iron. The authors believe that neutrons are emitted from this fission reaction:

$^{56}Fe \rightarrow {}^{27}Al + {}^{27}Al + 2n$

The arrithmetic is correct, 27 + 27 +2 = 56

But the energy threshold of this reaction is 42.3 MeV. Do the authors believe that mechanical energy supplied to the crashing machine is somehow used to make the above transmutation possible? Please explain."

X responded:
"I wonder if the crushing of marble not containing iron produces neutrons? This would correspond to a "placebo test" for drugs. In my--possibly crackpot--theorizing, there may be a rather ubiquitous oscillator present which can be split

to an electron and proton and shock-wave-deformed into neutrons. A crushing force could set up a shock-wave, making neutrons appear "magically." That is, if "Zerotron" isn't just a figment of my overactive imagination."

Ludwik responded:
"(1) The link I provided has a photo of two marble blocks that did not produce neutrons and two blocks that did produce neutrons. Only the second set of blocks contained iron. (2) Hitting a granite stone with another granite stone often produces sparks. This is plasma, between two surfaces. That is what came to my mind. (3) I have no idea how was the fission of iron idea justified. Perhaps it was based only on the 27+27+2=56."

X responded:
[You wrote] 'Plasma between surfaces, spark formation, Iron needed for the neutron formation.' None of this rules out my little speculation of the "Zerotron" involvement. The "Zerotron-splitting" in pair formation supposedly only occurs near 'matter' Deformation would require a smash into something which wouldn't get out of the way or deform easily, perhaps Iron atoms or ions fit that requirement."

Ludwik responded:
In other words, you do not believe their idea that fission of iron is responsible for neutrons. In any case, it is too early to speculate; let us wait till results are independently confirmed by others.

X responded:
As for me, I simply don't know, I tend to be skeptical about neutron formation because of my skepticism as to the presence of neutrons per se in atomic nuclei... The fission of iron could be the explanation. I'm pointing out that there may be some other explanation for neutron formation in a lot of cases. ..... "

Ludwik responded:
No, this kind of fission could not be the explanation. The energy threshold for that particular reaction is 42.3 MeV. Where would it come from?

386) Integrity or hypocrisy?

Ludwik Kowalski

Montclair State University, New Jersey, USA
December 19, 2009

The web site of The Physics Today had a discussion thread on integrity:

http://blogs.physicstoday.org/newspicks/2009/12/opinion-scientific-integrity.html

On December 18, 2009 I submitted the following comment:

Fred Dylla wrote: "There are of course interesting physical phenomena with fractoemission in solids and within cavitating liquids but not as nuclear energy sources."

Yes, something seems to be going on but it is not understood. Furthermore, experimental results, even those reported by recognized experts, are often not reproducible. I think that attempts to verify claims made by experts should be encouraged.

In a recently published book, “The Science of Low Energy Nuclear Reactions,” Ed Storms summarizes cold fusion claims and provides references. The book is available at www.amazon.com .

The so-called “cold-fusion episode” is unprecedented in many ways, especially from the point of view of sociology. It will become an important part of the history of science, no matter what.

Ludwik Kowalski
Professor Emeritus (Ph.D. in Nuclear Physics, 1963)

After being informed that my comment has been posted (by Paul Guinnessy
Manager, Physics Today web site) I checked that all four short paragraphs were posted, as above. But going to the web site later I discovered that two changes were made:

a) The third paragraph, referring to Storms’ book, has been removed.
b) The last line, below my signature, has also been removed.

Who decided to change the content of a message that had already been posted and why? I can only speculate about the motivation; probably someone did not want readers to know about Storms’ book. The name of the thread, by the way, is “Scientific Integrity.” The term “integrity,” according to Wikipedia, is

in contrast to “hypocrisy.” Was the third paragraph removed for the sake of integrity or was it removed for the sake of hypocrisy?

Added on December 20, 2009

Another message on the ongoing thread about Integrity was prepared. But I was not able to submit it. I tried about ten times and each time the error message told me that the displayed words were not typed in properly. That is practically impossible; they were easy to recognize and I was very careful in typing them. It must have been something else. In any case, here is what I wanted to post:

Like many others, I was very excited when the discovery of the so-called “cold fusion” was announced in 1989. Then I was convinced that no sufficient evidence was presented for a claim that a nuclear phenomenon, like emission of nuclear particles or transmutation, can result from a chemical process, such as electrolysis. In 2002 I was surprised to discover that the cold fusion field is not dead. I started reading reports of recent investigations and attended several international conferences devoted to cold fusion. I am still waiting for at least one cold fusion protocol reliably producing a nuclear effect due to a chemical process.

But I also discovered that many cold fusion researchers validate their findings in the same way as mainstream scientists. They perform experiments, they discuss them, they speculate about theoretical models, etc. In other words, they are not voodoo scientists; they stick to scientific methodology of validation. Unfortunately, they are often treated as if they were voodoo scientists. That is very unhealthy. Starting this thread Frederick Dylla wrote “Science is by its very nature an exploratory, trial-and-error venture which is also—sooner or later in every case—a self-correcting exercise.” He referred to a Soviet agronomist Lysenko, whose false theory was finally rejected. Stalin supported the theory by silencing qualified opponents.

The cold fusion controversy would be resolved much faster if investigations in that area were treated like other projects of qualified scientists. Silencing the proponents is not helpful. My objective reports and comments, on what is going on in the cold fusion field, can be found at

http://pages.csam.montclair.edu/~kowalski/cf/

The last item (#386, at the end of the long list of links) is devoted to this thread. In my opinion, Physics Today should occasionally inform its readers about new claims made in the cold fusion field. This would probably lead to useful results (clear yes or no answers about reproducibility). Scientific controversies, as we all believe, should be resolved by scientific, rather than administrative, means.

Storms’ book, available at www.amazon.com , is the only recent systematic review of the controversial cold fusion field, as far as I know. Ed Storms is a retired LANL nuclear chemist. I strongly recommend his book to serious scientists. The new name for “cold fusion," by the way, is CMNS; it stands for Condense Matter Nuclear Science. Another often used name is LENR; it stands for Low Energy Nuclear Reactions.

387) Future of CMNS

Ludwik Kowalski

Montclair State University, New Jersey, USA
January 31, 2010

1) Future of cold fusion has been mentioned in the private discussion list for CMNS researchers. Last night Ed Storms wrote:

". . . Physicists seem to think they are the only evaluators of reality and they have applied their approach to cold fusion. This approach involves ad hoc assumptions about ideal conditions and application of mathematical models. Such an approach cannot be tested because it does not describe actual reality in this case. If they had been the evaluators of early chemistry, early genetics, or even the invention of the light bulb, these fields would have been slow to develop as well. While you might think this conclusion rather extreme, nevertheless, no theory will be accepted because none can be tested until the nature of the required material is understood. Once Fleischmann and Pons claimed a nuclear process, which let physics into the discussion, they were doomed. The field will continue to be slow to develop until this attitude changes or until someone finds the active material by accident."

2) Responding to this I wrote: "Another very powerful trigger would be a single reproducible-on-demand demo of a strong nuclear effect, such as undeniable transmutation or emission of tritons, resulting from an atomic (chemical) process.

What would I do if I had the power and the means to proceed toward such a goal? I would start by selecting (in consultation with others) several most promising CMNS protocols. The protocols would be ranked as #1, #2, #3, etc. Then several teams of competent researchers would be asked to verify the claim made by authors of Protocol #1. Sooner or later they would come up with the answer. Their "yes" would mean that the goal has been achieved; their "no" would mean that Protocol #2 should be tried, by selected groups of competent researchers. They too would deliver a clear yes or no answer., sooner or later. Then the same for Protocol #3, etc., etc, till the last protocol is tried, as schematically illustrated in Figure 1. Yes, I know that this would not be easy in practice. But is it possible in principle? I think so. Do you agree?

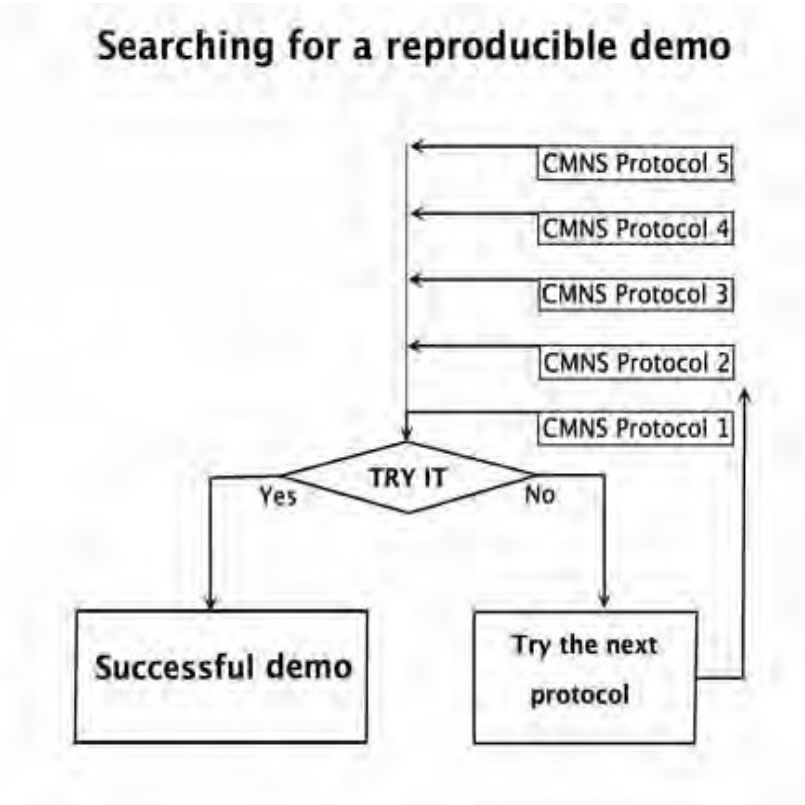

Figure 1
Desirable strategy for making progress in CMNS field.

3) Responding to the above, Larens Imanyuel wrote "I find your approach too rigidly methodical. A successful scientific debate in a difficult field is more like the case study of a Sun Tzu battle." [According to Wikipedia, San Tzu (6th century BC) wrote "It is said that if you know your enemies and know yourself, you will not be imperiled in a hundred battles; if you do not know your enemies but do know yourself, you will win one and lose one; if you do not know your enemies nor yourself, you will be imperiled in every single battle."]

4) Responding to Larens, I asked:

(a) What kind of battle are we fighting?
(b) Who are our enemies?
(c) What should we know about them?
(d) What should we know about ourselves?

5) Responding to the above, Larens Imanyuel wrote:

(a) "The battle is to have LENR recognized as a fundamental physics breakthrough within the international scientific policy process, so that LENR get the scientific resources they deserve.
(b) Scientists who have not been open-minded about LENR.
(c) We need to know which scientists to win over with which arguments, so as to destroy the alliance against us.
(d) We need to know those biases within us which have prevented us from winning the battle."
6)
6) One researcher wrote that CMNS "cannot be explained by conventional physics." Another wrote that "nothing about CF requires new physics. I agree, some physics will have to be modified in ways that have not been considered." This led to an argument. Referring to the second researcher, the first one wrote: "You are asserting your belief as fact here. It is your obligation within the discussion to present some type of proof that new physics is not required."

The proof will be in the pudding. A theory predicting reproducible experimental data will be accepted. Will it be based on conventional physics or will it be based on something totally new? This remains to be seen.

7) The most important task, for the time being, is to find at least one reproducibl-on-demand protocol yielding a strong nuclear process resulting from an atomic process. A challenge to theoreticians will be not only to explain that nuclear process but also to show that a successful theory predicts new reproducible phenomena. That is what I learned from those who described scientific methodology of validation and acceptance. I strongly believe that the discovery of the first reproducible protocol will speed up process of understanding of CMNS phenomena.

8) No one contributed so far. That shows that what is on my mind is not necessarilly on the minds of others. Here is how this unit was announces, about 15 hours ago: Capturing what we think about the future of CMNS (for future generations) is important. With this in mind I started composing a new unit:

http://pages.csam.montclair.edu/~kowalski/cf/387future.html

So far this link is "secret;" please do not share it with others. I will let you know when the unit becomes public. Ed already gave me permission to quote. I hope Larens will do the same. Please contribute to this thread. Or send me a private message with something to insert. In that way no one on this list will know who the author is. Unless I have permissions, names will be replaced with X, Y, Z, etc., if you prefer. But let me know.

Added on 2/2/2010

9) A question about resonant tunneling was asked by X. Not being a theoretician, I usually stay away from mathematical analysis of CMNS problems. What follows is quoted to show that, contrary to what many outsiders believe, disagreements and personal friction, also exist in CMNS community. We are not a mutual admiration society. Responding to X, Professor Y wrote:

In Professor Li's work, unlike mine, he solves Schroedinger's Equation for a complex wave function, which has a phase rather than merely an amplitude as I have. Therefore he can compute a reaction RATE rather than get a simple YES/NO answer.

Every one of the half-dozen theorists whom I mentioned in my MIT Colloquium presentation is doing some aspect of the problem in greater detail than am I and "my" answer could be improved if they would examine the same scenario that I did but with more detail.

For example, Drs. Talbot & Scott Chubb usually consider a 3D lattice whereas I [like Schiwinger] have simplified the problem to a 1D approximation in order to be able to get an answer more easily.

In Prof. Yeong Kim's work, he is solving the actual Schroedinger equation EXACTLY rather than just using the widely accepted standard approximate solution which is easier to use and is what I used. I have told Prof. Kim that if he considered the boundary conditions of the lattice (rather than just the two isolated nuclei) he would get an improvement in the theory which I have been advocating.

Likewise "my" theory could be improved if one included the phonon aspects, as does Prof. Peter Hagelstein, in order to include the subject of the post-fusion energy being transferred to the lattice in the form of lattice excitations or heat.

But NONE of the other theorists in the field has ever even cited the Y's work, nor any of my four "proofs" of varying degrees of simplification, much less improved upon it as I have often expressed the hoped that they would!

Added on 2/3/2010

10) X2 wrote: "There is a conflict here between political styles. I see the necessity of an initial political phase of building personal relations, before trying to win a political battle in a large forum. These behind the scene personal relations are what is going to insure victory in the large forum. If newcomers feel a "get to the back of the bus, we old-timers are running the show" attitude, the necessary positive social relations will not be built. That is why I am

working first to build working groups that can move our agenda up the scientific bureaucracy."

11) X3 responded:
"I agree with you, building trust and inclusion is essential. As far as I can tell, this is the general policy of the field, including my own. Relationships are currently being built between a wide variety of institutions. In the process, two other dynamics are operating. Efforts are being made to bring a higher standard of experiment and theory to the field. These efforts involve criticisms that can cause resentment. At the same time, some people care only about their own self-interest, which they promote by criticizing efforts to improve the quality of the work. Therefore, some conflict in the field is to be expected, as exists in all fields of human effort. The solution is to collaborate with those people who are working to advance the general field and who take a completely objective approach to the effort.

12) Another exchange between X3 and X2 (X3 in blue and X2 in red).

The November 13 DIA technology assessment makes clear that LENR experimentation has been rapidly expanding, and that this is bringing a "higher standard of experiment".

True, but I'm talking about the field policing itself by peer review. This process is happening as people exchange preprints and ask for critiques. Unfortunately, everyone does not do this and some take the criticism personally.

A comparable increase in resources has yet to occur on the theoretical side. Since Julian Swinger resigned from the APS over their hostile CF policy, people wanting to pursue the fundamental physics of LENR have had to be self-supporting.

True, with a few exceptions.

By "fundamental" I mean new simpler mathematical formulations that are correct by Occam's Razor. These do not require any new experimental LENR breakthroughs, though cleaning up the existing results will be useful both for theory and for being more persuasive to the larger scientific community. The theoretical breakthrough, can only occur, however, if the "newcomers" are granted enough resources to effectively collaborate on cleaning up relevant known fundamental theory. Their efforts to obtain these resources is currently at the stage of negotiating on the "shape of the table and the height of the chairs".

I agree, not much resource is being applied to theory. However, for a person to make a useful contribution, they need to master what is known, which is not an easy job.

When you talk about people "who take a completely objective approach" you are talking about an empty set. You by your own statement are strongly in the camp that new experimental results will be necessary.

By an objective approach I mean not being in love with your own ideas to the exclusion of other possibilities. I find many theoreticians are so sure they are right that no argument, no matter how well researched, has any effect on their approach. Of course, a person should be an advocate for an idea, but this has to have limits.

13) The issue of money was raised. Responding to this, X2 wrote: "If i were given 10 M$ to set up a laboratory and 5 years of guaranteed support, I would have no problem getting the people. This economy and the situation at LANL would provide many well trained and talented people if the lab were set up in Los Alamos or Santa Fe. This effort could also involve creating a department of LENR at UNM. No, the problem is the willingness to risk money on this subject. Money will flow into the field cautiously and it will be focused on the big laboratories such as NRL and SRI. Eventually, the so-called national laboratories will want a piece of the action. As this money produces success, more will enter the field and be directed by the conventional scientific establishment because they have the experience and the trust to properly direct money. However, a lot will be wasted because, as X3 says, a special knowledge set is required. The conventional money managers will not recognize this requirement. Talent is available, only awareness at the management and funding levels is lacking, at least in the US."

Added on 2/4/2010

14) As I often repeat, money and administrative support will probably materialize very quickly after at least one reproducible-on-demand demo of a nuclear process due to an atomic process is offered. An example of a nuclear process is emission of energetic photons or p rojectiles, changes in isotopic ratios, transmutation of elements, etc. An example of an atomic process is electrolysis or another chemical reaction, diffusion, glow discharge etc.

The best candidate for such demo seems to be creation of helium during electrolysis. This kind of nuclear transmutation was independently reported by at least three teams of highly qualified researchers, two in the US and one in Italy. These are the only studies in which excess heat and the nuclear effect were shown to be correlated. More than several MeV of excess heat is generated for each atom of produced helium. In one study (M. McKubre) the reported value was close to 23 MeV per helium atom. If I had the expertise needed to perform such investigations, and access to required instruments, I would certainly try to independently verify results reported McKubre, Miles and De Ninno. Focusing on reproduction experiments seems to be more desirable, at this stage, than searching for new CMNS phenomena.

Sustained commercial success--for example, in generation of excess heat, even without understanding of the mechanism, would also precipitate interest and support. Such scenario is possible, at least in principle. But it is very unlikely. I am thinking about the proverbial blind chicken trying to find a grain of corn by pecking randomly. Most new applications are now based on scientific understanding of underlying processes.

Added on 2/5/2010

15) The last comment above made think about two kinds of research projects, replication-oriented and discovery-oriented. The first kind is more likely to be successful than the second kind. Why is it so? Because in the first kind situation success depends only on the skill of researchers. To succeed in the second kind of situation one must not only to be skillful but also lucky (in choosing the topic). My thesis adviser told me this in France, nearly five decades ago.

My definition of “replication experiments” is broader than “strict replications” of what has already been done. It includes “analytical experiments” in which the goal is to learn something about a phenomenon know to exist, or to measure something. Trivial examples are (a) measuring the resistivity of a new alloy or (b) learning how that resistivity depends on temperature. What we need in CMNS field are strict replications verifying reported results, preferably in different laboratories (to confirm reproducibility).

By the way, most experiments performed in school laboratories belong to the first kind. The same is true for most experiments performed by professional researchers. A question is asked and an experiment is performed to answer it. For example, (a) “how does the cross section of a particular nuclear reaction depends on the kinetic energy of projectiles?” or (b) does a theoretically-predicted particle (such as neutrino) exit?” Success in performing such experiments depends only on qualifications of experimentalists. A success means to produce a convincing yes or no answer. Discoveries of unexpected things usually occur during analytical experiments. Most experiments in which I participated were analytical. Only once was I lucky to participate in a discovery of something unexpected.

16) Larens Imanyuel wrote:
“Since people have been accustomed to thinking in 4-D physics, they generally ask, "Where are all those new dimensions? when presented with a higher dimensional theory. In this posting I will present the answer to that question intuitively before I get into any formal mathematics.

3-D is exceptional, because the number of degrees of rotation equals that of translation. Instead of points, we can take helices to be the fundamental geometrical object, each with an axis of translation, a plane of rotation, and a phase. We may then use a three dimension array of numbers to develop the dynamics, which gives a 3 cubed = 27-D space. This is best decomposed into subspaces as 27 = 8 + 8 + 8 + 3. One 8-D space is the double of our conventional 4-D space, arising because helices, unlike points, exist in both left and right handed chiralities. Time and temperature are a new pair of dimensions. This pair easily admits a thermodynamic direction to time, unlike in conventional physics. Since in

27-D space there are multiple degrees of freedom for time, observed time is an average over them - the same as temperature is the average over degrees of freedom of energy. Time and energy are conjugate, of course, because their product is action.

The existence of three 8-D spaces may be associated with the temporal and philosophical triality of actors who exist in the present, observe the past, and act upon the future. The 16-D projection into the past and the future exhibits strong dualities in which there are equivalent ways of expressing the same physics. One of these is the particle/wave duality of conventional quantum mechanics. There is a cosmic one in which in one frame the observed universe is always the same size, and in another the universe is expanding from a Big Bang. A fundamental one is that the change from future to past may be represented by either the change in the sign of a number, or by switching between two completely different metrics.

The structure of one 8-D space describes the length preserving transformations in its associated 16-D space. Within a 16-D space one 8-D subspace represents a transformation of the other one. The Standard Model of Particle Physics may be derived from this structure. The triality appears alternatively as three generations of particle, and as the tripolar charges of the strong force.

The 3-D subspace of the 27-D space is a nonparticle space in which scaling effects more than one dimension at a time. For instance, scaling the area of the plane of rotation of a helix, will give you one nonparticle dimension in a set of three. This 3-D space is essential for the simple description of condensed matter science. Each dimension admits solutions to the general quantum three-body problem giving fractal binding energies. Canonical states of matter may be constructed using the known properties of isotopes and matched to important physical features. One of these relates to the geometrical mean between the largest and smallest times in the universe, i.e., the age of the Big Bang and the reduced Planck time. This ratio may be calculated from information theoretic considerations and matches observation to the accuracy of the condensed matter physics involved. Virtual states are needed to construct the cold fusion reaction. The "magic numbers" for atomic number and mass may be calculated from the number of elements in the 8-D space structure. LENR extends beyond these magic numbers, however, so a higher order theory needs to be constructed. Presumably this will use virtual light isotopes arising from heavier isotopes.

This theory differs from conventional string theory in using commutative operators over 8-D division algebra, rather than anticommutative operators over "geometric" algebra. By a long known result 27-D physics is an extension of conventional quantum physics. The closest conventional string theory is the exceptional 16-D compactification of the heterotic string."

17) Responding to the above I wrote: "I agree with Ed Storm that such mathematical speculations should not be part of CMNS struggle for acceptance. They should first be used to explain non-controversial experimental data. Mixing two not-yet-acceped considerations is likely to counterproductive. "

18) Larens Imanyuel responded"
"Ludwik, Science is not a popularity contest. All the declarative sentences of my "intuitive" explanation of 27-D physics are backed up by some type of more formal mathematical explanation. It is more likely to be proven correct than is the Higgs boson likely to be discovered. The double standard whereby the consideration of my theory is dismissed as "speculation" and the hypothesis of the Higgs boson presented as "fact" must be rejected itself for scientific progress to proceed. As I explained the 3-D nonparticle subspace of 27-D theory is essential for CMNS; and it does not exist in the old theory.

In case you haven't followed, the existence of the Higgs boson is being challenged by nonparticle Higgs mechanisms and the "un-Higgs" pseudo-particle, so conventional particle physics is having to get into this realm. There is no other serious, useful fundamental theory of physics other than the one I gave, because I have based it on fundamental mathematics. Another theory may use a somewhat different mathematical form, but must have basically the same physical content. Some of my intuitive statements will probably have to be modified once all the proofs have been worked out, but there is no good reason to think that the basic content will change much.

Only trying to first explain "non-controversial experimental data" would be a strategic disaster. To gain acceptance a

new theory must explain evidence that conflicts with old theory. All such evidence is by nature "controversial", because it does conflict with the old theory."

19) Ludwik responded: "I am probably not the only one on this list who knows very little about Highs boson or string theory. That is why I think that such topics do not belong to CMNS. The same applies to other exotic topics: vacuum energy, magnetic monopoles, etc. Such interesting topics are, or should be, debated outside of CMNS. Let us focus on four nuclear claims: (a) transmutation of elements, (b) changes in isotopic ratios, (c) emission of energetic radiations (alpha, beta, gamma, protons, etc.), and (d) generation of unexplained excess heat. What is wrong with this suggestion? What can be gained by making string theory part of CMNS? "

Responding to a comment made by another researcher, I added: "Yes, we do need some kind of a limit. But where should the limit be placed and how to implement it in practice? By the way, I do understand creative people's desire to share. Seeking readers and listeners is part of human nature. And I do not mind reading what they have to say, provided I able to follow it. The message to which I was responding was indeed quite interesting."

= =

Added on February 12, 2010

20) The discussion initiated several days ago restarted when X5 asked "Larens, how about educating an old man a little. Can you define for me, each of the 27 dimensions which are involved?" Responding to this I wrote " I know that there is a deep answer. But let me give you a naive one: Larens will probably reject it.

Suppose we use Newton's frame of reference; it is fixed with respect to distant stars. You need only three coordinates to identify position of the center of gravity of an object. To deal with velocity and acceleration of the center of gravity you also need time; that is the fourth coordinate. You also need coordinates associated with possible orientations of a rigid object. Suppose the object is not rigid, like who rigid spheres connected with a spring. You need to describe possible oscillations. Suppose the object is biological, for example a human being. Then you need a coordinate for the body temperature, a coordinate for heart beating rate, a coordinate for the rate of sweating, and coordinates for rate of breathing, digesting, thinking, etc. "

21) Responding to someone else Larens wrote: "Part of the problem is the difference in the meaning of "dimension" between math and physics. What physicists call "degrees of freedom" are often called "dimensions" in math. In mathematical physics the number of dimensions of a system is generally the number required to get a "true representation" of it.

A similar confusion occurred when Einstein extended the use of the word "dimension" from 3-D "space" to 4-D "spacetime". "Temperature" is a collectively defined variable, which may be included as a "dimension" along with time when we extend from "particle" physics to "condensed matter" physics. We need to double the size of 3-D space when we replace translations by rotations to get a realistic local action. Each rotation is coupled with a nonzero differential translation to get a helix. The nonzero condition arises, because with QM no particle with a finite wavelength can have zero momentum. The space is doubled, because helices come in two different chiralities.

The resulting 8-D space is tripled to 24-D by the "strong triality" of division algebra, but the 24 dimensions cannot be labeled "exactly" in conventional terms, because of multiple interpretations. One of the simplest to understand is that there are three "generations" of particles differing only in mass. The nonparticle subspace of 27-D physics is a 3-D translational space, the same as conventional 3-D space, but applies only to condensed matter physics and not to particle physics."

22) X6 responded: "Thanks, I now understand. In this definition, an equation of the form X = A +By +Cy^2+Dy^3 + Ey^n would have n dimensions. By 27-D you mean that 27 individual quantities are needed to define all aspects of a material. Being a chemist, I suggest this is a gross under estimation."

23) Larens responded: "You are coming from a position of dogmatic Western dualism. This is a temporary cultural

phenomenon arising from the fact that the physics of Western culture has not yet been mathematically sophisticated enough to address the existence of consciousness in the universe. It is time to move on.

Western physicists have also insisted on putting the labels of "length" and "time" on mathematics that is intrinsically "dimensionless". Correcting this problem results in multiple interpretations of the mathematical dimensions - which are in turn denied, because the physicists are not yet philosophically aware of their problem. To give an "exact" definition of all the dimensions will probably take mathematical physicists several decades. . . .

I have stated that my theory includes "actors that observe the past, act upon the future, and relate to one another in the present." This statement includes the concepts of cognition and volition that define consciousness. .....I stated earlier that 27 is the necessary and sufficient number. To get into a detailed explanation would require more mathematics than I can get into in an "intuitive" explanation of the physics, for my audience is not familiar with the mathematics.....I explained earlier that I am using the definition implicit in modern geometry, but that these dimensions may relate to different meanings in terms of conventional physics."

24) Ludwik wrote: "Conflicts can often be avoided when different meanings are not assigned to already-used words. In this forum the term 'dimension' should be used as defined in physical sciences. We refer to four essential dimensions: L, M, T and I. In the now-used system of unit (SI) these four dimensions are represented by meter, kilogram, second and ampere. Introducing another meaning to the word dimension can create confusion.

25) Larens responded: "By introducing another standard usage of the word 'dimension', different from either the way Ed and I were using it, you have highlighted one of the fundamental problems of language. No one can demand that their particular use of a word with multiple definitions is the 'correct' one. Everybody needs to be aware of potential confusion and to define their terms."

26) X6 responded: "No, the definition of words is universal. It does not matter what "dogmatic" view a person has, concepts cannot be communicated unless the words have shared meaning. I find that people who have no idea what they are talking about want to keep the meanings ambiguous so that their ignorance is not revealed. I'm not suggesting this applies to you. I agree, many things about this world are not easy to define because so little is known. However, simply throwing out a collection of arbitrary words does not help this situation. For example, if you use the word consciousness, then I assume you know the meaning you intend this word to have. I can understand what you mean only if you give a definition. To me, the word means being aware of self and being able to demonstrate that awareness. A rock, for example, is not conscious because it has no means to be aware of self. Even a dead person is not conscious even though he might be having an after-death experience because he cannot communicate that experience. What is your definition of consciousness?

I take your point and an exact definition of all dimensions is, I agree, too much to ask. However, some basic definitions would help. Simply stating that 27 dimensions exist is not helpful unless you have some reason to believe this is true. Why choose 27? Why not 50? No matter what number you chose, each example has to be described by the same general definition of dimension. What is the general definition?"

27) Ludwik added (referring to his last message above) : "We often use x and y axes to show how one quantity depends on the other, for example, acceleration versus time. In that case dimensions are different along each axis, [(L/T^2) for acceleration and (T) for time. But this is no longer true when coordinates are used to represent space, either 2D or 3D. In this case all dimensions must be (L).

The fourth dimension, introduced in the theory of relativity, is said to be time. This is not true. The forth dimension is c*t, where c is the speed of light. In other words, all four quantities are dimensionally identical; their dimension is (L). Is the same true when one deals with the 27D space?

28) Larens responded: In 27-D physics dimensions are labeled by factors of action or their inverses. Multiplying all the dimensions together should give you the number one. You may also interpret all these labels as coming with constants of proportionality in the manner you did with c, so that each dimension is equivalent.

29) Ludwik: I have no idea what the factor of action is. It is obvious that I am not prepared to understand Larens. The same is probably true for most people on this list. He should address people with the same theoretical backgound. Why is he wasting so much effort on us?

30) Dean Sinclair wrote. " . . . As to different Chemistry and Physics approaches, the theoreticians of both "Fields" tend to cloak their ideas in abstruse mathematics. The more abstruse it is, apparently the more prestigious it is. Actually, the separation of the field of science into many disciplines obscures the fact that all are examining the same thing, the mystery of existence."

31) Larens responded: "Ludwik, I am sure you understand what a "factor of action is". It is just that you have not seen the phrase before. Length, area, time, mass, velocity, momentum, energy, action, etc. are all factors of action, with action most often being factored as momentum times length or energy times time.

32) Ludwik: Why does he need a new term for what is usually called physical quantity?

33) Larens: " 'Physical quantity' is a more comprehensive term than 'factors of action'. Electromagnetic units are physical quantities, for instance, but not factors of action."

34) Ludwik: As far as know, electromagnetic units (such as volt, ampere, ohm, tesla, or V/m) are not physical quantities. They are used to evaluate physical quantities (how much, how strong, etc.).

35) Larens: "As long as we are splitting nanowires - unit quantities are a subclass of quantities."

36) Ludwik (not posted). I know what units are but the meaning of the new term "unit quantity" is not obvious to me. Why do we need it? I do not want to argue about definitions. That is why I am giving up responding. What the CMNS field urgently needs, at this time, are reproducible experimental results demonstrating reality of chemically-induced strong nuclear process. Speculations should be based on such results.

37) Responding to another researcher, Ludwik wrote:
"A mathematician does not need experimental data; s/he can make any set of assumptions and derive resulting consequences. Consequences are valid, unless there is a mathematical (logical) error in the derivation.
But absence of logical errors in a derivation is not sufficient in physical sciences. In that area theoretical derivations are evaluated by reproducible experimental data. Theoretical physicists make predictions and experimentalists test them, in order to validate theories. That is what X7 is saying. I agree with him. We are not mathematicians."

I made this observation before and no one objected on the list. I wish the CMNS forum were dominated be comments about new and old experiments, and by testable theoretical predictions. Unfortunately this is not the case.

Added on February 20, 2010

Larens continues posting messages which i do not understand. But that does not mean that his observations are not valid. I would be even more confused by reading observations of well known theoretical physicists, such as Pauli and Dirac.

38) Responding to X8, Larens wrote:
"The 'strength' of a particular reaction is a function of the 'range' and 'coupling constant' of the relevant gauge boson. 'Range' and 'coupling constant', however, are mathematically independent concepts."

This prompted me to ask the following question: "I suppose that the term 'strength' is the same as cross section, usually expressed in barns. But what is the 'coupling constant' and in what units is it expressed? How is it determined for typical well known reactions?" I hope this question will be answered tomorrow. I know what the spring constant is (expressed in N/m), for example, when it couples two macroscopic objects. Perhaps Larens' model consists of nucleons connected by linear springs. That would be a reasonable model. But he did not say this.

Meanwhile Larens posted another message: "OK, here is a question for the experimenters: What should theory provide for the experimenters, so that they may increase the reproducibility of LENR enough to support the design of commercial equipment? Your answers may help the theorists set their priorities in a field where theory is quite difficult." That is a good question. Pauli, for example, predicted existence of particles, named neutrinos, and described their properties. Knowing what to expect experimentalists were able to design experiments confirming existence of predicted particles. Hundreds of experimentalists, all over the world, have been studying properties of neutrinos for many decades. Neutrino experiments, for example at BNL, are reproducible-on-demand.

Responding to Laren's question (about how to help experimentalists), X10 suggested that theoreticians should tell us how to maximize the reaction rates. That would indeed be very useful if experimental results were reproducible. Unfortunately, we are still waiting for this luxury. For the time being the most important task of a theoretician (who wants to help) is to tell us what to do to make experiments reproducible. In other words, to use the term NAE (Nuclear Active Environment), introduced by Ed Storms, a theoretician should tell what the NAO is and how to create it. Naming something is not the same as knowing what it is..

Added on February 21, 2010

Not surprisingly, **Storms responded:**
"This is a good question, Larens, and at the risk of wasting your time, I will provide an answer. A theory must do the following at least:

1. Identify the materials and real-world conditions required for the LENR mechanism to operate.

2. Describe a mechanism that is consistent with all observed behaviors both with respect to LENR and to all other fields of science.

3. Describe a mechanism that does not violate any basic laws of Nature.

4. Identify behaviors uniquely related to the mechanism that can be clearly tested in the laboratory.

5. Provide a clear description of the mechanism with a rational justification of its reality. This is necessary to justify the investment of time and money to test the claims.

Without #1 being satisfied, experiments cannot be made reproducible. Without #5 being satisfied, no one will take the time to test a theory. So far, no theory has satisfied these two essential requirements. Most violate some or all of the other requirements.

I say this after having taken the time to evaluate all published theories. This has resulted in a paper that might be published someday. Meanwhile, Brian and I are searching for a mechanism that does satisfy all of these requirements. This is a difficult task unless a very open mind is used to explore ALL possibilities. I suggest, professional theoreticians have largely failed to find a useful explanation because of their obsessive commitment to a particular approach, even in the face of their failure to explain essential behavior. Theory needs the same open mind that we in the LENR field insist skeptics show when evaluating the claims based on experiment. In addition, theoreticians need to explain their ideas with tolerance and care so that their ideas can be understood and applied by experimentalists."

39) Another experimentalist, Dennis Cravens, wrote:
As an experimenter, I look for definite predictions of theories. Predictions connected to my "knobs" that I can turn. Theories that say that the reaction is via particle X, Band structure Y, nuclear reactions Z do not help me too much. I what to know things like: does it predict to turn up my temperature, increase currents, make smaller points on my cathode, make materials with magnetic properties, add some materials that allow for spin exchanges, use light of a given frequency, avoid material X, make particles of size Y, pulse the current, impose a temperature gradient, impose a magnetic field, ……

After most theories I read, I see nothing that helps me know what to do in the lab. Most don't seem to give me

anything I can use in the lab. Give me nuts and bolts.

In short, give me a theory that makes predictions and is connected with physically real and obtainable conditions and materials. Which knob do I turn and how far.

40) Edmund Storms wrote:
". . . Physics is based on a mathematical view of reality from which easily verified predictions can be made, i.e. either a behavior, event or consequence exists or it doesn't. Chemistry or more exactly materials science is different. Such systems are so complex that mathematical predictions are very limited. Nevertheless, the mathematicians make an effort. The result, especially in LENR, is not very useful because it is not related to the real world of knobs, as Dennis says.

Math is based on assumptions, which some people simply ignore. The mathematical equations simple extend and connect these assumptions. If the assumptions are wrong, the math has no meaning. So, I suggest we start examining the assumption for a real connection to reality."

Unless reproducibility on demand is achieved, the future of cold fusion can be described as in a little poem below. Yes, I know that not everything that rimes can be called a poem; I am not a poet. Note that in this context (as opposed to the context of my just-published autobiography, from where it is extracted),"good" stands for "promising expectations" why "evil" stands for "disappointments." Both theoerticians and experimentalist should focus on the absence of reproducibility on demand.

Both good and evil will survive.
To fight each other and contrive,
To show and hide, and to refuse,
To offer something and confuse.

To give and take, to kiss and bite,
To make and break, and to excite.
To promise something in the sky,
To ruin hopes and say good-bye.

To feed and starve, to love and hate,
To burn, to smash and to create.
To wreck, to torture, to destroy
To build, to cherish and enjoy.

Ludwik Kowalski
December, 2009.

41) Larens wrote (responding to my question):
" 'Coupling constants' are dimensionless numbers that express the strength of fundamental reactions with "sizes" being determined by QM relations. The problem is that they are not really "constants", but are functions of energy with different functions for different forces. There is presumed to be a grand unification energy at which the functions for EM, weak, and color forces converge to a single coupling constant. This is far above the energy of any existing instrument, so values of different functions extrapolated to zero are generally given. EM is particularly simple, so extrapolation only gives the fine structure constant."

I am lost again. In any case, the adjective 'constant" should not be used to describe something that is not constant. I still think that the reaction stregth is represented by its cross section.

Larens' 27-D theory should first be tested by comparing its results with reproducible-on-demand data, such as fission cress sections, scattering of neutrons, nuclear transmutations at high energies, etc. Consider the n+U235 fission. The cross section, for neutrons of very low energy, is several hundred barns. For neutrons of higher energies, such as 2

MeV, is becomes close to one barn. How would Larens' theory explain this? Similar questions can be asked about the energy dependence of cross sections (i.e. strengths) of other nuclear reaction. That is what I would do to promote a theory. I do not think that promoting it by using the CMNS results will be successful among typical theoretical physicists. I would discuss the theory on their websites, not of the website where most people are not theoretically oriented.

42) Storms wrote (responding to Dennis):
Physics is based on a mathematical view of reality from which easily verified predictions can be made, i.e. either a behavior, event or consequence exists or it doesn't. Chemistry or more exactly materials science is different. Such systems are so complex that mathematical predictions are very limited. Nevertheless, the mathematicians make an effort. The result, especially in LENR, is not very useful because it is not related to the real world of knobs, as Dennis says.

Math is based on assumptions, which some people simply ignore. The mathematical equation simple extend and connect these assumptions. If the assumptions are wrong, the math has no meaning. So, I suggest we start examining the assumption for a real connection to reality.

Larens responded:
a) Ed, You have made a good summary. A good theory can make rough phase diagrams for ideal materials. The material scientist can then take these, learn how to compensate for non-idealness, and measure specific values for the phase transitions. These can then be used to refine the theory to improve its usefulness. A theory that can explain the 0.875 loading threshold for PdDx has an excellent point of connection with LENR reality, for instance, if it also has good reality connections to the rest of the universe. With at least one such excellent reality connection, there is good hope for it to be predictive of previously unknown phenomena.

b) One cannot expect too much to come out of the theorists rapidly, however. To give an example, in 1955 a group of mathematicians set out to classify all the finite simple groups. After about 500 papers by about 100 authors totaling tens of thousands of pages they announced success. Some holes were discovered. These were patched by 2004. A simplified theorem of only about 5000 pages is now being worked on. The classification includes 27 "sporadic" simple groups (if one includes the Tits group). "Sporadic" means "not in an infinite family" and is equivalent to the word "exceptional" elsewhere in math. It is conjectured that the number "27" is not an "accident", but relates to the 27-D physics I mentioned earlier. This suggests that what we are likely to see in the near future will not be a complete "proof" of principle, but will be a hierarchy of theories that are increasingly ad hoc as they approach the laboratory situation.

c) Chemically assisted nuclear transformations clearly involve energy transfer between different nuclear reactions, because otherwise some of the reactions would violate the conservation of energy. What we need is a joint accounting of all the isotopes before and after a run along with the energy. The complexity of this is comparable with that of contemporary high energy physics, but the equipment for LENR will be much less expensive. The complexity of results should be a good match for the complexity of the theory, so reasonably rapid discovery and development should occur. The LENR community needs to discuss a general plan to obtain and utilize the necessary resources. The offer of resources in the 2004 DOE report might be a point of leverage for discussing the matter with the larger scientific community.

43) Tom Barnard wrote (responding to an earlier message of Storms):
Ed, I have been doing this a long time too. I have read your book. I make judgments, based on my own long experience, on what to believe. You may not like my judgments, I don't like many of yours; we're even. Most experiments are not vetted and not repeatable, so one has to be extremely leery. There aren't too many experimental results in this field that I would call "facts"; just me and my hard won experience talking. I appreciate the criticism. Keep up the good work.

Ed Storms wrote (responding to Larens):
" a) The PdD0.875 threshold has no relationship to the mechanism because this is the average composition of the cathode, not the composition where the effect actually occurs. The challenge is to identify which property is important

to a mechanism. Is it the deuterium content, the availability of important energy levels, or a magnetic effect, to give a few examples? Unless the important basic property is identified, too many materials become possible candidates.

b) I agree, the process will be slow and filled with false starts. However, some approaches are useless and should not be used to waste valuable talent and money.

c) We now know that helium production is the main nuclear product and that the energy released is close to that known to result from D-D fusion. The big issue is the unique condition that initiates the reaction and how energy is released to the outside world. Unfortunately, money is not available to explore all of the possibilities as would be the case if this were an accepted phenomenon."

Added on February 22, 2010
There were an avalanshe of messages, most of them about theories. It is not my role to record all the. Future investigators will be able to find them in the list's archive. But how can I resist quoting four papers posted by experimentalists?
44) Jack Dufour wrote:
"Dear Andrew, I think the point you raised (coupling constant of the strong force) is well documented. For distances between nucleons higher than 1 fm, experimental data are well fitted with $g^2/hc = 14{,}5$. This has been fully accepted by the referees I am discussing with. See also "Le monde subatomic" by Luc Valentin -Hermann (1986) tome 1 p.62. For lower distances, this is no longer valid, but d/d nuclear reactions imply distances higher than 1 fm. The coupling constant of the interaction mediated by the neutral and virtual electron-positron pair (range $h/2m_ec = 193$ fm) experimentally determined in the alpha disintegration case (which I did) is $3.8 \times 10^{-6}\ g^2$ (# $8 \times 10^{-3}\ e^2$). You cannot invoke higher values, otherwise you get trouble with the very well experimentally documented alpha disintegration case. So the (hypothetical) Yukawa plays only a role for energies of the deuteron of a few keV (same order of magnitude as the electrons screening). Its role is totally negligible at eV (room temperature) levels. (NB In the formulas I wrote, h stands for h bar.)"

X9 wrote:
I'm at a loss to understand your attitude, Larens. I simply told you a fact. The value you quote is the average composition of the cathode and it is a fact that the reaction is not occurring at a composition equal to the average. It does not matter to me if you believe this or not. It only matters that you understand what I actually said. Also, I have no theory and I offered none. I simply suggested several examples of properties that might be important. I'm willing to discuss CF with you, but I expect in return you will trying to understand what I'm actually saying.

P.S.
Excuse me for being unclear.

My comment concerned the statement, "The reality is that there is a tight correlation between heat output and loading above the 0.875 threshold", which was then disputed. The statement is fairly accurate, albeit I do not believe this is known to three significant figures. As to the 27-D theory, it or any other theory will have to 'put its neck on the chopping block' based upon experimental data.

Ed Storms wrote:
Tom, I share your definition of like and dislike. Of course, some data is better than others and some data is clearly wrong. That is why I rely on patterns of behavior that is supported by many studies. In addition, I expect people will have different opinions about what to accept and what to reject. I only ask that these opinions be based on logic and fact, not on emotion. My role has been to examine all the published information and apply objective criteria to its evaluation as much as possible. In my comments to you, I'm only trying to share this evaluation. Of course, you are free to accept or reject the information. Nevertheless, people in the field and especially theoreticians need to agree on what is real and what is imagined in both theory and experiment. Otherwise, we will all be going off in scattered directions with no hope of arriving at agreement.

I agree, the meaning of the word 'fact' is sometimes in the mind of the beholder. However, we need some way of distinguishing information that has good support and consistency with scientific understanding from opinion. In my

case, I try to use information that can be well defined and I call this 'fact'. If you disagree, please explain why you think something I said is not "fact" and I may change my mind.

Michael McKubre wrote:
"All, The correlation between the ability of a cathode to attain and maintain "high" loading (>8.5-9.0) and the capacity to produce excess heat was first reported simultaneously and independently by K. J. Kunimatsu's group at IMRA Japan an my group at ICCF3 in Nagoya. This result has significance both as a means of explaining earlier null results and, as Larens notes, as an insight into potential mechanisms.

For the latter it is worthwhile perhaps exploring a little further what has been reported and what that might mean for the lattice condition that facilitates or hosts excess energy production. The resistance ratio measurement that we co-opted for use to determine the D/Pd loading necessarily measures a bulk average value. In the SRI experiments (for the most part) we kept the cathode as uniform as possible* and the diffusion coefficient of D in Pd is very high (>>10^-7 cm^2 s^-1). For both reasons, at the time of interest (after long, slow loading), the activity of D in the Pd is rather uniform throughout the length and depth of the cathode material so that an average value has general and specific significance**.

Although I am not going to cite any data or sources here it seems clear that the energy producing reaction occurs not homogeneously throughout electrodes (no matter how uniform their environment) but rather in small, discrete, "special" places***. What causes these "special zones" to become specially effective after very long times at effectively uniform deuterium activity? Is it something intrinsic to the lattice - already built in? Or is it something that grows in the lattice or on the surface with the long initiation time?

I have some ideas but do not have the answers. I do appreciate the "new thinking" provided particularly by Andrew, Tom & Larens, under pedagogical probing from Ed. It is crucial to understand the environment in which the effect occurs, and then to understand what triggers it. Given both, theory will seem (in hindsight) to be obvious. But it is precisely in getting to that place of understanding that theory can help most in guiding experiment.
-Mike
- - - - - - - - - -
* Ed mentioned lattice geometry effects, and there does seem to be a difference in threshold (and consistency of heat production) between wire and foil cathodes that I attribute largely to the intrinsic inhomogeneity of current density and loading (and deuterium flux) of foil cathodes in "sandwich" anodes compared with wires with axially symmetric anodes.

** This is easily modeled. Anyone in doubt should calculate (say) the deuterium flux needed to sustain a compositional gradient of ±0.01 D/P for a 50 µm thick foil (or even 1 mm dia. wire) - and then recognize what that flux is doing to load or unload the Pd.

*** Thermal imaging, helium production (and partial retention), and "common sense" place this zone at or near the surface; Ed has called it the "Nuclear Active Environment" or NAE."

larens wrote:

The problem is that you are assuming a conventional 3-D geometry, and then assuming your conclusions thereof are a "fact". I choose to use the 3-D "nonparticle subspace" of 27-D physics. In this case the average composition of an electrode controlling behavior apparently at its surface is not a contradiction, but is the preferred interpretation ofevents. My choice of 27-D physics is not to fit this particular case, but is to provide explanations for many phenomena that do not have a plausible explanation using conventional geometry and physics. Your assumption of conventional physics leads you to no theory for LENR and therefore no way of optimizing it as a technology.

Added on March 2, 2010

I am skipping ma lot messages, nearly all of them theoretical and without obvious connection to the CMNS field. Some of these messages contained personal insults. One prominent CNMS contributor declared that he will stop posting comments. Here is my contribution; it was a reply to X10:

44) Ludwik Kowalski wrote:
1) As often emphasized by Ed, in order to be accepted, a new theory must not conflict with those theories that have been successful in explaining and predicting real things. Special theory of relativity, as you certainly know, is in perfect agreement with Newtonian theory at low velocities. I agree with Ed that everyone who has a new theory should first use it to explain well known facts (such as elastic and inelastic scattering, alpha decay, thermonuclear reactions, fission, etc.).

2) Elastic scattering is not the only phenomenon demonstrating the reality of Coulomb barriers. Why do you think the half-life of alpha decay, T, depends on the energy of the emitted particles? Typically, T is longer when energies are lower. I am saying "typically" because T also depends on other factors (spin, parity, etc.). Without Coulomb barriers all alpha-unstable nuclei would decay immediately (after being formed). For high energy decays (emission of alpha particles with higher energies) the barriers are less high. That is why tunneling probabilities are higher (than when decay energies are low). This tendency, known as Geiger Nuttall rule, was recognized before Gamow's theory of tunneling was formulated.

3) I also agree with Ed that everyone who has a new theory should first use it to explain well known facts (such as elastic and inelastic scattering, alpha decay, thermonuclear reactions, fission, etc.). I see three advantage in doing this:

a) You would be sure that experimental data are more reliable.

b) It would be much easier to promote your theory , i.e. to publish papers in widely circulating journals. Editor will not reject your papers without sending them to referees, as they often do with CMNS-related papers.

c) You would be addressing people who know theoretical physics, and mathematics, much better than most of us on

the CMNS list.

Once again I am skipping I am skipping a lot messages.

45) Ed Storms, responding to Larens, wrote:
I see we come at the problem from different directions. You look at the problem from the bottom-up like a basic scientist and I look at it from the top-down like an engineer. I identify the environment first because the effect is obviously very sensitive to the environment. In contrast, the nuclear world that you use as your basis is not sensitive to the environment, hence the environment can be ignored. Cold fusion is an anomaly because it combines nuclear reactions with the chemical environment. As a result, nuclear physicists and chemists are needed but are incapable of communication with each other because they use entirely different concepts and words.

You probably have not spent much time in the laboratory trying to study the CF phenomenon, so that you don't appreciate the role of materials as much as I do. It is obvious, no matter what you want to measure, an instrument must be used for the measurement to be made. But first, you need to decide which behavior should be measured. So, I first ask you, what behavior should people measure? People have measured the deuterium composition, the power production, the various radiations, helium-4, helium-3 and tritium. People have looked for superconductivity, magnetic effects, and interaction with laser light. What property should we look at next? What property do you think is most important to understand?

But, to justify setting up expensive equipment, a person must be confident the phenomenon can be made to occur. That is the most serious problem right now. You say that "The characteristics of materials seem mainly to be whatever is necessary to create the necessary densities and fluxes". Yes, but what are these materials? That is the question I'm trying to answer. You ask for an accounting of energy. How would you suggest this accounting be done? What instruments should be used? These are the kind of answers I need in the laboratory before I can provide you with the answers you need. I'm must happy to provide information so that you can answer your questions, but I need my answers first.

Larens responded:
I look at the problem comprehensively like a basic scientist. You look at it with a narrow focus like an engineer. I defined the problem as LENR, with its many reactions. You redefined the problem as "cold fusion", a narrower concept that you are personally interested in. I use the entire universe as my basis, since I must maintain consistency with all proven math and physics. You, with your tunnel vision, can only see the nuclear part of my universe.

I understand the importance of your question, "What behavior should people measure?" Before that, however, is the question, "Of which phenomenon should we measure the behavior?" LENR is too complex for us to build a comprehensive model without setting priorities. Using existing data we should build a phenomenological model until we see that there are key questions that need to be answered with new experiments. With the new data we can further build the model, thus iterating the research process. At the moment the existing data is incoherently scattered about, because too many people have been pushing their own pet ideas to the point of suppression of more important ideas. Before I can answer your questions with confidence, I must stop finding so many dusty corners with important data. In the meantime, people's suggestions as to what they think is most important for model building are most welcome.

Ludwik wrote:
Neither theoreticians nor experimentalists should think in terms of their own superiority. Mutual respect and mutual help are needed. It is difficult to become a good experimentalist; it is difficult to become a good theoretician. Theories must be validated in terms of experimental data and experimental data must be explained in terms of theoretical considerations. We need each other.

Responding to Larens Storms wrote:

Once again Larens, you can't seem to restrain your judgmental compulsion. First of all, I don't define the problem with a narrow focus. To me, the title "cold fusion" is only a convenient description and not meant to be limiting. My focus is as wide as yours. The difference is one of practically. In my mind, we have to learn how to crawl before we can walk. A broad basic theory, similar to a philosophy that can't be applied, is useless. We need to start with ideas that have a direct relationship to observation. Second, I agree, the explanation must have mathematical consistency and be consistent with what is already known, as I have said many times. The challenge is to get to this universal goal. Our conflict is over the best path. So, please suggest a useful path and drop the these irrelevant judgments. You have a lot of scientific knowledge that this field could use if you are willing to debate and teach. So, please help us find a useful path.

Agreeing with the above, X wrote:
". . . For a man with a hammer, every problem looks like a nail. ..... ".

Responding to X Storms wrote:
I agree, no published theory has been useful. However, this is not the whole story. Everyone who does experimental work always has a model in their head that guides their work and is used to understand the results. These models are never published until the observations demonstrate that the final version is correct. Generally speaking, the person who has the most adaptive model that is close to reality wins the race. In my case, I'm often amazed how often the results are totally unpredicted and, as a result, send the work in a new and unexpected direction. My analogy is the exploration for gold. We are prospectors who are searching in random directions. Occasionally, largely by chance, we find a nugget. Once this happens, all the other prospectors rush to the spot and start digging to find the ore body. So far, the ore body remains elusive. Hopefully, someone will find a map to its location. So far, all the maps have sent people in the wrong direction and many have even ignored the locations of nuggets that were found. To carry the analogy further, some people even want to suggest that the discovered nuggets are not even real gold. sigh

Larens wrote:
I see that Ed is taking my "modest proposal" satire in earnest by expanding to the hijacking and derailing of this thread. Per my satire he rephrases my ideas and claims them as his, then creates a "conflict" by claiming there is a basic "difference" between our two statements. He does this well enough to get Bill to agree with "him", even though Bill is really agreeing with the basic ideas that I first presented. Having claim jumped my ideas Ed can then assert that I am not presenting anything "useful". He then presents a gold digging analogy to focus on the incoherence of the situation, thus derailing my attempt to have a thread which presents a "useful path" of coherence to CMNS by which to build a phenomenological theory.

Ed has previously stated his motives for doing this. He believes that LENR can be explained by conventional physics and that discussing the proposition that it requires new fundamental physics will inhibit the acceptance of LENR phenomena by the scientific establishment. As an editor of scientific journals he feels justified in engaging in rhetorical warfare on CMNS to block the discussion of such new physics. He has a highly committed position, for he is willing to ignore - that to the degree that new physics is required to explain LENR - he is destroying the possibility of the scientific establishment accepting LENR as theoretically well founded.

To solidify his position he takes my invitation for people to offer "what they think is most important for model building" and twists it to demand that I as theorist must offer all the suggestions. He offers no suggestions - demanding that I must tell him how energy "accounting be done" and "What instruments should be used?" - even though research engineers who have hands-on experience with contemporary equipment are generally the ones best able to handle these details of experiment design.

Ludwik wrote:
Let us face reality--the CMNS field is still waiting for a recognized reproducible-on-demand demo of a strong nuclear process due to a chemical process. That is why we have no choice but to lean on already-validated theories. Doing anything else would amount of combining two unverified things: experimental claims, and theories. This seems to be a bad strategy; it is like one blind leading another blind.

Unverified theories should FIRST be tested on experiments which are reproducible. That is what I would I do first, if I

had a new theory and wanted to offer it as a guide for experimentalists in the CMNS field. What is wrong with this position?

Lorens wrote:
Ludwik, The reality is that when establishment mathematical physicists see the type of explanations on CMNS that "lean on already-validated theories" they refer to them as "handwaving", or perhaps some more derogatory term, and to the people who believe the explanations as "idiots". You might as well be saying that we have "no choice" of strategy but to shoot ourselves in the head.

I have been pointing out that the successful extension of fundamental theory is probably too difficult to get good short term results, and that the proper way to deal with this is to build a good phenomenological theory. Establishment mathematical physics will be able to understand this problem and respect this strategy, because they well understand the complexity of modern physics.

There are two things wrong with your proposition that new theory "should FIRST be tested on experiments which are reproducible", and not in the CMNS field:

1) CMNS experiments ARE largely reproducible, so are a valid first target for new theory. To think otherwise is to concede a lack of confidence in the field.

2) The ONLY tests that validate a new theory are ones in which the predictions differ from the old theory. The relevant fields of testing are a small set, and all suffer problems of acceptance because they differ from the conventional wisdom. One of the best ways to pick a field is to find one where there are strong economic rewards for success. CMNS is clearly the best field to choose in this regard.

Ludwik, responding to Lorens

*) I wrote: "the CMNS field is still waiting for a recognized reproducible-on-demand demo of a strong nuclear process due to a chemical process.

*) You wrote: " CMNS experiments ARE largely reproducible."

1) Which demo, according to you, is recognized (by mainstream scientists) as "reproducible on demand?"

2) What is wrong with the idea of FIRST validating your theory by using recognized reproducible-on-demand data?

3) What is wrong with FIRST presenting and defending your proposed theory in journals for theoretical physicists (where it is more likely to be understood)?
l
Ed Storms wrote:
Since, thanks to Larens, the discussion has drifted from science to philosophy, I would like to add my two cents to what your have described. You raise the issue of whether theory at some level has to have a relationship to reality or can stand on its own as a consistent mathematical construction. Once this construction has been created, it is maintained as a representation of reality only because the theoreticians who accept this construction will not allow any other construction to take its place. They use denial of publication and personal attack, as Larens is good at doing, to discourage debate.

I suggest the solution, as has been the case in all other fields, is to obtain so much experimental information that the accepted construction cannot stand. A change in attitude is not based on a proof, as Larens describes, but on an accumulation of so much consistent information supporting a different conclusion that rational people gravitate to the new idea. This gravitation is gradually occurring in CF. For example, the idea that clusters of deuterons are involved was not considered initially, but now is being accepted as producing fusion as well as transmutation. This is progress and it is one small step toward a basic theory. This means that a theory must examine the nature of the cluster in addition to addressing the nature of the nuclear process. Once this idea is accepted, all theory of LENR will take a

different path and be more successful.

Larens responding to Ludwik (point by point) :
1) None of them [demos] are, because mainstream scientists have been mostly seduced into a fictitious world where all CMNS experiments are the results of incompetence or fraud, and are never published in peer reviewed journals. When dealing with such fantasy, one must focus on the best means psychologically for disintegrating the fantasy. Pointing out clearly unjust machinations of editors is much better than trying to find "perfect" experiments, because experiments are relatively expensive and more difficult to interpret.

2) Because there are none, per my answer to question 1).

3) To penetrate the PURE theoretical physics world is even more difficult than promoting CMNS. Clubs of dozens of paid theorists who do not have to produce any testable results have developed in the last couple of decades around Planck scale string theory. An unpaid outsider cannot compete in such a contest, because he will not be able to produce the necessary volume of "elegant" mathematics. Indeed, because he "is too small to succeed", he will not even be able to get through the door far enough to get the feedback necessary to find the best formulation of his work for future acceptance.

On the other hand, if he goes the more realistic route of doing combined PURE and APPLIED physics by showing that his theory gives successful results where the old theory does not, that takes us right back to the problem of dealing with experiments of questionable acceptability.

Larens responding to Ludwik (point by point) :

On the other hand, if he goes the more realistic route of doing combined PURE and APPLIED physics by showing that his theory gives successful results where the old theory does not, that takes us right back to the problem of dealing with experiments of questionable acceptability.

Ludwik wrote, addressing Larens:
1) I am surprised by your answer to the third question. Is this a well known fact or is it only your personal opinion?

2) The CMNS field has a reasonably well organized opposition, fighting discrimination. Does something like this exist among string theory practitioners? Please elaborate.

3) I suppose most string theorists are Ph.D.-level researchers. Is this correct?

Larens wrote (responding point by point):
1) Lee Smolin and Peter Woit have each written popular books saying that string theory hegemony is destructive for theoretical physics. I was just giving it my personal spin.

2) There is not yet an organized opposition, because, even though many people are concerned, there has been the lack of any clearly superior alternative to organize around.

3) Yes, [most of them are Ph.D.-level researchers]..

Ludwik (not posted):
1) I still think that attempts to validate theories should be made in platforms (lectures, journals,. discussion lists, etc. Most people on our CMNS list, including myself, are totally unqualified to provide the feedback needed by a string theorists. Larens is probably well aware of this.

He wrote: "To penetrate the PURE theoretical physics world is even more difficult than promoting CMNS. Clubs of dozens of paid theorists who do not have to produce any testable results have developed in the last couple of decades around Planck scale string theory." This looks like a division within the string theory community (the Plank scale group versus others), not a conflict between mainstream theoretical physicists and string theory specialists. In that sense, the situation is different from what we have in CMNS.

I do not know what the PURE is. Does it mean not APPLIED? Does it mean “mathematics only?” The “PENETRATE" probably means to have a theory accepted (recognized as valid). Mathematicians would validate any logically derived theory; the only cause for rejection would be a mathematical error. Physicists, by contrast, reject theories whose conclusions conflict with reality.

388) Energy Amplifier?

Ludwik Kowalski

Montclair State University, New Jersey, USA
March 2, 2010

(A) On February 26, 2010 Bill Collis posted the following message on the private list for CMNS researchers:

Dear Colleagues, A recently published patent

[LINK #1] www.wipo.int/pctdb/en/wo.jsp?WO=2009125444&IA=IT2008000532&DISPLAY=DESC

describes the use of Piantelli's Ni / H setup. Reading through the patent I was unable to find any disclosure of any innovatiion other than the obvious safety precautions of shielding the apparatus! The patent mentions "catalytic action of optional elements", but these are not specified.

The patent applicant is engineer Andrea Rossi, owner of a small company, Eon srl, employing 2-5 people. In the patent he claims that "A practical embodiment of the inventive apparatus, installed on October 16, 2007, is at present perfectly operating 24 hours per day, and provides an amount of heat sufficient to heat the factory of the Company EON of via Carlo Ragazzi 18, at Bondeno (Province of Ferrara)." (Italy). This suggests that power output at least tens of kilowatts!

Two other links for information about this invention, posted by others are:

[LINK #2] http://www.journal-of-nuclear-physics.com/files/Rossi-Focardi_paper.pdf

and

[LINK #3] http://www.journal-of-nuclear-physics.com

After downloading the Journal of Nuclear Physics paper of Focardi and Rossi (LINK 2) I was very excited to see a reprint of an article published in a journal. But clicking on the LINK 3 resulted in a disappointment. I became aware that the Journal of Nuclear Physics is the name of a blog. Seeing something in a blog is not the same as seeing it in a refereed paper. Let me summarize the content of what I find by following the links above:

(B) LINK #1

a) I see a list of references, including the ICCF8 report; it is the last reference.

b) They place Ni powder into a tube (temp 150-500C) and introduce hydrogen (pressure 2 -20 bars).

c) They use some unspecified catalyst to produce an isothermic nuclear reaction which “transforms” a Ni nucleus into a Cu nucleus. They produce more energy than used to run the apparatus. But how much more? This is not stated here. They ask: “Why do we believe that Ni turns into copper?” And they answer: Because atomic masses of Cu are smaller than atomic masses of Ni. Coulomb barrier is not even mentioned.

The “boron layers” were probably introduced to absorb slow neutrons. Why are they concerned with slow neutrons?

d) Lead plates are said to transform radiation energy from copper into heat. They say, “The above mentioned coatings are so designed as to restrain all radiation emitted by the exothermal reaction and transform said radiation into thermal

energy."

e) This prompted me to post a message about the coulomb barrier, at the CMNS list. Responding to mit, Bill wrote that three miracles must occur to make the reported results theoretically acceptable; absence of the coulomb barrier is only one of them. The other two are absence of prompt gammas from proton capture and absence of delayed radioactivity from beta decay. He also reminded us that gamma radiation and neutrons were reported by Pintelli, who performed similar experiment s (on much smaller scale) long time ago.

f) Responding to someone, I wrote: "Yes, they did say that samples of fluid, removed from the pipe after experiments, were no more radioactive than their tap water. On the other hand, they said that layers of lead were used to convert radiation (except neutrinos) into heat. That implies a lot of radiation during experiments. I am puzzled."

g) Another researcher is puzzled by the fact that so little is stated about the patented setup. This is not consistent with what is required; "a patent MUST disclose all what is necessary to build the apparatus for a person skilled in the art."

h) And here is what Bill wrote about radiation:

"Piantelli & Focardi's previous publications record that low levels of charged particles, neutrons and gamma radiation are emitted from certain Ni / H devices. Given that the Rossi has scaled up the power by 3 orders of magnitude he probably took the precaution of shielding the neutrons with boron and the gammas with lead. This precaution implies nothing regarding actual radiation. If he were to report measuring radiation, he might get caught up in health and safety regulations and his chances of demonstrating his device would be limited. :)

So my guess would be that Rossi and Focardi, like Piantelli before them, have in fact measured penetrating radiations but they are still at a low and safe level. As I stated earlier, lack of radiation implies that copper may not be the product of major heat producing reactions. Apart from the 2 stable natural isotopes of copper (63 & 65), all the others are very beta radioactive with short half lives.

No doubt this latest result will stimulate some thought and debate as to the nature of the primary reaction(s) and we can expect new papers will be published on the subject. I'll guess that whatever explanation becomes accepted, it will not require any new physics, it will substantially confirm most of the experimental observations of the last 20 years, and we'll all be asking ourselves, "Why were we all so blind when the evidence was staring us in the face?".

I'm expecting to present a paper myself on the Ni / H gamma spectrum next September. It's certainly a very exciting time to be working in the field!"

(C) LINK #2

a) Here I see another indicator that the authors are a rather limited knowledge of nuclear physics. It is their sentence "There exist no natural Fission processes." They are not aware of spontaneous fission of natural uranium. It was discovered in 1940.

b) The importance of the Coulomb barrier is recognized in this paper. This prompted me to post another short message at the CMNS list. I wrote:

"I see that the Coulomb barrier problem is recognized. Two arguments are presented. The first is the experimental fact; they do see a big difference between the input energy, for example 5.1 kWh, and the output energy, for example, 1006.5 kWh (line 4 in Table 1). This is a very powerful argument. Experimental results, if reproducible, should prevail, no matter what is expected. The second argument is theoretical and it has to do with screening by electrons, in one way or another. Let us hope that the commercial success, which is equivalent to reproducibility tests, will convince mainstream scientists that CMNS processes are worth studying.

I was surprised to learn that their 2009 experiments were performed "with the assistance of " both the DOE (Department of Energy) and the DOD (department of defense). That is what they say on page 4. Am I the only one

surprised of the DOE and DOD involvement? How can this be explained?"

c) So how does their Energy Amplifier work? After clicking the LINK2 read some details.

*) They say : "A practical embodiment of the inventive apparatus, installed on October 16, 2007, is at present perfectly operating 24 hours per day, and provides an amount of heat sufficient to heat the factory of the Company.....The electric resistance temperature controlling thermostat has been designed to switch off said electric resistance after 3-4 hours of operation, thereby providing self-supplied system, continuously emitting thermal energy in an amount larger than that initially generated by said electric resistance, which mode of operation is actually achieved by an exothermal reaction."

*) They say: "The heat generated by the particle decay and nuclear transformations will heat the primary fluid, comprising borated water, thereby said primary fluid, in turn, will exchange heat with the secondary circuit, in turn heated by said primary fluid and conveying the produced thermal energy to desired applications, such as electric power, heating, mechanical energy, and so on."

*) They also say that "In fact, few grams of nickel and hydrogen would produce an energy amount equivalent to that of thousand oil tons." And this is "without pollutions, greenhouse effects, or carbon dioxide increases, nuclear and other waste materials."
They mention catalysts but details are not provided."

d) Another researcher reminded us about related articles, already published in New Energy Times:

http://www.newenergytimes.com/v2/news/2008/NET29-8dd54geg.shtml#dpnr
http://www.newenergytimes.com/v2/news/2008/NET29-8dd54geg.shtml#pf

(D) LINK #3

a) Most of what one can see here is the paper already shown under the LINK2, except the format is different. Only the very beginning is very different. It shows the pattent number and other formal details. The abstract (description of the apparatus) states that the "niclel tube is filled with nickel powder." This seems to conflict with the what was in LINK2. There they said that the powered is on nickel surfaces (some kind of coating. The diagram of the apparatus is shown, but the image resolution is so bad that labels are not readable.

(E) APPENDED ON MARCH 3, 2010

a) Responding to X, Bill Collis wrote: "I don't think Sergio Focardi is named as an applicant nor inventor on the Rossi patent.

The evidence for any Nickel to Copper transmutation is skimpy. Basicly they assume that a nuclear reaction is taking place simply because a chemical reaction cannot explain the power production. On the other hand a nuclear reaction is not a reasonable explanation either because expected nuclear products are not detected.

The major natural nickel isotope is 58Ni so we would expect radioactive 59Cu as the major product of proton capture. However no SIMS measurement of any mass 59 product appears to have been made. No radioactivity was detected. There were no gammas from positron anihilation or beta decay.

Rossi and Focardi have done a brilliant job at demonstrating an industrial prototype. They deserve our congratulations. However the procedures documented in their patent and paper are not original. They rely on the previous work of Francesco Piantelli. Piantelli is the real inventor and his achievements were recognised with the award of the famous Truffle Prize at the second Asti Workshop on Anomalies in Hydrogen / Deuterium Loaded Metals in 1995.

Now that Rossi and Focardi have demonstrated that a compact device can provide tens of kW of practical high

temperature heat, it is likely that there will be a flurry of new research and industrial investment. As scientists, some of us are probably more interested in the underlying science rather than solving engineering problems. But both are necessary.

As I said during the summing up at ICCF13, Sochi, no government will licence new nuclear technologies unless the science is understood. (The public has a pathological fear of all things nuclear). A glittering prize awaits whoever provides that understanding.

My guess is that there will be a scramble of claims and counter-claims as scientists and industrialists attempt to stake out their respective territories and intellectual property - as in 1989."

b) I hope that Bill's expectation--a rush of activities in this field--will materialize. If I had a device producing so much excess heat for many days, as described in the paper, I would make regular public demonstrations, for example, each month. Competent scientists, engineers, and government officials would receive personal invitations to attend and to examine the device.

c) Another CMNS researchers, Peter Gluck, referring to an article in Italian press, wrote: "An Italian patent is threatening the energy monopolies? Are the results reported really real and controllable and upscalable? Mamma mia, if YES, that's an breakthrough! " But then he adds that this can be another hot potato in our controversial field. In other words, I am not the only one who is waiting to be convinced that the claim is valid.

d) Responding to X, Bill Collis posted a table with energies released (Q) after different stable isotopes of nickel fuse with protons.

1H + 58Ni --> 59Cu(beta+) .....Q=+3.419 MeV
1H + 60Ni --> 61Cu(beta+) .....Q=+4.801 MeV
1H + 61Ni --> 62Cu(beta+) .....Q=+5.866 MeV
1H + 61Ni --> 58Co(beta-) . + 4He .....Q=+0.489 MeV
1H + 62Ni --> 63Cu(stable)..... Q=+6.122 MeV
1H + 62Ni --> 59Co(stable) + 4He..... Q=+0.346 MeV
1H + 64Ni --> 65Cu(stable)..... Q=+7.453 MeV
1H + 64Ni --> 61Co(beta-) + 4He .....Q=+0.663 MeV

Energies of protons (1H) are extremely low, even at 500 C specified in the patent. Coulomb barriers for fusion, on the other hand, are very much higher. That is why I remain sceptical. If I had nothing else to do I would calculate the rates at which these nuclear processes take place when excess heat is produced at the rate of 10kW, for example. The rate of gamma emission, associated with the beta decay, could also be estimated; it would probably be very high, confirming that the environment would be lethal, without layers of lead.

The above table is actually a simplified version of what was posted by Bill. He managed to squeeze more information into a short table, as shown below. Note that PV stands for "Parity violation," while numbers between square brackets are spin differences. The g refers to ther ground state.

^{1}H (100.%) + ^{58}Ni(68.1%) -> g + ^{59}Cu(beta+) +3.419 MeV [0]
^{1}H (100.%) + ^{60}Ni(26.2%) -> g + ^{61}Cu(beta+) +4.801 MeV [0]
^{1}H (100.%) + ^{61}Ni(1.14%) -> g + ^{62}Cu(beta+) +5.866 MeV [0]
^{1}H (100.%) + ^{61}Ni(1.14%) -> ^{4}He(100.%) + ^{58}Co(beta-) +0.489 MeV [0] PV
^{1}H (100.%) + ^{62}Ni(3.64%) -> g + ^{63}Cu(69.2%) +6.122 MeV [0]
^{1}H (100.%) + ^{62}Ni(3.64%) -> ^{4}He(100.%) + ^{59}Co(100.%) +0.346 MeV [3] PV
^{1}H (100.%) + ^{64}Ni(0.93%) -> g + ^{65}Cu(30.8%) +7.453 MeV [0]
^{1}H (100.%) + ^{64}Ni(0.93%) -> ^{4}He(100.%) + ^{61}Co(beta-) +0.663 MeV [3] PV

(F) APPENDED ON MARCH 6, 2010

a) A suggestions was made, two days ago, that someone should visit the place where spectacular results are available on demand. The visitor would either confirm or refute what has been reported. I do not think that an outsider would be able to evaluate the setup. What is needed is a blueprint and a detailed protocol. Following the protocol a team a team of competent researchers would try to build the device from scratch and to measure excess heat with their own instruments. Only team members should be allowed to enter the room in which the device is being constructed.

Yes, I am thinking about possibilities of fraud. Fraudulent people, like those who solicit profitable partnership by email, do exist. Precautions of that type would not be necessary if data confirming commercial success (many satisfied homeowners) were available.

b) The Italian newspaper article, that was online yesterday, is no longer there, according to one person. "Strange enough !" he added. Peter Gluck responded: "As editor of a websearch newsletter I am familiar with such unpleasant events. The trouble is with the Stampa Libera site, not with this very paper. You can find it in other places searching for:

"un brevetto intaliano minaccia i monopoli energetici? di Marco Pizzuti

The paper is sensationalist but press is press everywhere. News is information with hypertension, strange hybrid of truth and lies."

Another researcher added: "If the thing really works according to the claim it should find its way to a larger audience all by itself." I agree with this.

c) A German science reporter, Haiko Lietz, wrote: "From my email exchange with Dr. Andrea Rossi I can tell you the following:

- The kW module is operating in the Leonardo facility in the New Hampshire, US, since 2008
- There is no apparatus in Italy
- The group is working on a MW module
- The group is not interested in anything that distracts them from making the MW module operational and safe
- When the MW module is operational there will be a presentation of the plant and a press conference
- They have only published a scientific paper because the patent application required it

Good luck to them and all of us"

In another message Haiko Lietz added "From what he [Dr Rossi] has told me they will not allow anybody into their facility at the moment." That is just the opposite from what I would do at this stage.

d) Responding to the above, I wrote,

"They say 'The group is not interested in anything that distracts them from making the MW module operational and safe.' This is a big mistake. Even a 10 kW unit, which they already have, would be a giant step forward. Waiting for a much more powerful device (perhaps several more years) is probably not motivated by scientific or technological considerations.

Why do I say that they already have a 10 KW device?

*) Because that is what one would need, at least, to keep a very small factory workable during a winter in New Hampshire.

*) In one of their experiments the total amount of excess heat was reported as 1006.5 kWh. Assuming that amount of thermal energy is produced in 24 hours, one gets the the average power of 1006.5 / 24 = 42 kW.

*) If the device operated for 4 days, then the average power would be about 10 kW, as estimated by Bill, several days ago.

*) If the device operated for 40 days, then the average power would be about 1 kW

e) Even 1 kW, if reproducible on demand, would be spectacular. So why do they want to wait for a one thousand times more powerful device?

Can the DOE and the DOD--said to be already aware of spectacular results--speed up the process, in the name of all inhabitants of our planet? ”

f) If all researchers were Americans then the DOE would probably be able to initiate a process by which researchers would be “drafted” to lead a Manhattan-like project. Should I use the term “subpoenaed” instead of “drafted?” But they are Italians, with a laboratory in the US. Why did Rossi decide to set up the shop in the US and not in Italy? Does the Italian government, or the UN, have the power of forcing him to do what seems to be desirable?

G) TO BE ADDED to HTML (3/13/2010)

a) Reflecting on the safety aspect of a MW device, **X wrote**: "Yes I can understand the safety concerns. They apparently already have a nuclear device which produces GJ [giga-joules of energy] in a confined space and they have no certainty as to what the underlying reactions are. Without any guiding theory, control may be somewhat haphazard. If they have a device which amplifies energy by a factor of 100 or more, what will they do when the multi-MW "reactor" goes critical and requires no external power? The temperature keeps rising, and melts its way through any container....

I just hope there's a negative temperature coefficient of reaction rate. This is likely as at high temperatures where NiH is unstable. Even so, as these phenomena are capable of melting nickel, Rossi is taking a very risky step."

This made me think about what Peter Gluck calls omnipresent "poisons" of NAE (Nuclear Active Environment). In fact, X just reminded us that hydrogen, in Piantelli's experiments had to be at least 99% pure. A very small amount of

deuterium stops the generation of excess heat. Deuterium might be used to play the same role as control rods play in our existing nuclear reactors.

b) **Ludwik** (posted at CMNS list on 3/11/2010):
. . . My second guess is that several people on this list are able and willing to verify the validity of the claim. I am not one of them. But I would very much like them to form a team.

*) The first task of the team would be to agree on the goal, for example, a device reproducibly generating excess heat of the average rate higher than 200 W, for at least two days. This is three orders of magnitude less than what has been claimed (heating a small factory) by Rossi et al.

*) Once the "confirming result", has been operationally defined, the team would develop a protocol. That is a difficult, but not impossible, task. The protocol, based on what is known, should be as simple as possible. The estimated costs should be listed. .

*) The protocol should then be posted on our list. That would be the end of the preliminary work.

*) Ideally at least three or four "able and willing" people would then start using the protocol "online." By this I mean performing experiments and sharing all results with us. Feedback from non-participants would probably be useful to those who perform experiments. Working in unison people can be more productive than working separately.

*) Final conclusions would eventually be published somewhere, for example, in JCMNS, at one of our conferences, or at the www.lenr-canr.org website.

c) Y1 responded:
I strongly support your suggestion to organize a group to replicate the Rossi patent and I offer myself to assist. I have a modest laboratory and am well equipped to undertake gas absorption experiments.

A private message from Y2 has me concerned about the veracity of this patent and I suggest we closely monitor this situation which may be fraudulent (in the USA). Perhaps you should contact Y2 directly. I sincerely hope the patent can lead to success.....

d) Y3 wrote:
If I remember correctly one of the experimenters commented that surface preparation was the key to establishing a repeatable result in their experiment. That included preparation of the materials in particular gas environment. I don't remember if it was O or H free. He talked about years of experimenting to get that part understood.

If you are not privy to these details then it would seem to me that the odds of successful replication are quite low. Rather like the initial replication attempts of the F&P experiment where experimenters did something that was similar and considered close enough but as we know know destined to fail.

Perhaps I am being overly critical here, but assuming that all of the relevant information is in the patent is assuming quite a lot.

Ludwik responded:
*) No, you are not being over critical. Your kind of observations could convince the team of tentative researchers to give up, after preliminary discussion. I was thinking about those who participated in earlier discussions of Piantelli's work (mentioned by Bill). I was also thinking about a possibility that Rossi might be willing to help. A person who wants to be secretive would not publish a paper.

*) I am not competent for this kind of research. The only thing I can do, after reliable 0.2 kW excess heat is produced, is to send some CR-39 and to look for tracks of nuclear particles. But this would be at the ending phase of the project--just a shot in the dark.

Y4 wrote (providing a link to R. M. Santilli's paper--see below):
The experiment should be easier to reproduce than many - but there are strong warnings about radiation levels. [See

http://www.i-b-r.org/NeutronSynthesisNCA-I.pdf

The author of this paper, Rugerro Maria Santili, informs us that "this his paper was rejected by Physics Letters, Il Nuovo Cimento and Physical Review Letters with "reviews" solely based on theoretical theologies that can only be qualified as being scientifically pathetic."]

Ludwik responded:
The abstract of the Santelli's article

http://www.i-b-r.org/NeutronSynthesisNCA-I.pdf

is worth thinking about. (The above link was posted by Andrew, this morning.)

Abstract

We report measurements, necessarily preliminary due to their novelty, toward the laboratory synthesis of the neutron from protons and electrons, in the hope that they are not judged via theoretical conjectures, but subjected instead to independent re-runs for their verification or denial, said process being requested by possible new clean energies so much needed by our increasing environmental problems.

NOTE:
This paper was rejected by Physics Letters, Il Nuovo Cimento and Physical Review Letters with "reviews" solely based on theoretical theologies that can only be qualified as being scientifically pathetic.

Information about very impressive Santelli's scientific background is at:

http://www.i-b-r.org/Ruggero-Maria-Santilli.htm

Most of us probably agree with the author that experimental results should be verified in laboratories; they should not be rejected on the basis of conflicts with accepted theories. He claims that his papers were rejected on that basis. This probably becomes obvious after reading the letters of rejections.

Here is a private message I just sent to Dr. Santilli:

Dear Dr. Santilli,

This message is prompted by your three-times-rejected 2008 article. In the abstract you wrote: ". . . " Rejecting experimental results conflicting with accepted theories is a disease that might kill science. I anticipate writing a short note on that subject; your case can be used as illustration. That is why I would very much like to know how the editors of the three mainstream journals explain rejections of your manuscript.

Ideally, I would like to quote their rejections. But that is a delicate matter; I would probably need permissions to quote etc. Equally useful would be your descriptions of the contents of these letters, provided I can quote your "personal e-mail information."

389) Joke or Ignorence?

Ludwik Kowalski

Montclair State University, New Jersey, USA
March 14, 2010

A) A reference to Santilli's article was made at the end of Unit 388. Then the following was posted by one CMNS researcher: "I attache another extraordinary claim. The article containing it is circulating around. The title is "Ecological Nuclear Energy." I downloaded the file, and appended it it to this unit (see below). After reading the article, I posted the following message on our CMNS list.

The article, downloadable from

www.nuenergy.org/pdf/electronically-activated-radioisotopic-carbon-generator.pdf

is probably a joke. If I were a referee I would ask the following questions:

(a) What experimental evidence does Perreault have that electrons fuse with atomic nuclei, as in process (1)?

(b) Yes, the process (2) is exothermic (Q=+13.4 MeV). But the reverse process (1) would be endothermic (Q=-13.4 MeV). In other words, no net energy can be generated by two processes, unless something else is involved. What can this "something else" be?

(c) An experimentalist can be forgiven for not being able to speculate about (b). But s/he cannot be forgiven for not providing convincing evidence for the excess energy. How much energy is released in each round trip--process (1) followed by process (2)?

(d) An experimentalist claiming that most of the released energy appears in the form of beta and gamma rays is expected to provide evidence for such radiation.

No one responded so far. Interesting comments and observations, if any, will be appended at the of this unit (after the end of the article). Some sentences in the article are too long for my taste. But I am not going to correct anything.

Can the Electron Capture process, competing with the beta+ decay, be called fussion? I do not think so. In fact, I am not aware of nuclear reactions induced by electrons. Scattering of high energy electrons, on the other hand, was studied to measure sizes of atomic nuclei.

ECOLOGICAL NUCLEAR ENERGY FOR THE HOME

Translated and edited by Bruce A. Perreault on 11-20-2006

I have forced myself to write this article to shape my practical experiences that I have made about nuclear energy to the order of many people whom have requested for me to make references of the case.

Nuclear energy is a subject that has been badly focused and badly used from the beginning of the times, from the discovery of the radiations and the experiments performed by the Curies, the Uranium and all that derived from it in a technology at the moment is very complex, of high cost, dangerous and generates polluting by-products. What makes this single energy possible is that it is available only to the countries that can pay for such expenses. Furthermore, never can this form of energy be used to take to the home or to use it to impel automobiles or to feed a generator for our houses for the same reason before mentioned, but we watch around us the enormous amount of processes of disintegration and nuclear reactions that surround us everywhere on the Earth we see here that IF a system can be made nuclear simple, ecological and very cheap.

Common occurrences such as electrical discharges, lightning, etc…, produce nuclear reactions, which also includes processes that simply happen in electrical circuits. If we can design an electrical circuit that produces a nuclear reaction within itself in stable form and controlled, everything is certain.

We do not need to look for difficult things and dangerous things like Uranium, Plutonium, etc… if we watch the spontaneous nuclear reactions that happen in our planet we will see that the radioactive elements participate more in the same way as the one that is perhaps one of most abundant of the planet and that is CARBON, and pure coal is something very easy to obtain, the more typical nuclear reaction we see in nature involves carbon. When carbon is bombarded by electrons in a process of nuclear fusion electrons are attracted to the nuclei of carbon atoms to form Boron in the following reaction:

$$^{12}_{6}C + ^{0}_{-1}e = ^{12}_{5}B \quad \textbf{(1)}$$

When carbon transforms into boron the electron must appear with energy within the rank of thousands of electron-volts, once the Boron is formed, the boron atom is seen that it is an unstable isotope and therefore is disintegrated again to transform itself back into the stable Carbon atom of the principle of this reaction:

$$^{12}_{5}B = ^{12}_{6}C + ^{0}_{-1}\beta \quad \textbf{(2)}$$

The electron is emitted or given back. Now, I illustrate through the symbol of the beta particle because the energy whereupon leaves with the electron from the nucleus which is initially much greater, no longer is it thousands of electron-volts, the exit energy is extreme, now in the 13 million electron-volt range, that is to say, an energy thousands of times to initiate the reaction, it is feasible to capture these beta rays of great energy, for example, in a toroid and thus to obtain immediate electrical energy of the nuclear process with no need of an intermediate process.

Reactions 1 and 2 are reversible reactions because the carbon once transformed into Boron returns to be reconstituted to initiate indefinite cycles, the later giving off more energy than the former but does not break any law of power conservation because the excess of energy corresponds to the stored internal energy in the atoms resulting in the conversion of matter into energy, this can be illustrated.

For the person who does not understand; as if we went to a zoo and we threw a peanut to an elephant, then the elephant takes the peanut and returns it to the thrower with the power of his trunk with many times greater energy, this is the

same. In addition to this fact, one knows that of each 100,000 carbon atoms that are bombarded with electrons only 1 enters the reversible reaction that it gives us. I calculate that 8KW of power is available per gram of transformed carbon. It is not necessary to resupply the system with coal because the system regenerates, but after a certain time it is advisable to change the coal source which is subject to wearing down. Not only is light and heat generated from all nuclear reactions but electrons are also freed.

Practical implementation:

How then we can accelerate electrons and shoot them into coal so that it will catch electrons in the form of beta radiation? Very simply, we obtain a pure coal bar and discharge a condenser into it, depends on the capacity of the condenser and of the voltage of the energy of discharge required for the reaction in equation 1 will be reached. All we know that when we discharge a condenser, especially in a short circuit through a coal bar, very high currents will take place that guarantee a high electron flow to favor greater collisions, and it is that simple, nothing of nuclear reactors, systems of cooling, pumps of high vacuum, only a simple electrical circuit will transform the nuclear energy released directly into electricity since the same emitted beta radiation is captured and stopped to feed an electrical load, which makes it more efficient than a nuclear system of a power station. For example; in which the reactor warms up the water for in the end with the pressure of that steam moving a turbine and generating electricity, we did not need any intermediate process here, because the nuclear energy becomes directly processed into electricity. The following figure shows the system and the process in general form that I have actually used:

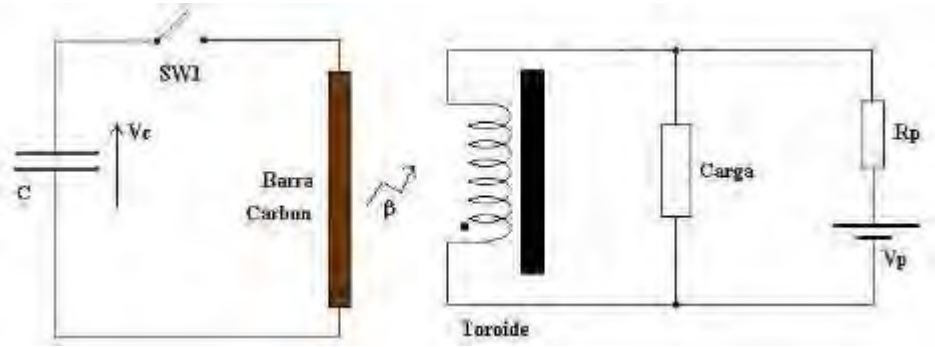

Fig 1. Practical system of direct transformation of nuclear energy to electrical

In the figure a condenser *C* is loaded initially to a Voltage *Vc* and is discharged when closing the switch SW1, said switch can actually be a FET of high current, in conjunction with a pure coal bar the awaited nuclear reaction will take place and it will free to the desired beta rays which are captured by the illustrated toroidal coil, as a simple coil catches the radiation, said toroid acts as a transformer of current for the current circulates through the coal bar but in addition to that the toroid is polarized initially with a continuous source composed by the Vp battery and the Rp resistance makes a low current circulate around the toroid, in order to guarantee beta rays they do not go through the toroid but are turned aside onto itself and thus to capture most of the released possible energy.

The practical results I have obtained are remarkable, to begin with it is appreciated that the effect of the polarization of current around the toroid hugs the coal bar, when not polarized the collected energy varies until it is at a factor of 3, and with a small system of a bar-toroid, with a maximum dimension of 15 cm, I easily managed to obtain 6KW with the load by all means placed in the output of the toroid, and as the power output of the system is much greater than the input simply refed in the tests and the initial starting battery was removed, this is justified by the enormous energy available because it is like the calculations before referred to which we have 8 KW of useful power per each gram of transformed carbon.

It is possible to finally emphasize that although the beta radiation is the practical fuel of the system here it is used completely being transformed into useful energy, unlike the conventional technology where the radiations are a dangerous by-product, in any case in the process of the safety of this system we are due to follow strict safety measures oriented to prevent damages to the health to the builder of this system by radiation exposure either through burns or repeated exposure to the medium or long term exposure, that is to say, during the tests to use suitable sealing,

suitable shields that are of lead, concrete or another material and a radioactivity indicator, leaving until the emission level during the tests is at a tolerable level, and by all means for the end assembly of the generating unit sealed, isolated to guarantee during its life utility that there is never is going to exist a radiation leak, even if in case of faults or accidents since this it is a passive system, if the bar is not excited its radioactivity will no longer be present, it is enough to disconnect the feeding without the problem of an explosion, critical mass or a chain reaction, only to take our own precautions to work with radiations with people who activate the circuit, the users only use these calibrated activated systems and they don't mention it and do not have to worry.

Conclusion:

The fact that conventional nuclear technology is so complex, expensive, dangerous and damages ecological systems seems to be something more than an accident of history, that is to say, all we know that from a sample of history that such technology wanted to be used to make a nuclear pump and all the pursuit oriented to that without fully accounting for the expenses involved and it moved forward as rapidly as possible, it is very probable the scientists who worked in those projects knew of all this but given the circumstances to make something possible or to pressures they received and the idea that anyone could simultaneously develop the technology that we today now call nuclear energy, I do not want to propose that people who use this technology are mistaken or making expenses at the cost of others, I only want to show the light of this evidence that anyone can verify on their own that nuclear technology could be today in our houses, impelling our automobiles, airplanes and spaceships without the contamination fear or damage to the ecology when anyone can have a system of these for their own use, coal abounds in our planet and is an inexhaustible and limitless source of energy.

Original Article: http://econuclear.tk/

B) Responding to my message (see the top of this message) Z1 reminded us about intersting Japanese experiments (Kohji KAMADA, Hiroshi KINOSHITA and Heishitiro TAKAHASHI) in which excess heat was produced by exposing the aluminum loaded with deuterons to beams of electrons of several hundreds keV. My reply was:

1) To avoid confusion I would make a distinction between a nuclear process and a nuclear reaction. Any nuclear reaction is a nuclear process but some nuclear processes are not nuclear reactions. Consider a situation in which the released nuclear energy is received by a crystal lattice, rather than by a nucleon or a small cluster of nucleons, such as an alpha particle. I would not call this a nuclear reaction. Radioactive decays are usually not called nuclear reactions; they are not triggered by collisions of two nuclear objects. (A nuclear object is a nucleon or a group of nucleons bound by strong nuclear forces).

A nuclear reaction is often defined as a process in which two nuclei or nuclear particles collide to produce products different from the initial particles. Electrons are not nuclear objects. I never heard of processes in which nucleons, or clusters of nucleons, are emitted from atoms bombarded by electrons.

2) Thank you for summarizing spectacular results reported by Kamada, Kinoshita and Takahashi. Why should we argue about how to call their experiments? Are they nuclear reactions or are they nuclear processes? They are interesting experimental facts. That name is sufficient, at this stage.

3) My attitude toward the Perreault's paper at

www.nuenergy.org/pdf/electronically-activated-radioisotopic-carbon-generator.pdf

is the same as described several hours earlier. I still suspect a joke. Naturally, I can add more questions to those four

that were already asked. For example,

e) What were the numerical values of Vc, C, Rp and L?

f) How was the excess energy measured and how large it was? Answers to (e) and (f) would be essential for researchers trying to verify your results.

g) How many experiments were performed and how reproducible your results were?

h) Why do you say that each gram of carbon produces "8 kW of useful power?" One gram would correspond to a certain amount of energy (kWh, not kW). For a given amount of energy, the power depends on the rate at which the fuel is consumed.

Do you people agree that the article is very weak? Is my reaction (pretending I am a referee) justified? If not then what should it be?

390) Conspiracy or Defence?

Ludwik Kowalski

Montclair State University, New Jersey, USA
March 15, 2010

1) This unit is a continuation of what was recorded at the end of Unit #388 My private message to Dr. R. M. Santilli was shown in that unit. This morning I received the reply with the link to the newer version of his paper. Also provided is the link to his cosmological paper. My background in cosmology (general relativity, gravity, etc.) is too limited and will probably focus on his first paper. Santilli informed me that this paper has just been "accepted by a reputable refereed journal. The new title is: "Experimental Confirmation of the Novel \ Intermediate Controlled Nuclear Fusion Without Harmful Radiations." the title of the rejected paper was "Apparent confirmation of Don Borghi's experiment on the laboratory synthesis of neutrons from protons and electrons."

2) Responding to Santilli I wrote: "My intention, as I wrote to you yesterday is to focus on what you call politics in science. Quoting rejection letters from editors of three mainstream journals (or quoting your descriptions of these letters) would be an essential part of the note I plan to publish. That is why I would like to have this input before starting to compose anything."

3) Two versions of the paper do not seem to be very different, as far as the basic claim is concerned. The described setups are said to synthesize neutrons from protons and electrons. What a coincidence, the same claim was made in Perreault's paper. The author thinks that 12B is produced when 12C is bombarded by electrons whose energy is several hundred keV. This implies that an electron and a proton fuse to produce a neutron, inside the 12C nucleus. That 2006 paper is in my unit #389. If I were a referee I would suggest the rejection of the paper, unless it were totally rewritten. Eight critical comments were made in my fictitious referee report.

My overall impression was that the article was a joke written by an incompetent author. Santilli, on the other hand, is a Ph.D.-level nuclear physicists and the author of many publications. I am ready to start reading his paper carefully, first the rejected 2008 version and then the accepted 2009 version. This time I will pretend being a reviewer, rather than a referee. This will also allow me to make comments. Will they be the same as those I made addressing Perreault? This remains to be seen.

4) On 3/20/2010 Ludwik posted the following blue message (3/20/2010) on the pivate forum for CMNS researchers. That was about 24 hours ago. No one responded. Others are probably also not satisfied with absence of clarity combined with the unusual format of Santilli's paper.
"Dear all,

A) Three recent CMNS claims were:

(a) Rossi's patent (converting nickel into copper in order to heat a factory)
(b) Parreault's article (converting carbon into boron in order to heat homes)
(c) Santilli paper (turning protons into neutrons and getting energy from decaying neutrons)

As recorded in my unit 388

http://csam.montclair.edu/~kowalski/cf/388amplifier.html

The claim (a) does not belong to the realm of science; it belongs to the realm of patents where claims are validated on the basis of honest commercial successes, i.e. on large numbers of satisfied customers.

B) All who commented on claim (b) think that the article is not credible. It contains several indicators of poor familiarity with science. I suspect the article is a joke, as described in my unit 389. And what about the claim (c); it has also been mentioned at the end of my unit 288. The author's credentials are very impressive and I contacted him. I wrote:

"This message is prompted by your three-times-rejected 2008 article. In the abstract it you wrote: 'We report measurements, necessarily preliminary due to their novelty, toward the laboratory synthesis of the neutron from protons and electrons, in the hope that they are not judged via theoretical conjectures, but subjected instead to independent re-runs for their verification or denial, said process being requested by possible new clean energies so much needed by our increasing environmental problems. (NOTE:This paper was rejected by Physics Letters, Il Nuovo Cimento and Physical Review Letters with "reviews" solely based on theoretical theologies that can only be qualified as being scientifically pathetic.) '

Rejecting experimental results conflicting with accepted theories is a disease that might kill science. I anticipate writing a short note on that subject; your case can be used as illustration. That is why I would very much like to know how the editors of the three mainstream journals explain rejections of your manuscript.

Ideally, I would like to quote their rejections. But that is a delicate matter; I would probably need permissions to quote etc. Equally useful would be your descriptions of the contents of these letters, provided I can quote your "personal e-mail information."

C) Dr. Sallini sent me a new version of his paper; it has just been accepted for publication in a reputable referee journal. But he did not send me what I asked for. In the next message he gave me permission to share the accepted version of the manuscript with others. But neither rejection letters nor paraphrasing were sent to me. I asked again but my third message was not answered. That was the end of our correspondence.

D) The manuscript that was rejected three times can be downloaded from:

http://www.i-b-r.org/NeutronSynthesisNCA-I.pdf

the recently accepted manuscript can be downloaded from

http://www.santilli-foundation.org/docs/ICNF.pdf

The contents are very different. Let me comment on what I read. One thing became clear to me at once; these two manuscripts are poorly written; I would certainly sent them back to the author, asking for more clarity. That is what the editors probably did. The most annoying is constant mixing of experimental facts with theoretical conclusions. Presenting experimental facts in the form of reports from analytical laboratories is not consistent with common practice. I am not going to list numerous shortcomings of each article; the bottom line is that the articles are very difficult to read with understanding.

E) The apparatus used by Scallini consisted of an electric discharge chamber filled with hydrogen, at a pressure of several atmospheres. Two tungsten rods, facing each other, were introduced into the chamber, in order to create the arc. In one case the gauge pressure was about 2 atm, the distance between the tungsten tips was 0.125," and the current was 30 A. The arc duration, in that case, was 3 seconds. Presence of neutrons and gamma rays was demonstrated by using several kinds of commercial detectors.

The author reminds us that "the neutron synthesis requires 0.78 MeV over the sum of the rest energies of the proton and of the electron. Where does this energy come from? At Point 3, in Section 5, Santelli speculates that the 0.78 MeV

of energy, needed to turn a proton into a neutron, “originates from the aether as a universal substratum with very high energy density.” That speculation is not repeated in the new version of Santelli's article. Both articles, however, refer to the so-called “Standard Hydronic Theory.” Unfortunately, I am not familiar with that theory; it was developed by Santilli.

F) The second version of Santilli article is not limited to production of neutrons from protons. Section 4, for example, describes experiments in which nitrogen was produced from deuterium and carbon.”

Added on 3/23/2010
Responding to the above, one CMNS researcher, Dr. Dean Sinclair, wrote to me in private:

*) About Rossi, My work would say that his idea is not beyond the realm of possibility" however, I suspect that his results are actually H:H to D, Probably through an HHH+ unit.

*) As to Perrault's Carbon to Boron, the only Carbon to Boron transform that I can see off the top of my head is C-11 to B-11, and I can't see where the C-11 source would come from.

To me, the most interesting is Santilli's work.

*) I suspect that Santilli is correct that he is producing neutrons as he is creating a SHOCK WAVE.
I agree with his comments about "Aether" involvement as I don't think that he is synthesizing them from electrons and protons: By my work, he is literally creating them from the usually overlooked Null Set that is part of any unit. I shall explain.

Possibly the most controversial aspect of my work is my opinion that "annihilation" and "pair production" are symmetrically reversed processes and indicate the presence of a ubiquitous combination unit which I call the "zerotron," a unit which is SHOCK WAVE DEFORMABLE TO A NEUTRON.!

In terms of my theorizing, I'd say Santini's work is probably valid; but, not exactly as he anticipated.

392) Unexpected rejection of our important paper

Ludwik Kowalski

Montclair State University, New Jersey, USA
June 12, 2010

Introduction

The Curie Project was described in unit 375. Participants were Jeff Driscoll, Mike Horton, Ludwik Kowalski, and Pete Lohstreter. Our independent attempts to verify Oriani's claim of reproducibility turned out to be negative. On most experimental surfaces (31 out of 34) the mean track densities were essentially the same as on control surfaces. On the remaining three experimental surfaces the densities were much higher than those reported by Oriani. They were tentatively attributed to contamination. The purpose of this unit is to describe our attempt to publish that paper.

Submitting the paper

On October 16, 2009, I received the following message from Dr. Jan Marwan, who was certainly familiar with our project. "Dear Dr Kowalski, The American Institute of Physics (AIP) offered me to edit a book titled **"Low Energy Nuclear Reactions Sourcebook**" based on the New Energy Technology Symposium that I am organizing.

I work as the only editor together with the AIP on this book, and we want to give many research groups working in the LENR field the opportunity to publish their results here. This covers on the one hand brand new results recently discovered, but may also be a brief review of the work you performed over the last 20 years. The book we are planning is going to be a general sourcebook, covering most of the topics (experimental and theory) of LENR, with which the scientific audience worldwide, reading this book in the future, may get the general idea of what LENR is but also may go into very detail. We think that with this work, based on your article among many others, we are going to publish a book of high demand to which scientists and students at Universities, Research Institutes, Industries etc worldwide will have access for a very long time.

This AIP book is officially a proceeding based on the New Energy Technology Symposium held in San Francisco, CA, March 2010 at the American Chemical Society (ACS). However, the AIP agrees that people who, due to the difficult funding situation at this time, may not be able to attend the meeting, are given equal chances to publish in AIP, same as, of course, those who attend the meeting in San Francisco. This book, again, will cover new results but may also contain results already presented and published elsewhere (permission by the first publisher, of course, needed, and if no verbatim used) and so to give LENR scientists the opportunity to briefly review their long term work in this field. Those who already published in ACS LENR Sourcebook volume 1 & 2 are given equal chances to publish again (preferably new discoveries), this time in AIP. I think we all feel the same that this offer by the AIP does not come up very often in our life..... "

Naturally, we wrote the paper and submitted it before the deadline. It was hard to believe that our establishment (American Institute of Physics) was going publish a book with papers describing cold fusion. I am not inserting our paper here because it is too long (eight pages) and, more importantly, because its future remains undetermined. It was first accepted in May 2010, and then rejected in June.

The unexpected rejection

On June 11, 2010, I received the following message from Dr. Marwan

Ludwik,
I am sorry to let you know that the other reviewer surprisingly rejected your AIP paper.
I therefore decided not to include your paper into this AIP book. I truly apologise for the inconvenience.
Jan

Inconvenience? It is more that this. A report from the "other reviewer," Y, was attached to the message. The report of the first reviewer, X, was sent to me on May 8, when the book was accepted. Responding to this June 11 message I wrote:

"a) I am also very sorry. On what basis was our paper rejected?

b) How many reviewers did you send the paper to?

c) What options do we have in this unexpected situation? "

That was more than 24 hours ago. It is Saturday; I will probably not receive the answer before Monday. Meanwhile let me summarize the X and Y reports.

X ==> "Publish as received, or with minor corrections as indicated." All these corrections were minor and easy to make.

Y ==> "I strongly recommend the editor to reject this paper for publication."

Another big difference was in ranking of our paper. Five categories of ranking were:

a) Technical Quality
b) Significance
c) Comprehensiveness
d) Originality (when applicable)
e) Clarity.

Three choices for each category were: "good," "average," and "poor."

*** Ranking by X ==> a, c and e are " good," d is "N/A," and b is "average."

***Ranking by Y ==> all five categories, even d, which is not applicable, are "poor."

The rejection of our paper by Dr. Marwan, on June 11, was a sudden reversal; a previous message on June 10 asked for minor formatting corrections (elimination of blank lines between paragraphs).

What would I do if I were in Marwan's place?

It is not easy to be an editor; I am glad I am not in Jan's place. AIP ethical standards (Google found them for me) describe what is acceptable and what is not acceptable, as far as reviewing papers is concerned.

Suppose the manuscript is clear and comprehensive to me (in Marwan's place) while the referee's ratings for these categories are "poor." That would be an indication of a possible bias. The "poor" for all categories would also be a warning that something is not right.

I would ask Ludwik to comment about what referee Y wrote. Then I would send the manuscript to at least one more referee, and would inform Ludwik about this. In choosing referees I would eliminate those who might have vested

interests in defending the teams criticized in the submitted article. And I would be open-minded about what is recommended by referees. Their role is to suggest; decisions about rejections belong to editors.

Please note that we made no attempts to replicate SPAWAR experiments. Our comments (about that field) were based on results published by respected researchers (more specifically, authors of references 10 and 11). This was clearly stated in our manuscript. Ignoring this, reviewer Y wrote:

"This paper specifically addresses the reproducibility issue of the SPAWAR experiments. Kowalski and his co workers, in attempting to replicate this experiment, failed, and from that they questioned the results obtained by the SPAWAR and the Oriani group and concluded that the broad range of the SPAWAR research using CR 39 tracks to detect nuclear particle emission is wrong and totally misleading. Moreover, in his final conclusion Kowalski interpreted this issue as a failure of the whole LENR/cold fusion subject and convincingly predicted this research topic to become out of interest.

However, does the fact that Kowalski and his co workers not able to replicate the SPAWAR results means that SPAWAR, and a few other research groups who successfully replicated these experiments, have been misinterpreting their results, or does it rather mean that the Kowalski group failed because of lacking scientific background and experimental skill? On the one hand, the SPAWAR researchers working in this field are highly recognized and published their work in more than 20 peer reviewed papers. If Kowalski were right, it would mean that the reviewers had been wrong. On the other hand, it is not very much convincing to claim irreproducibility of the SPAWAR results on the basis of the work carried out by high school teachers. Although everyone wishes to replicate other researchers' experiments it still requires experimental expertise, and now one could argue that a high school teacher may not have the skill compared to a highly qualified research scientist.

To evidence the truth of LENR/cold fusion requires detailed experimental data that the SPAWAR group has provided, to prove this research wrong requires experimental data as well that I was missing reading this paper. Therefore, I strongly recommend the editor to reject this paper for publication."

I do not think that we, as a group, were unqualified to replicate Oriani's experiments. In fact, we complemented each other. I am a nuclear physicist (Ph.D. in 1963), J.D. is an engineer, M.H. and P.L. are experienced chemistry and physics teachers. We were an ideal team for the selected task. Aware of our limitations, we did not attempt to perform SPAWAR-type experiments. What else can I say? I also participated in numerous research projects; my list of publications, in peer reviewed journals, click to see it is also impressive.

The paper we want to publish will eventually be appended to this unit. I am not doing this now because this might conflict with our attempts to publish it. Those who read it will see that no attempts were made "to claim irreproducibility of the SPAWAR results **on the basis of the work carried out by high school teachers."** We were comparing results published by distinguished CMNS researchers, more specifically, by authors of references (10) and (11). The readers will also see that over 90% of our manuscript is devoted to our own investigations of the Oriani-type effect. Why were recent SPAWAR-type experiments marginally mentioned? Because they have something in common with Oriani-type experiments. In both cases thin Mylar films are used to protect CR-39 detectors from the electrolyte.

Conclusions and interpretations

Referring to our experimental results we wrote: "The overall conclusion is that experimental data reported in [8], and summarized in Figure 2, are not reproducible. Track densities measured on our thirty-four CR-39 surfaces were either much lower or much higher than those reported by Oriani. The origin of high track densities, in Experiments #10, #11 and #12, is not clear."

And here is our final observation: "Experimental results supporting two recent claims of emission of charged nuclear projectiles due to electrolysis are not reproducible. Focusing on reproducibility is probably more important, at this stage, than focusing on interpretation of experimental results. The future of the so-called "Cold Fusion" field--now called "Condensed Matter Nuclear Science" (CMNS)--remains uncertain. The attitude of those who control scientific

research (editors of mainstream journals, directors of granting agencies, etc.), toward the CMNS field remains highly negative. The field is in real danger of disappearing without producing clear yes-or-no answers about its extraordinary claims. It will probably be rediscovered later in this century."

Refering to this Y wrote: "Moreover, in his final conclusion Kowalski interpreted this issue as a failure of the whole LENR/cold fusion subject and convincingly predicted this research topic to become out of interest."

Where does the term "out of interest" come from? And we did not say "failure of the whole LENR/cold fusion subject;" we were referring to "the uncertainty" about the field future. Furthermore, we are not "convincingly predicting" anything. Is it not true that the field is in real danger of disappearing? In any case, our last observation could easily be modified to avoid possible misrepresentations. In Marwan's place I would ask Ludwik to rewrite the final observation. That can easily be done. Rejecting the entire paper (with valuable experimental results) because of one questionable formulation (at the end of the last paragraph) is not reasonable. Each of us put a lot of work into this piece of scientific research; why should it be wasted? We are pleased that no technical mistakes were found in our paper.

A constructive suggestion

Suppose the potentially-controversial ending sentences are removed. This would reduce our final observation to: "Experimental results supporting two recent claims of emission of charged nuclear projectiles due to electrolysis are not reproducible. Focusing on reproducibility is probably more important, at this stage, than focusing on interpretation of experimental results." Would such personal observation, or something similar, be acceptable? I hope so. If not then the entire last paragraph could be eliminated. This seems to be more reasonable than throwing away the data. Do you agree?

393) My note (see below) was rejected

Ludwik Kowalski

Montclair State University, New Jersey, USA

August 23, 2010

This unit is the follow-up of what was described in unit 395. I am being prompted to compose it because of the e-mail message received today. I was informed that my short note has been rejected by European Physics Journal, Applied Physics.

1) My rejected note is shown first:

Four questions and a comment

Ludwik Kowalski
Montclair State University
kowalskiL@mail.montclair.edu

I read the paper by P. A. Mosier-Boss et al, [1] with great interest. Can a chemical effect, such as electrolysis, trigger a nuclear effect? This question has been debated since 1989, when the discovery of the so-called “cold fusion” was announced by Fleischmann and Pons [2]. Great progress toward answering this question has been made, as summarized in [3]. But the world is still waiting for a reproducible-on-demand, and convincing, demonstration of a chemically-induced nuclear reaction. The name “cold fusion,” by the way, has recently been replaced by CMNS (Condense Matter Nuclear Science). According to [1], triple tracks discovered in CR-39 detectors are due to neutrons, with energies higher than 9.6 MeV emitted during electrolysis, rather than, for example, to cosmic rays.

I have four questions and a comment. The first question is about the phrase “neutron flux of 10_7 n/s" (in the last paragraph in Section 2). The phrase seems to be contradictory. If the number 10^7 refer to “flux” then the unit should be (n/(cm^2 *s); if the unit is correct then the term “neutron flux” is not appropriate. I suspect that 10^7refers to the neutron source intensity (strength). If this is true then to estimate the flux one would have to divide the 10^7 by 4*PI*r^2, where r is the distance between the center of the source and the CR-39 detector.” My second question is about r; how large was it?

My first comment has to do with the number of tracks. As stated in Subsection 3.3, codeposition experiments “typically last two weeks.” The number of triple tracks per detector was “at most 5 to 10, including both the front and back surfaces.” That is indeed a very small number. It is reassuring that no triple tracks “have been observed in background monitoring detectors.” That rules out the “cosmic rays” interpretation. This argument would be stronger if the total numbers of experiments were reported.

Suppose that ten detectors are used in all codeposition experiments, and that the mean number of tracks per detector is 5. Then the total would be about 50 triple tracks. Suppose that only five triple tracks were found on ten background monitoring detectors. The difference between 50 and 5 would certainly be more significant than the difference between 10 and 3.

My third question has to do with the neutron source exposure time of 4.5 hours. Was this time chosen to produce about as many triple tracks as during a typical codeposition experiment (lasting two weeks)? What was a typical number of triple tracks found after 4.5 hours of DT irradiation?

My last set of related questions has to do with the overall strategy. What to do next? The world is waiting for a reproducible-on-demand, and convincing, demonstration of a chemically-induced nuclear reaction. What kind of codepositionon experiment is more likely to lead us to that end? The last SPAWAR paper [1], focusing on rare events, can be contrasted with earlier codeposition papers [4,5], where the reported racks were much more abundant.

2) The rejection note:

Your manuscript, “Four questions and a comment,” has been carefully considered by the referees of The European Physical Journal-AP. As you can see on the enclosed reports, the referees have raised serious concerns regarding its suitability for publication.

I therefore regret to inform you that your manuscript has not been accepted for publication. Thank you very much for having submitted your article to our journal and I hope that you will nevertheless consider EPJ-AP for the publication of your future articles.

3) Comments made by three referees (sent to me by the editor):

Referee 1:

In 2009, we reported on the observation of triple tracks in CR-39 detectors used in Pd-D co-deposition experiments [1]. A search of the literature indicated that triple tracks are diagnostic of the 12C(n,n')3alphas carbon breakup reaction in the detector with an energy threshold of 9.6 MeV [2-5]. At the time, it was only possible to compare images of triple tracks observed in CR-39 detectors used in the Pd/D co-deposition experiments with those reported in the literature and it was found that the Pd/D co-deposition generated triple tracks were similar to nuclear-generated triple tracks. The intent of this effort was to expose CR-39 detectors to a DT neutron source and to compare the resultant triple tracks with those we have observed in our Pd/D co-deposition experiments. Figures 3 and 4 of our paper [6] show side-by-side comparisons of symmetric and asymmetric triple tracks in CR-39 detectors used in Pd/D co-deposition experiments and exposed to DT neutrons. The two sets of tracks are indistinguishable.

Since the on-line publication of our paper [6] comparing DT and Pd/D co-deposition generated triple tracks in CR-39, Kowalski has asked why the CR-39 detectors were exposed to the DT neutron source for 4.5 hours. There is no significance in the exposure time used to irradiate the CR-39 detectors. Our intent was to obtain a large sampling of DT-generated triple tracks to compare with those triple tracks observed in the Pd/D co-deposition experiments. This is particularly important given that the carbon break-up reaction can proceed to the four-body final state through one or more of the following reaction mechanisms [7] .....The observed shape of the triple track in the CR-39 detector is, consequently, dependent upon the reaction mechanism that occurred.

Kowalski has also asked why the neutron flux was reported in units of n s^-1 as opposed to n cm^-2 s^-1. That was because nine CR-39 detectors were placed on the neutron tube. The position of those detectors relative to the target was not known. Therefore, the distance between the detectors and the target, r, was not known. Consequently it was not possible to report the flux in n cm^-2 s^-1. Furthermore, the purpose of the experiment was to see what DT neutron tracks look like and to compare them with the tracks observed in our Pd/D co-deposition experiments. Those goals were met. As this was a qualitative comparison between DT-generated triple tracks and Pd/D co-deposition triple tracks, Kowalski's comments on flux units and exposure time are not relevant. We also note that Kowalski does not dispute the fact that one cannot differentiate DT-generated triple tracks and Pd/D co-deposition triple tracks.

Kowalski has asked ?What was a typical number of triple tracks found after 4.5 hours of DT irradiation of CR-39.? That was not the goal of this effort and again his question is not relevant to the results presented in our paper [6]. However, Kowalski's question was addressed by both Abdel-Moneim and Abdel-Naby [3] and Phillips et al. [8].

Kowalski has indicated that the observation of "at most 5 to 10 triple tracks" in CR-39 detectors used in Pd/D co-deposition experiments is a very small number and suggests that it would be more significant to list the total number of triple tracks found in all co-deposition experiments. Again Kowalski's statement is not relevant. We would like to point out that we only look for triple tracks in areas where the track density is low. Consequently, the number of triple tracks is, in all likelihood, under-reported. Also we have conducted over a hundred experiments using CR-39 detectors. This includes Pd/D co-deposition experiments as well as control experiments. As we noted in our papers [1,6], triple tracks have only been observed in experiments involving the use of palladium and deuterated water. They have not been observed in copper electroplating experiments nor in Ni-screen electrolysis experiments in either D_2O or H_2O. Nor have triple tracks been observed in blank detectors.

Kowalski states that "the world is waiting for a reproducible-on-demand and convincing demonstration of a chemically-induced nuclear reaction.? He then asks ?what kind of co-deposition experiment is more likely to lead us to that end" The intent of our research is not to provide the world with such an experiment. Our intent is to conduct experiments to gain a better understanding of the phenomenon. CR-39 is simply one tool we are using to gain that understanding.

Kowalski's last sentence "The last SPAWAR paper focusing on rare events, can be contrasted with earlier co-deposition papers were the reported tracks were much more abundant" is puzzling. Presumably this statement is meant to discourage us from reporting on the existence of triple tracks by disparagingly saying that they are too few to warrant further attention. It should be noted that the discovery of new subatomic particles and CP symmetry violations in physics have been the result of "rare" events. The rarity of such events does not invalidate them. There are other such examples in nature. Clearly Kowalski does not appreciate the significance of triple tracks in CR-39 detectors used in Pd/D co-deposition experiments. Nor does he appreciate the fact that the Pd/D co-deposition triple tracks are indistinguishable from DT neutron generated triple tracks. For us to not report on the existence of triple tracks in our Pd/D co-deposition experiments would have been scientifically negligent.

Referee 2:

The SPAWAR group has been researching particle emission from Pd codeposition experiments for several years, and they have published a variety of remarkable results. Kowalski has now for years played the role of the critic, skeptic, or questioner. In the present manuscript, Kowalski is continuing this role.

Two of his comments/questions refer to the exposure of CR-39 plates by a neutron source; he wants to know why a 4.5 hour exposure was used; he points out the 10 million neutrons/sec is not a flux, and he wants to know the flux.

One of his comments has to do with the statistical significance of the triple tracks.

The final comment seems to have to do with strategy, but is in actuality a criticism.

It is the case that the SPAWAR group should probably have given an integrated flux number as neutrons per unit area. We presume that they picked the exposure time in order to get a useful signal. This issue of how many such tracks have been seen is important, and readers would benefit if SPAWAR could shed light on this. The final comment/criticism is not as helpful or interesting.

There is no physics contribution in this manuscript. It would be appropriate for a simpler version of this comment to be published, along with a short response from SPAWAR immediately following.

However, given the negative history of the interaction between Kowlaski and the SPAWAR group, we need to be mindful to minimize the nontechnical content of the comment. It should be revised to a few sentences that request

(1) clarification of the integrated neutron flux in units of neutron per unit area; and

(2) additional information about how many triple tracks have been seen total in how many experiments, and perhaps additionally how many hours of run time.

Referee 3:

This paper does not contain any scientific advance, nor any improvement on earlier work.

3) Quick comment (I will probably write more later).

a) I agree with the Referee 3; the purpose of my short note was to ask for clarifications, not to publish new information. I expected my note to be published in the same issue in which the three questions would be answered by one of the SPAWAR authors.

b) Referee 2 wrote “given the negative history of the interaction between Kowlaski and the SPAWAR group ...” That hurts; I am trying my best to be useful. Do not forget that I was among the first CMNS researchers who published results that were identical to those published by the SPAWAR team. I started using solid state track detectors in 1961 (using mica, not CR-39). A year later I wrote a review article on the subject (in a Polish journal “Postempy Fizyki,” volume 13, page 463). I summarized what I learned from an American, R. Walker, in France. He brought this new method of detection to Europe; I was probably the first European to observe fission fragments with them.

Offering constructive criticism should not be called “negative interactions.” I would be very happy to have friendly interactions with SPAWAR people; I admire their work. Their results are reproducible on demand and that is very important.

c) Referee 3 wrote “Kowalski has indicated that the observation of “at most 5 to 10 triple tracks” in CR-39 detectors used in Pd/D co-deposition experiments is a very small number and suggests that it would be more significant to list the total number of triple tracks found in all co-deposition experiments. Again Kowalski’s statement is not relevant.”

I disagree, it is very relevant, considering the context in which this observation was made. Here is that context again :

My first comment has to do with the number of tracks. As stated in Subsection 3.3, codeposition experiments “typically last two weeks.” The number of triple tracks per detector was “at most 5 to 10, including both the front and back surfaces.” That is indeed a very small number. It is reassuring that no triple tracks “have been observed in background monitoring detectors.” That rules out the “cosmic rays” interpretation. This argument would be stronger if the total numbers of experiments were reported.

Suppose that ten detectors are used in all codeposition experiments, and that the mean number of tracks per detector is 5. Then the total would be about 50 triple tracks. Suppose that only five triple tracks were found on ten background monitoring detectors. The difference between 50 and 5 would certainly be more significant than the difference between 10 and 3.

I was a little surprised that not a single triple track was observed in background detectors. My expectation would by about 3 or 5, in ten such detectors. That is why seeing 50 would be more reassuring than seeing only 10. But I do understand practical difficulties mentioned by Referee 3. (By the way, my guess about ten chips exposed to neutrons was actually very close to reality. The actual number was nine, as written by the Referee 3 above.)

Yes, the final comment was not necessary. It was not an attempt to “discourage” anything; it was a statement about the strategy I would prefer. I would focus on what has already been shown to be reproducible on demand and would start “playing with parameters.” But, as they say in Russia, “na wkus i na cviet towarishchej niet.” Or “in matters of taste there are no friends.”

394) Philosophical Aspects of Cold Fusion Controversy

Ludwik Kowalski (see Wikipedia)
Professor Emeritus
Montclair State University, Montclair, NJ, USA
March 7, 2012

Abstract
The field of Cold Fusion (CF), now called Condensed Matter Nuclear Science (CMNS), remains controversial. The original 1989 claim made by M. Fleischmann and S. Pons (F&P) was that a chemical process in an electrolytic cell could initiate a nuclear reaction-fusion of two deuterium nuclei. This conflicted with known behavior of such nuclei. In the US, CMNS claims were evaluated by the Department of Energy (DOE), in 1989 and 2004, as summarized in this article. The controversial F&P claim, and the DOE investigation of it, are examined in the context of scientific methodology of validation of claims, both empirical and theoretical. Neither F&P nor the DOE followed the expected methodology.

1. Introduction

The philosophy of science is concerned with the assumptions and methods of scientific explorations. One of these assumptions is that activities of scientists are properly described by Merton's **CUDOS** norms: **C**ommunalism (discoveries are not private); **U**niversalism (of the scientific methodology of validation of claims); **D**isinterestedness (of scientists motivated by love of truth); **O**riginality (search for new data and explanations); and **S**crutiny (checking and double-checking of claims). The purpose of this essay is to address these norms in the context of the still ongoing Cold Fusion controversy. That controvesy--started in 1989 (1,2,3,4,5,6)--divided physical scientists into two feuding camps (7,8,9,10).

Scientific methodology refers to the set of norms developed to deal with difficulties, especially with mistakes and controversies. Most scientific mistakes are recognized when new results are discussed with colleagues, or via the peer review process. Occasional errors in published papers are subsequently discovered during replications conducted by other researchers. Scientific results, if valid, wrote Huizenga (5), must be reproducible on demand. “When errors are discovered, acknowledged and corrected, the scientific process moves quickly back on track, usually without either notice or comment in the public press.” The scientific process, in other words, is expected to be self-corrective.

The purpose of this presentation is to analyze the ongoing CF controversy, an example of a situation in which self-correction has not worked for 23 years. Why is it so? The author of this article, and three other researchers, tried to verify one recent CF claim-emission of alpha particles during electrolysis. The results were negative, as described in (11). The most recent CF claim was made by an Italian engineer, Andrea Rossi (12), the inventor of a new kind of nuclear reactor. That claim cannot be independently verified because of imposed secrecy. Rossi's appeal to believe in the efficiency of his "secret catalyst" is not consistent with the methodology of validation practiced by scientists and engineers. His claim may or may not be valid. But there is not a good reason for accepting it as truthful. Secrecy is certainly not consistent with the "scrutiny norm" of CUDOS.

2. In Science Theories Guide But Data Decide.

Why is the CMNS controversy started in 1989 unresolved? Because CF claims are still not reproducible on demand, and because they conflict with accepted theories. A theory, in this context, is a logical/mathematical structure that agrees with a wide range of already verified experimental data. Empirical scientists know the rule-theories guide but experiments decide. But they are very reluctant to abandon accepted theories. To be reluctant means to insist on

additional verifications of new experimental results. A recent claim that neutrinos travel faster than light, for example, was received with great skepticism; it has already been shown to be due to an experimental error.

Referring to such situations, Huizenga wrote: “There are occasionally surprises in science and one must be prepared for them.” Theories are not carved in stone; scientists do not hesitate to modify or reject theories when necessary. Rejecting a highly reproducible experimental result “on theoretical grounds” would not be consistent with scientific methodology. Unlike mathematics (and other formal sciences), empirical science is based, in the final analysis, on experimental data, not on logical proofs. In that sense methods of validation of claims in physical and social sciences are similar. Scientific theories are models of objective reality; they are changed, or modified, when new facts are discovered.

Mathematics, on the other hand, is more like theology than like empirical science. A mathematical truth, called a theorem, is based on initial undeniable assumptions (axioms), and on logical reasoning based on them. The only way to refute a theorem is to find a logical error in its derivation. In that sense mathematical or theological truth is said to be eternal; it is not refutable by experimental data. One similarity between theology and mathematics, however, should not prevent us from seeing important differences; one of them has to do with disagreements about axioms. Such disagreements among theologians are frequent; disagreements among mathematicans are rare.

3. Scientific Claims: Data And Explanations.

Basic principles of scientific methodology of validation of claims are usually known. Less widely known are differences between validation of facts and validation of scientific theories. A typical process of acceptance of a fact is schematically illustrated in Figure 1 below. A preliminary experimental result is presented to a scientific community. This often leads to attempts to either confirm or refute what is presented. Results are accepted when they become reproducible on demand. Absence of such reproducibility puts data into the domain of protoscience, which may or may not become science.

More important claims call for greater scrutiny, against possible errors and possible fraud. Fraudulent data have recently been discovered in applied sciences, for example about efficiency of certain drugs or medical treatments. Such episodes are not consistent with CUDOS rules. How can they be explained? Complexity of research and its fragmentation--large teams working on small parts of projects and not communicating with each other--is probably an important factor. Such situations are more common today than when CUDOS norms were formulated.

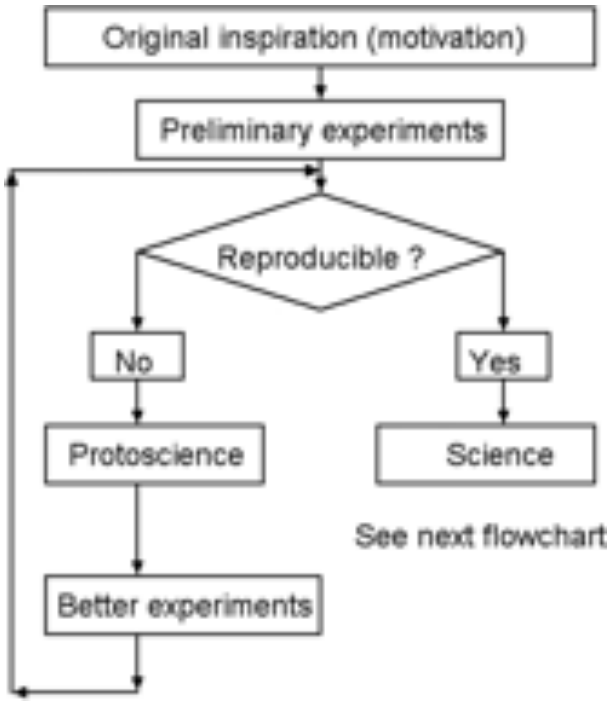

Figure 1

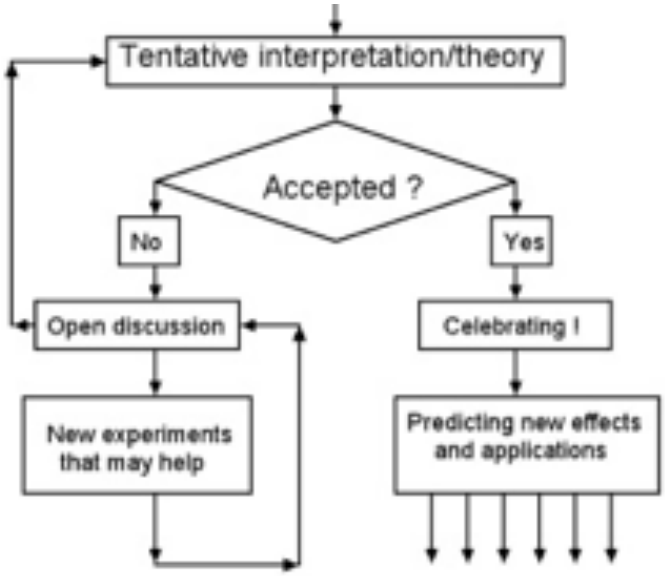

Figure 2

The "love of truth," a component of CUDOS, refers to the pleasure scientists derive from discovering facts and explanations. To explain something usually means to identify causes, and to construct logically satisfying models of reality. The process of acceptance of an explanation, schematically illustrated in Figure 2, is often the continuation of the process diagramed in Figure 1. An attempt to explain one fact, or to resolve an apparent logical conflict, often leads to discoveries of other facts.

A classical example of this was the "theoretical prediction" of the existence of planet Neptune, in 1846. A more recent, and less widely known example, was the discovery of a subatomic particle named neutrino. Experimental data, collected in 1920's showed that most beta rays (electrons emitted in beta decay) had energy lower than expected on the basis of the $E=mc^2$ formula. Austrian theoretical physicist W. Pauli solved this "logical inconsistency" by suggesting that tiny neutral particles, later named neutrinos, are responsible for the missing energy. His hypothesis was formulated in 1933. Experiments designed to confirm reality of neutrinos turned out to be successful, 23 years later. They were performed by American experimental physicists, C. Cowan and F. Reines.

4. The original mistake of Fleischmann and Pons

The strategic mistake made by F&P was an attempt to interpret experimental data before their results were recognized as reproducible (see Figure 1). Trying to establish priority, under pressure from Utah University, the scientists announced their results at a sensational press conference (March 23, 1989). At the same time they claimed that the reported amount of excessive heat was due to fusion of deuterium nuclei -ionized hydrogen atoms introduced into palladium.

. . . . .  . . . . Martin Fleischmann, on the right, with the author of this article (2003)

It is well known that two hydrogen nuclei can fuse, releasing energy. But this happens only at extremely high temperatures. At ordinary temperatures the probability of the reaction is practically zero, due to the well-known coulomb repulsion of positive nuclei. F&P had no evidence that the excessive heat was due to a nuclear reaction. They wanted to study the CF phenomenon for another year or so but were forced to announce the discovery by the university administrators (13). The only thing they knew was that the excessive heat could not be attributed to a

chemical reaction.

Suppose their experimental results had been described without any interpretation, and the phenomenon had been named “anomalous electrolysis.” Such a report would not have led to a sensational press conference; it would have been made in the form of an ordinary peer review publication. Only electrochemists would have been aware of the claim; they would have tried to either confirm or refute it. The issue of “how to explain the heat” would have been addressed later, if the reported phenomenon were independently confirmed.

But that is not what happened. Instead of focusing on experimental data (in the area in which F&P were recognized authorities) most critics focused on the disagreements with the reliable hot fusion theory. Interpretational mistakes were quickly recognized and this contributed to the skepticism toward their experimental data. Jumping from the process described in Figure 1 to the process described in Figure 2, was premature.

5. First Investigation Of CF By The US Government

The significance of CF, if real, was immediately recognized. Some believed that ongoing research on high-temperature fusion, costing billions of dollars, should be stopped to promote research on CF. Others concluded, also prematurely, that such a move would be opposed by “vested interests” of mainstream scientists. Responding to such considerations, the US government quickly ordered a formal investigation. A panel of scientists, named ERAB (Energy Research Advisory Board), and headed by John Huizenga, was formed to investigate CF in 1989. The final report, submitted to the DOE several months later, interfered with the normal development of the field.

It should be noted that ERAB scientists investigating the CF claims were not personally involved in replications of experiments. Conclusions and recommendations from their report (14), based on visits to several laboratories rather than participation in experiments, are summarized in the Appendix. Only one of their conclusions (item 2 in the Appendix) refers to CF experiments. Conclusion 4 was about anticipated practical uses of CF while the remaining four conclusions (1, 3, 5, and 6) were about various aspects of the suggested interpretation of experimental results. Instead of focusing on reality of excess heat critics focused on the fact that the hypothesis was not consistent with what was known about hot nuclear fusion.

The same observation can be made about the ERAB recommendations. Only one of them (item 9) refers to possible errors in experiments. Items 7 and 8 refer to future funding while items 10, 11, and 12 refer to what was expected on the basis of the suggested hot-fusion interpretation. It is clear that the ERAB observations were based mostly on ”theoretical grounds,” and not on identified errors in experimental data. Recommendations about future financial support for CF were very important. But the DOE ignored them. Support for CF research practically stopped in 1989.

Another result of the first DOE investigation was that editors of some scientific journals started rejecting manuscripts writen by CF scientists, bypassing the peer review (25). They also started to impede communication between nuclear scientists. Sixty letters to the editor of Physics Today--related to the second DOE investigation--were received, according to (26), but not a single one was published. Editorial discrimination directed against a targeted group of nuclear science experts is certainly not consistent with CUDOS norms. How can it be explained? Why was the scientific methodology of validation of claims-theories guide but experiments decide - not followed by the DOE-appointed scientists? Why did “rejections on theoretical grounds” prevail?

6) Second Investigation Of CF By The US Government

The second DOE investigation of CF was announced in March 2004, nearly 15 years after the first one. Links to three online documents related to that investigation - Conference Agenda, Meeting Agenda, and DOE CF Report - can be found in (15). The six most important scientific questions, based on new experimental claims, were:

(a) Is it true that unexpected protons, tritons, and alpha particles are emitted (9, 16) in some CF experiments?

(b) Is it true that generation of heat, in some CF experiments is linearly correlated with the accumulation of ^{4}He

. . . and that the rate of generation of excess heat is close to the expected value of the 24 MeV per atom of ^{4}He (9, 17)?

(c) Is it true that highly unusual isotopic ratios (9, 18) have been observed among the reaction products?

(d) Is it true that radioactive isotopes (9, 19) have been found among reaction products?

(e) Is it true that transmutation of elements (20, 21) has occurred?

(f) Are the ways of validating of claims made by CF researchers [see conference reports presented at (16, 17,18)]
. . . consistent with accepted methodologies in other areas of science?

A positive answer to even one of these questions would be sufficient to justify an official declaration that cold fusion, in light of recent data, should be treated as a legitimate area of research. But only the (b) question was addressed by the selected referees. They were asked to review the available evidence of correlation between the reported excess heat and production of fusion products. One third of these referees stated that the evidence for such correlation was conclusive. That was not sufficient; the attitude of the scientific establishment toward cold fusion research did not change.

7) Conclusion

Long-lasting controversies about scientific discoveries are widely known. Let me mention "Alfred Wegener, whose hypothesis was rejected by the 'cognoscenti' for half a century, but which now represents the basis, not simply for a theory, but also for a true paradigm shift in science - plate tectonics." I am quoting from a comment made by a university colleague, Dr. J.C. Delany. The CF controversy seems to be different in terms of its intensity and caliber of adversaries on both sides of the divide. Huizenga and Fleischmann were indisputable leaders in nuclear science and electrochemistry. Most CMNS researchers are also Ph.D. level scientists. The same is true for those scientists who believe that the announced discovery of CF was a “scientific fiasco”.

Why was so little accomplished to solve the CF controversy during more than two decades? Because CUDOS, and other rules of scientific methodology, were not followed. Scientists are only human; competition among them, as among other groups of people, tends to produce not only positive but also negative influences. Cold fusion will be viewed as an interesting episode in the history of science, regardless of verdicts about validity of numerous CMNS claims. More specifically, the long-lasting CF episode will be remembered as a social situation in which the self-correcting process of scientific development was not allowed to flourish. To what extent was this due to extreme difficulties in making progress in the new area (without financial support from the DOE, NSF, etc.), rather than to negative effects of competition, greed, jealousy, and other "human nature" factors? Such unanswered questions are worth addressing in the context of philosophical debates about science and society.

8) Appendix: The 1989 US Government Investigation of CF

As stated in Section 4, the first investigation of the CMNS field took place in 1989. The final report, submitted to the DOE several months later, interfered with the normal development of the field. It should be noted that ERAB scientists investigating the CF claims were not personally involved in replications of experiments. Their report (14), based on visits to several laboratories rather than participation in experiments, can be summarized by the following statements:

Conclusions:

1. There is no evidence that a nuclear process is responsible for excess heat.
2. Lack of experimental reproducibility remains a serious concern.
3. Theoretically predicted fusion products were not found in expected quantities.
4. There is no evidence that CF can be used to produce useful energy.
5. The CF interpretation is not consistent with what is known about hydrogen in metals.
6. The CF interpretation is not consistent with what is known about nuclear phenomena.

Recommendations:

7. We recommend against any extraordinary funding.
8. We recommend modest support for more experiments.
9. We recommend focusing on excess heat and possible errors.
10. We recommend focusing on correlations between fusion products and excess heat.
11. We recommend focusing on the theoretically predicted tritium in electrolytic cells.
12. We recommend focusing on theoretically predicted neutrons.

395) A strange story worth recording

Ludwik Kowalski

Montclair State University, New Jersey, USA

July 23, 2010

(1) On July 21, 2010 I learned about a new SPAWAR paper. It was published in EPJ AP, on July 7, 2010. The title is "Comparison of Pd/D co-deposition and DT neutron generated triple tracks observed in CR-39 detectors;" the authors are: P. A. Mosier-Boss, J. Y. Dea, L. P.G. Forsley, M. S. Morey, J. R. Tinsley, J. P. Hurley and F. E. Gordon. I downloaded that interesting article and informed the CMNS list about its existence. After sharing the link I wrote: I will read their article more carefully later. The first quick reading convinced me that a big step froward has been made by SPAWAR team. I hope their article will be discussed on this forum."

After reading the article I posted this message on the CMNS list (also on July 21): "I suspect that in order to estimate the neutron "flux" (at the end of Section 2) the number 10^7 should be divided by $4*PI*r^2$, where r is the distance between center of the source and the irradiated CR-39. Is this correct? If so then how large was r? "
(2) Another list subscriber, Abd ul-Rahman Lomax, responded (also on July 21): "I think there is a misunderstanding or incomplete text here. The 'flux' has been stated, there, for the exposure from a "Thermo Fisher Model A290 neutron generator," as 10^7 sec^{-1}. Either there is a missing unit, i.e., "cm^{-2}," or the figure is total neutron emission from the source, which then would require a distance (and specified intermediate material) in order to be meaningful, quite as you note. My suspicion is that the "cm^{-2}" was simply omitted, since we really only care, in understanding what's happening at the detector, about the actual flux passing through a particular area, not total neutron emission, and the flux would also be dependent upon beam pattern, etc. If I'm correct, then, the figure is 10^7 neutrons/cm^2/sec, for 2.5 hours, which specifies the figure we need to know. Otherwise, without the other data, the figure is almost meaningless.
(3) Responding to the above (on July 22) I wrote: "Yes, indeed. The effect produced by neutrons in a given location is directly proportional to the flux [n/(s*cm^2)] while the source is usually described in terms of its intensity [n/s]. The pending question is about 10^7. Is this the flux or is it source intensity?" Why did no one from SPAWAR answer our questions ?

(4) On July 22 I received a message from X. Actually, it was not sent to me; it was sent to edjap (typing error in this address), and to Pamela Boss. The author has a 1964 BS degree in history and physics and a 1967 MA degree in psychology). Prompted by a detail from that above message I responded (sending the CC to Pamela Boss, but not to epjap): "Suppose the electrodes (anode and cathode) are removed from a SPAWAR cell. Suppose the 6kV DC is applied to copper plates in contact with external parallel surfaces of the plastic cell. My expectation is that the field (due to 6 kV) inside the electrolyte would be very small but not zero.
- - - - - - - - - - - - - - -
Let me elaborate. All materials, even plastics have finite resistance, often many giga-ohms. Suppose each wall of the SPAWAR cell has the resistance 30 giga-ohms. The resistance of the electrolyte is much smaller. Suppose it is only R2=100 ohms.

a) How large is the electric current flowing from one copper plate to another? V=6000 V, R=60 giga-ohms=$6*10^{10}$ ohms

I=V/R=6000/6*10 =10 A or 0.1 micro-ampere.

b) What is the potential difference between the walls (inside the electrolyte)?

U=I*R2=10^{-7}*100=10^{-5} volts=10 micro-volts

c) How large is the electric field inside the electrolyte (assume the distance between the walls is L=2 cm)?

E=U/L=10/2=5 micro-volts per centimeter. This is a very low fields, in comparison with 6000V / 2 cm = 3000 V/cm

For an ideal dielectric R would be infinity, I would be zero, and E would be zero. But ideal dielectrics do not exist."

(5) The above was sent to X last night. Several hours later (on July 23) X responded. The reply was addressed to epjap@edpsciences.org; with my name in the CC field. I was not aware that this was a formal submission of a comment to European Physics Journal Applied Physics (EPJ AP).

(6) Then I received the message from EPJ AP. They wrote: "We are pleased to tell you that we have received [your] manuscript and we would like to thank you for choosing EPJ AP. As you are aware, we can only consider articles that have not been published or are currently submitted for publication in any other journals or another EPJ section. We will inform you of the editorial decision as soon as possible."

The EPJ Inquiry System at : https://articlestatus.edpsciences.org/is/epjap/ is at your service to follow up the status of your article. Your author ID for access is: ..... and article reference number: ....

(7) Replying immediately, I wrote: "I did not submit any manuscript to epjap yesterday. Please ignore anything submitted last night under my name. It was probably a joke. Also, please send me that manuscript. Thank you in advance. "

(8) They responded: "The message has been sent by Rich Murray. It seems to be a comment on an article which has been accepted for publication (please see the attached file)." That file was nothing else but what I wrote to X. I am the first author, he is the second author.

(9) Here is my second message sent to epjap: "Thank you for the quick reply. Rich Murray, who I do not know, did ask me a question yesterday. It was about the electric field. (The cell has flat plastic walls. The outside surfaces of these walls are coated with copper and 6000 V dc is applied to copper. How strong is the electric field inside the electrolyte?)

I answered Murray in a private message. Without asking for permission, he took my reply and submitted it as a comment. I stand for what I wrote, and I have nothing against his comment. But I do not want to be the co-author of it. Please remove my name. I did read the last SPAWAR paper (about triple tracks) with great interest and would like to comment on it. Please describe the rules governing your forum."

(10) Their response was: "We have removed your name on the comment sent by Murray Rich. Unfortunately, we don't have any forum on our web site but if you want to make a comment on the article, you could send us the comment and we will send it to the authors in order to know whether they want to make a reply or not. (As you have already done for the article "The Use of CR-39 in Pd/D Co-Deposition Experiments")

(11) Why did no one from SPAWAR answer questions about the flux? They were posted on the CMNS list two days ago. Frustrated by this I quickly composed the same questions in the form of a short note, to be submitted to EPJ AP. Then I read the latest SPAWAR paper again and formulated several more questions. A two-sentence note became a one-page manuscript (with five references). I submitted it. The title is "Four questions and one comment." Will they publish it? It depends on the referees. I would very much prefer to discuss the paper on our private CMNS list.

(12) I am glad that my name was removed; most experiments described in the last SPAWAR paper were performed without using the electric field. In the last paragraph of my submitted manuscript I wrote: "The world is waiting for a reproducible-on-demand, and convincing, demonstration of a chemically-induced nuclear reaction. What kind of codeposition experiment is more likely to lead us to that end?" In other words, should we be focusing on extremely rare triple tracks (at most 5 to 10 per 4 cm^2 during two weeks of electrolysis) or on much more abundant tracks discovered in earlier codeposition experiments? My advice, to those who want to contribute, would be to return to the first SPAWAR protocol. I was one of several people who used it independently, and who reported the same results as Pamela et al. That was in 2007. I would prefer to study more abundant tracks, trying to show that at least some of them are due to nuclear reactions induced by electrolysis. Neutrons are not more convincing signature than charged particles. What is wrong with using the same protocol over and over till a convincing yes or no answer is obtained?

(13) Today (July 24) the question was finally answered, by one of the authors of the paper. As I suspected, the 10^7 is not the flux. Responding to the clarification I wrote: " My recollection is that neutrons are generated in a metallic foil loaded with tritium. The foil is bombarded with a focused beam of D ions, accelerated to a chosen energy, for example, 1 MeV. The foil is located in a vacuum chamber. Suppose the distance between the source and the CR-39 detector is 10 cm, as guessed by Akito. In that case $4*PI*r^2=1256$ and the flux is $10^7/1256$, or nearly 10^4 n/(s*cm^2). But the "neutron pipe" might be longer than 10 cm. The flux would be only ~ 100 n/(s*cm^2) if r were 100 cm. I am assuming that the source is not pulsed. For a pulsed source the 10^7 n/s might stand for the source intensity during each pulse, and the mean intensity (over long time) could be several orders of magnitude smaller.

Why am I digging into this? Because I want to understand why the irradiation time had to be as long as 4.5 hours."

(14) Responding to the above Akito Takahashi wrote: " On Jul 22, 2010, at 4:19 PM, Ludwik Kowalski wrote: *Yes, indeed. The effect produced by neutrons in a given location is directly proportional to the flux [n/(s*cm^2)] while the source is usually described in terms of its intensity [n/s]. The pending question is about 10^7. Is this the flux or is it the source intensity?*

Dear Ludwik, Pam kindly replied that the operator of A290 NG told 10^7 n/s yield. Accordingly, I revised my previous speculation, as follows:

**) " Basic data for $^{12}C(n,n')3$ alphas for 14MeV neutron incidence : 0.206 b for reaction total. Branching ratio to the ^{12}C excited state 9..64MeV: 33% (See K. Kondo, et al.: JNST, 45(2008)103-115). Sub-branching ratio to the four body direct break-up; the channel (4) of Pam; n' + 3Alphas; not exactly known, but let's assume 20%.

**) Cross section to the channel (4): 0.2x0.33x0.2=0.013b
**) Thermo Fisher Model A290 NG: http://www.thermoscientific.com/wps/portal/ts/ I did not find A290. I however guess it would be like an old KAMAN type pulsed DT neutron generator (NG) in shielded tube (several microsec pulse) to produce 10^{10} n/s on the order. Actual time-averaged yield was 10^7 n/s due to the pulse repetition.

**) Pam set her CR39 at about 10cm from NG (on the surface of NG tube), 14MeV neutron flux is 10^4 n/s/cm^2.

**) She irradiated CR39 for 4.5 hrs, so that 14MeV neutron fluence (flux times irradiation time) is: $4.5x60x60x10^4 = 1.6*10^8$ n/cm^2

**) Reaction (event) rate of the channel (4) for producing triple tracks is: Assuming ^{12}C density in CR39 as $6*10^{22}$ C/cm^3 and 0.1 cm thickness of CR39, Triple track events: $(6*10^{22})*(0.013*10^{-24})*(1.6*10^8) = 1.2*10^5$ [tracks/cc] Triple track-events by $1cm^2$ CR39: $1.2*10^4$ tracks/cm^2

**) From Fig.1 of Pam's paper (EPJ AP 51 (2010) 20901), we assume one triple track in $0.025*0.025$ $cm^2 = 6.25*10^{-4}$ cm^2 area of an optical microscope observation for comparison with Phillips. Pam would find $(1.2*10^4)*6.25x10^{-4}= 7.5$

by NG. This is a total number of stars (triple tracks) in a CR39 with one cm^2*0.1cm size. We need to consider the actual etching condition of CR39 after irradiation.

**) In Pam's co-deposition experiments, she found 5-10 tracks per a CR39 detector. This result would correspond to $[(1.6*10^8)/(1.2*10^4)]*(5-10)= (1.3-0.65)*10^5$ fluence of around 14MeV neutrons. It corresponds: 0.16*(1.3-0.65)= 0.1-0.05 n/s/cm^2 flux of DT neutrons, if we assume two weeks run of her co-deposition experiment. CR39 was set very close to the cathode of co-deposition, so that its solid angle to see the source (cathode) is about 2*pi. Neutron (maybe DT) production rate in the co-deposition experiment is estimated to be 0.2-0.1 n/s.

**) If about 100mW excess heat observed were nuclear origin (suppose 10^{11} events per a joule), the observed level of "DT" neutrons was very low, on the order of 10^{-11} of the nuclear heat level.

BTW: Neutron energy Pam estimated by Eq.(5) would be En – En'. This might mean that the incident neutron energy were more than 13.46 MeV. As we do not know En', inelastic scatted neutron energy, of the corresponding event of the star (triple track), we may merely say so.

My speculation may be too much at the moment. We shall wait for a quantitative study by the SPAWAR group

(15) Next morning I wrote: "Thank you Akito. Several years ago I exposed CR-39 chips to neutrons of several MeV (from a Pu-Be source). At least 99% tracks seen after etching were due to protons, that is to hydrogen nuclei on which neutrons are scattered inside the CR-39 plastic. Occasional larger pits were most likely due to single alpha particles. I do not recall seeing triple tracks. This is not surprising; less then 1% of neutrons, from a Pu-Be source, have energies higher than 10 MeV. But I am surprised that SPAWAR CR-39 surfaces were not totally covered with highly overlapping pits due to recoiling protons, after 4.5 hours of exposure. That is why I suspect the flux might have been much lower than 10^4 n/(s*cm^2). We still do not know r, the distance between the neutron source (where deuterons are focused), and the irradiated CR-39. I suspect that your guess (r=10 cm) was an underestimation. But why should we be guessing? Even a very approximate answer would be sufficient."

(16) How important is the issue of tracks produced by neutrons from a DT source? The central issue is emission of neutrons due to electrolysis, presumably from a sequence of two fusion events. First two deuterons fuse producing ^3H. This is the CF reaction (7). Then the product of the reaction, ^3H fuses with another deuteron. This is reaction (9). Another sequence of two fusion reactions (8) and (10), is responsible for production of high energy protons.

Thermonuclear reactions 7, 8, 9, and 10 are well known. According to most textbooks, however, they are practically impossible at low temperatures. That is the essence of the cold fusion controversy. But in the context of SPAWAR hypothesis an attempt to compare tracks produced during electrolysis with track due to ~14 MeV neutrons is highly justified. I was very excited when I read, in the abstract, that "In this communication, triple tracks in CR-39 detectors observed in Pd/D codeposiotion experiments are compared with those generated upon exposure to a DT neutron source. It was found that both sets of tracks were indistinguishable." That is what prompted me to post the message quoted in (1) above. Yes, a step forward was made. But will it lead to a demonstration the world is waiting for? That remains to be seen.

(17) If I were to asked to verify the hypothesis advanced by SPAWAR--occurrence of reactions 7, 8, 9, and 10--I would focus on high energy protons, rather than on high energy neutrons. Ranges of high energy protons from reaction 10, in all materials, are much longer than ranges of alpha particles of several MeV. For protons with energies between 12 and 18 MeV the ranges in CR-39 are ~1.5 mm and ~3.0 mm. respectively. Some of these protons (incidence angles close to zero degrees) would travers the CR-39 deterctor (1 mm); others (larger angles of incidence) would be stopped in it. Many tracks, on both sides of the detector, would probably be strongly elliptical. This is only a guess; I have never exposed CR-39 to high energy protons. The local ionization density, due to protons with energies up to 30 MeV is still sufficiently high to produce etcheable tracks. (P.S. Googling the Internet I found a paper describing CR-39 tracks due to protons of 9.6 MeV and 30 MeV. I suspect that even 100 MeV protons might be detectable in CR-39.)

What energy would a 15 MeV proton have after traversing 1 mm (132 mg/cm^2) of CR-39? The answer is 10.5 MeV. Protons of that energy are cerainly detectable in CR-39. In other words, a 15 MeV proton, traversing a CR-39 chip perpendicularly, would produce a circular pit at the exit side of the detector. The diameter of that pit would be about 1/3 of the diameter of a pit due to an alpha particle from Am-241. A similar (but slightly smaller) pit would be produced at the point incidence. Some protons entering the detector at non-zero angles will exit the chip (producing a pair of pits), while others will be stopped in the CR-39 material (producing only one elliptical pit).

Recognizing strongly elliptical pits would probably be easier than recognizing triple tracks produced by neutrons from reaction 9. Furthermore, protons are charged particles and their detection efficiency is close to 100%. In other words, nearly every high energy proton crossing a CR-39 surface would probably create a visible track. The efficiency of detection of Mhigh energy neutrons, by contrast, is usually smaller than 0.0001%.

It is interesting that presence of strongly elliptical tracks is not mentioned in the SPAWAR paper. That probably means that no such tracks are produced in codeposition experiments. How can this be interpreted? Does it mean that the probability (cross section) of the CF reaction 8 is many orders of magnitude lower than the probability of the CF reaction 7? Note that thermonuclear reactions 7 and 8 have practically identical cross sections, in a wide range of energies. . . .

(18) Trying to get people involved I just posted another short message (on July 26). I wrote: "SPAWAR paper is very interesting. It is certainly worth discussing on this list. Please visit my just updated unit 395."

(19) It is 7/28/2010. I am surprised. My observation about strongly elliptical tracks due to protons from the Reaction 10 was posted two days ago. But no one commented on it. Even SPAWAR people remain silent. Why is it so? Their paper was published in a refereed mainstream journal. In their place I would be pleased to address reader's concerns immediately. Something is not normal. Am I asking nonsensical questions? Is my form of asking them not appropriate?

Another comment about still unspecified neurton flux was posted today by Abd ul-Rahman Lomax. He reminded the list that the source strength (approximately 10^7 n/s) was given to the SPAWAR team by the operator. But we cannot use this number unless the value of r is also know. He wrote: " I'd have assumed that the neutron source has a known intensity and known characteristics, such that the placement of the CR-39 in a particular position would produce a known flux per unit area per second. While this is not essential for seeing the characteristic triple tracks, for which it could be asked "Just give me a pile of neutrons," it is not only triple tracks that are of interest, it is also the far more numerous apparent proton recoil tracks. It should be possible to determine from the CR-39, from comparison of the track characteristics and density, two estimates of neutron flux integrated over the experimental period; the estimates from triple tracks and from proton tracks should be roughly equal.

But to do this we would have to know the neutron flux from the DT source, the total neutron emission of 10^7 /sec is almost meaningless, except to establish an upper bound. Surely this would be a known value to the operatiors of the equipment. I'm a little bit troubled by the appearance in a peer-reviewed journal of a number, presented as a fact, that turns out to be simply something 'told by the operators'. But perhaps I'm naive as hell. "

(20) Responding to the above, a member of the SPAWAR team provided information about circumstance under which the irradiation with fast neutrons took place. But nothing was said about the flux. This prompted me to post the following short message:

"What they [the SPAWAR team] did is reasonable. But what prevents them from calling the operators and asking about the distance between the irradiated CR-39 detector and the center of the source? The operators know what the distance was, at least approximately. That would be enough for us to estimate the flux. This additional information is likely to enrich the already-very-impressive results published by the SPAWAR team. Their work is admirable. Let us hope it will lead to what the world is waiting for. Best wishes to Pamela, and to her coworkers."

From the reply posted by Pamela I lerned that several CR-39 detectors were placed around the tube. My question

about the distance r was not answered again. My reply consisted of one sentence: “what was the diameter of the tube? ”

It is August 2. Responding to my question about the diameter, another member of the SPAWAR team posted a message which I prefer not to quote. It amounted to something like 'mind your own business and stop bothering us.' Once again, my question was not answered. I am disappointed. Why knowing the flux is so important? Because the reader of the paper must be able to compare what is reported with what is expected. The expected results cannot be calculated unless the flux, and the exposure time, are known. I have no idea why only the exposure time was specified (4.5 hours). How can this information be used when the flux is not given?

Yes, it is their experiment, not mine, as stated by the author of the last message. It is time to stop asking the same question. My disappointment is not with SPAWAR science, which is admirable. It is with human relations. Will my unit 396, announved the day before yesterday, bring some contributions? I hope so.

PS
R. Murray sent another message to the editor of EPJ AP. The CC was again sent to me and to Pamela Boss. Murray's submision was refused and he was commenting on the rejection. It was mostly about the electric field inside the cell. I do not know why Murray speculates about the "possibility [that the] solar system dark matter" may be involved. But his concern about the possible of "microleaks" makes sense to me. SPAWAR people are experienced chemists and their plastic cells were probably very clean. My calculation was based on this assumption. But suppose the opposite walls are coated with a conducting layer of dry electrolyte. In that case the electtic field inside of the the would be much higher than I calculated.

Rossi again? I have nothing positive to report.

Ludwik Kowalski; 3/12/2012

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

= = = = = = = = = = = = = = =

1) FeedBlitz often sends me articles about scientific-technological developments in the world. The title I received this morning is "Steven Krivit and the troubling case of Andrea Rossi." It is an interview with a science journalist Krivit about Rossi. I also followed Rossi's claims, as documented in unit 399 at this Cold Fusion website (click the link below). I think that Rossi's claims are not consistent with what is known and understood by authors of basic nuclear physics textbooks. That is why I am also not optimistic about Rossi's E-cats. But "not being consistent with what is known and understood" does not exclude the possibility that something new and important has been discovered by Rossi. It only lowers the probability of Rossi's claims being valid. That probaility is likely to be below 1%, in my opinion.

2) Most of you already saw the draft of my article **"Rossi's Reactors--Reality or Fiction?"** The final version has been printed in the January 2012 issue of Progress in Physics (pages 33-35). The online version is available at their website (Google will take you there).

3) Below is the abstarct of my "letter to the editor" of Progress of Physics. The letter, entitled **"Social Aspects of Cold Fusion: 23 Years Later"** will be printed in the April 2012 issue. The online version might be shown in March. Why am I quoting only the abstract? Because journals usually want to be the first to publish.

ABSTRACT: "The field of Cold Fusion, now called Condensed Matter Nuclear Science (CMNS), remains controversial. The original 1989 claim made by M. Fleischmann and S. Pons was that a chemical process in an electrolytic cell could initiate a nuclear reaction--fusion of two deuterium nuclei. More recent CMNS claims, made by experimental scientists, are: emission of charged nuclear projectiles during electrolysis; accumulation of 4He; production of radioactive isotopes; and transmutation of elements. In the US, CMNS claims have been evaluated in two Department of Energy (DOE) investigations, in 1989 and 2004, as summarized in this article. These investigations did not lead to any resolution of the controversy. Scientists and adminstrators are not ideal; competition among them, as among other groups of people, tends to have both positive and negative influences."

Comments, as always, will be appreciated.

Ludwik (see Wikipedia)

P.S. 3/6/2012

4) The entrire paper has just been published.
click to download it

5) The article entitled "Rossi's Reactors--Reality or Fiction," mentioned above, can also be seen:

click to download it

The paper shows why I think that Rossi's claims conflict with what is written in our nuclear physics textbooks.

6) Here is what a colleague X from Montclair State University posted, on a discussion list, after reding my "Social Aspects of Cold Fusion: 23 Years Later" article:

I believe that there is little controversy at this point. There are a handful of investigators who continue to pursue this hypothesis on a vain hope that it will prove to be correct in spite of the large body of evidence and existing knowledge to the contrary. It is not the responsibility of the scientific community to refute every hypothesis that is forwarded on the basis of irreproducible results. If those who continue to pursue CF can provide a working prototype and instructions that a competent scientist can follow to build it, then this "controversy" will instantly disappear. It is impossible to prove that CF cannot be induced by electrochemical means involving heretofore unknown physics. The onus of proof is on, and should remain on, those who make such extraordinary claims.

I believe that the scientific community has been unusually kind to the CF proponents. To propose that one has developed an energy source that violates much of currently accepted physics takes a certain type of individual. To continue to claim that it works without showing an independently verifiable prototype also takes a certain type of individual. Most of the time the term "charlatan' is applied.

On a side note, I do not know that Fleischmann was an indisputable leader in electrochemistry in 1989. I don't currently have access to the citation index to check on his pre-1989 contributions.

And here is my reply:

I agree that the burden of proof is on those who make claims. We cannot check all claims, especially those made by authors without scientific credentials. But I also think that the DOE, NSF, etc. have some obligation toward claims made by Ph.D. level scientists who worked in National Laboratories for decades, conducted first-class research and published widely in refereed journals. They should have access to referees as all other scientists. But editors of many scientific papers often reject CF papers by themselves. That is not normal. I am also skeptical about many cold fusion claims. But that does not mean that I should support topic-based discrimination.

You have seen how I reacted to a recent claim made by an inventor, Andrea Rossi (who is not a scientist). His claims conflict with what is in our nuclear physics textbooks. Does this mean that he cannot possibly be right that something totally unexpected has been discovered? No it does not mean this. But the probability that he is right is very low, most likely less than 1%, in my opinion. Neither the DOE nor the NSF should support his research. Let us wait and see; perhaps he is right in believing that his invention will be validated by a large number of satisfied customers. I am certainly not going to invest in his "great technology."

Several hours later X responded:

Hi Ludwik, I think we all *hope* that the CF side is right. I remember the excitement and skepticism in 1989... "Probably not, but what if?" We'd all like to see a cheap convenient way to exploit the fusion mass defect to produce energy. But, honestly, 23 years is more than enough time to make the Palladium-Deuteroxide reactor reproducible. That other approaches have been forwarded in the mean time seems a bit desperate to find some excuse to keep looking. So, I disagree about topic-based discrimination. We should not take papers on the Phlogiston Theory or on perpetual motion machines or on poly-water. If they want to publish in the top journals, let them produce a working reactor that others can replicate and test independently. If they are correct they will all be multi-billionaires and can laugh at us from their mansions.

A colleague of mine pointed out that Fleischmann was one of the first to report the surface enhanced Raman effect, though he erroneously attributed it to a concentrative effect. So I will take back any objections about him

having been a leading figure in electrochemistry. I wonder if his "miss" on surface enhanced Raman by being too conservative influenced his thinking 15 years later when he saw another unusual phenomenon in his lab.

My next-day reply was:

Those interested in Cold Fusion (CF), might enjoy reading McKubre's 2009 paper at the 15th International CF conference in ROME. The link is:

http://www.enea.it/it/produzione-scientifica/pdf-volumi/introduction-iccf15-proceedings-2.pdf

Mike is an electrochemist. I know him personally and I have no doubt that he is honest. In fact, he is a hero, in my view. How many people would be willing to continue probing for more that two decades under showers of spits? I think that he is motivated by the noble desire to help society.

Unfortunately, I did not go to the ICCF15 in Rome in 2009. But I did participate in, and contributed to, three earlier conferences (USA-2003, France-2004, and Japan-2005). My impression was, and still is, that most CF researchers (not all) are like Mike, and that their methodology of validation is scientific. Great scientists I met, including Frederic Joliot Curie, who introduced me to research, would agree. The difficulties described by Mike are real.

Subject-based discrimination (denying peer review process to Ph.D. level scientists) is harmful and totally unjustified. The DOE should support CF projects. A clear yes-or-no answer, about how to make excess heat experiments (described by Mike) reproducible on demand, could be obtained at a cost that is negligible (in comparison with how much is spent on supporting hot fusion studies). Yes, I am thinking about 0.1%, such as several million dollars versus tens of billions. Download Mike's paper and read it carefully; you will probably agree that there is nothing unscientific in it.

More on spectacular claims of Andrea Rossi

Ludwik Kowalski; 3/12/2011

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

= = = = = = = = = = = = = = =

1) The reactor invented by Andrea Rossi, about which I wrote a year ago (see unit 388 at this website), is again in the center of international attention, as one can see by going to

http://pesn.com/2011/01/19/9501747_cold-fusion-journals_warming_to_Rossi_breakthrough/

The recent public demonstration, at the Bologna University, could have been more effective than it was, without revealing the nature of the secret catalyst. Rossi could have provided the blueprint of the apparatus to a trusted authority, for example, Italian government laboratory, asking them to manufacture his simple device. They would bring it to the University of Bologna and allowed Rossi to place the secret fuel (nickel powder mixed with something else) into the cylinder. He would not be allowed to do anything else to the apparatus. That would eliminate a possible suspicion of a hidden energy source, somewhere within the apparatus.

This, however, would not eliminate another possible suspicion--that some chemical fuel was mixed with nickel. But suppose the powder supplied by Rossi is weighted, both before and after the experiment. Suppose the change in weight is negligible, in comparison with what it would be expected for the most effective chemical fuel. That would be a sufficient indicator that a non-chemical process was responsible for the released thermal energy.

2) Unit 388 reminded me that in the patent application Rossi claimed that "a practical embodiment of the inventive apparatus, installed on October 16, 2007, is at present perfectly operating 24 hours per day, and provides an amount of heat sufficient to heat [his small] factory." That was nearly four years ago. Suppose the rate of heating was 50 kW; suppose the heating time was 4 months per year (totaling 4*3=12 months, or 8640 hours). How much thermal energy was generated? The answer is

50*8640=4.32 * 10^5 kWh, or 4.32 * 10^5 * 3.6*10^6 = 1.555* 10^12 J

This is the same as from burning 5.29 tons of coal.

3) Was the thermal energy, reported by Rossi, released from a nuclear reaction? This would produce a measurable amount of reaction products. Addressing this issue, I posted the following message on the website for CMNS researchers, on January 24, 2011.

Andrea Rossi and Sergion Focardi, have a reactor capable of producing 12,400 watts of heat power from an electrical input of just 400 watts." In other words, the net heat generation rate is 12,400-400=12,000 W =12,000 J/sec = 7.7*10^16 MeV/sec

Suppose a typical fusion reaction contributes only 2 MeV of heat (escaping neutrinos, neutrons, and gamma take away the rest of the released energy). That would mean that nearly (7.7/2)*10^16, or about 4*10^16 fusion reactions is taking place each second.

Suppose that the atomic mass of a detectable combustion product is about 60 amu (1 amu=1.66*10^-27 kg).

What is the total mass of all products created during one hour of operation? The mass production rate is: 60*4*10^16=2.4*10^18 amu/sec=4*10^-9 kg/sec=4*10^-3 mg/sec

The mass produced in 36,000 second (10 hours) would be 36,000* 4*10^-3=144 mg. That would be detectable with a standard analytical balance.

The mass would be considerably larger for non-radioactive products (because no energy is removed from the reactor by neutrinos, neutrons and gammas).

The bottom line is obvious; detection of heat, at the rate of 12.4 kW, correlated with detection of nuclear combustion products, should be trivial, for qualified chemists.

The reactor described by Rossi (see above) operated for about 12 months (not only 10 hrs, as in my illustration). That is 864 times longer. The accumulated mass of reaction products (and their daughters, if any) would thus be 0.144*864=124 grams. For a reactor operating at the rate of ~40 kW (rather than 10 kW) the mass of the accumulated reaction products would be four times larger, or about 500 grams. In other words a sizable fraction of the nickel fuel would be consumed, producing 500 grams of new products. The isotopic composition of the spent fuel would be drastically changed. What prevents Rossi from announcing existence of such change? This can easily be done without revealing the nature of the catalyst. Both scientists and potential investors would be convinced that something totally new has indeed been invented by Rossi.

He is certainly aware of this. Here is what Rossi wrote in 'Journal of Nuclear Physics:'

http://www.journal-of-nuclear-physics.com/?p=62&cpage=2

Actually, this is a blog, not an on-line journal. But that is not my point.

(A) the Ni powder I utilized were pure Ni, no copper . At the end of the operations in the reactor the percentage of copper was integrally bound to the amount of energy produced. A charge which has worked for 6 months, 24 hours per day, at the end had a percentage of Cu superior to 30%

(B) About the Ni isotopes: the isotopes after the operations were substantially changed in percentage. We are preparing a campaign of analysys with a Secondary Ions Mass Spectrometer at the University of Padua (Italy), at the end of which the data will be published on the Journal Of Nuclear Physics.

Why were such spectacular results--conversion of at least 30% of nickel into copper and drastic changes in isotopic composition--were not published at a scientific conference, or in a real journal? That puzzles me. How can this be explained?

4) Here is how the most recent demonstration of the device was summarized in

http://pesn.com/2011/01/19/9501747_cold-fusion-journals_warming_to_Rossi_breakthrough/

'Focardi and Rossi demonstrated a novel boiler on 14 January 2011, which converted water at about 13 degr C to steam at 101 degr C. The device reportedly produced energy from nuclear reactions between nickel and hydrogen. An electrical heater in the device drew about 1000 W at startup. Later, once the reactions started and provided heat, the input power was reduced to about 400 W. Consumption of hydrogen gas was essentially negligible. The input water flow was about 150 grams each half minute. Given the measured input and output temperatures, that flow rate, and a measurement that the steam was dry, it is easy to compute that [in the steady state] the device delivered over 10 kW of thermal [power] to the water. '

The reactor, shown on available illustrations, was a small cylinder; the amount of nickel powder is probably less than two or three kilograms. Accepting this estimation, I conclude that the 30% of produced copper, reported by Rossi,

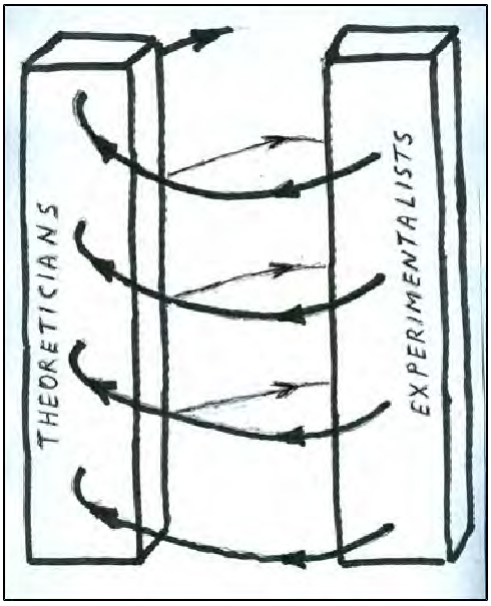
translates into about 1 kg, after a prolonged operation. My very conservative estimate, 144 mg after 10 hours of operation (see point 3 above) is probably consistent with what he reported.

According to Rossi (see the link to The Journal of Nuclear Physics in point 3 above) production of copper takes place when hydrogen nuclei, which are protons, fuse with nickel nuclei. Fusion of protons with nickel nuclei has been studied by many physicists, including myself (as reported in The Physical Review, Vol .163, Nr. 4, 1074-1077, November 1967). But our protons had the energy of 14.3 MeV, Rossi's protons, by contrast, had low temperature energies, close to 0.04 eV.

The probability of nuclear fusion, expressed in terms of measurable cross sections, is known to decrease rapidly with energy. How can 0.04 eV protons fuse with nickel, whose atomic number is 28? Rossi does not have to answer this question; his role is to provide experimental evidence that such fusion does occur, under the influence of a catalyst. I am sure that a theoretical explanation will be found, soon after his experimental results are independently confirmed, and after information about the catalyst is published.

One of the well known facts is that the cross sections of a nuclear reaction does not depend on the chemical composition of the target bombarded by protons. The target can be a crystalline nickel, a compound containing nickel, a melted nickel, or vaporized nickel. No exception from this rule has been found. But the rule has not been tested for all conceivable solid compounds. As far as I know, it has never been tested for protons of very low energy. Rossi, like several other scientists, probably believes that the rule is not universal and that exceptions are possible, especially at very low energies. His experimental results, if confirmed, would validate such expectations.

The 'all swans are white' rule, I remember reading somewhere, was valid up to the time at which black swans were discovered. In science, unlike in mathematics, validations, in final analysis, are based on experimental results, not on logical proofs. On the other hand, predictions based on logic, have often been successful; in other words, they were later validated by experimental data. Disagreements between new experimental results and existing theories should not be ignored. Yes, the 'theoreticians often guide while experimentalists decide.' But theories are based on verified results from experiments and observations. The chicken and the egg dilemma? Not really. Why not? Because the process of accumulation of scientific knowledge is not circular; it is spiral, as illustrated below.



Concecutive spiral loops, representing accumulation of knowledge about something, do not coincide. They wind throught two supporting blocks, labeled experimentalists and theoreticians. At any given elevation scientists in a given block exchange contributions with scientist in another block. What is being exchanged is never the same; in fact, it is usually very different at each level. Note that each block is both a receiver and a giver.

Added on May 11, 2011

The above was submitted to four mainstream journals, during the last two months. Unfortunately, it was rejected by editors (not by peer reviewers). The rejected manuscript can be seen at:

http://pages.csam.montclair.edu/~kowalski/cf/rossi.html

How can this be explained? This is not what editors are expected to do.

Added on May 13, 2011

The nature of the catalyst remains secret; independent replications are impossible. That is why most messages posted on the private list for CMNS researchars, have been theoretical. Here is a good summary, posted two days ago by Abd ul Rohman Lamax.

*Many theoretical physicists worked on CF theory, including more than one Nobel laureate. It is obviously a very tough theoretical problem. The first problem was that far too many, who might be otherwise competent, took a shallow look, said "impossible," and then dismissed the growing body of experimental evidence as *necessarily artifact, error,* since, *impossible.**

That was obviously a systemic failure, or, as Huizenga called it, perhaps not realizing the irony, The Scientific Fiasco of the Century.

*In normal problems with artifact, the research was done to demonstrate the artifact, cf. Polywater and N-rays. With both polywater and N-rays, there were *confirmations,* then demonstrations that the observations were artifact, not merely argument from impossibility. With cold fusion, there was only replication failure, and, by definition, replication failure cannot demonstrate artifact in the original work! It can only demonstrate one of two things: failure to replicate, conditions not the same or a chaotic effect, or, secondly, total error or fraud on the part of the original experimenter, or possibly some unidentified artifact that isn't reproducible. The latter possibility declines and rapidly vanishes with successful replication.*

If it's replicable -- and cold fusion was -- then any artifact should be identifiable, by controlling it in and out.

Once it was known that He-4 was being generated at the right heat ratio, and that was confirmed, as it was -- it's a reproducible and reproduced experiment, properly described -- it should have been all over. Before the close of the century.

But what is happening to cause this effect to appear? As Dr. Storms has pointed out, there are "plausible explanations," but no theory has been validated in any strong sense. Normally, what we want to see is predictive value, for theory is needed for prediction, as well as understanding. (Non-predictive theories can have a value for organizing thought, but not for engineering, and these are of some interest, but it's not really "scientific." Some non-predictive theories can usefully suggest avenues of approach, a good example might be the general wave theory of Dr. Irving Dardik.)

From my sense of the situation, any cold fusion theory is going to involve one or two "leaps," possibly more, that is, assumptions that lead to some possible understanding of a mechanism, but, because more than one are probably necessary, not to a complete understanding, adequate to make accurate predictions and answer objections. What is needed in this situation, my sense, is far more experimental discovery of the effect of controlled conditions.

My sense is that this is precisely what Rossi did. My own idea of approach would be to move in almost the opposite direction from much of the research, to design experiments that are smaller and cheaper and simpler, for thus it would become easier to vary the conditions, and to run the same experiment many times, to determine how much variation is still uncontrolled. Thus the effort to make it "bigger" and thus "better," worked against what is needed for understanding, particularly when funding was limited.

Rossi also apparently had a lot of his own money to put into this.

(In all this, I'm assuming that Rossi's heat is really being generated and is not fraudulently simulated. "Artifact," i.e., simple error in measurement or interpretation, seems highly unlikely at this time. Because of how much is at stake, "fraud" should not be casually discarded as a possibility, but I hasten to add that this is not an accusation of any kind, it is simple prudence. If there are hundreds of millions of Euros at stake, or more, what would be preposterous in a small scientific matter becomes not-so-inconceivable. Only when we have truly and fully independent replication -- which should happen this year if the effect is real and they are not blowing smoke, will we be able to leave "fraud" completely behind. And fraud may still take place in other ways! I predict there will be people who will claim other "discovery" who won't have actually done it, and further attempts to fleece unwary investors, even if Rossi and Defkalion are completely honest.)

So, right now, if anyone wants to pursue the Rossi track, and I know that there are people doing it, I suggest Smaller is Better. Make the tests as small as you can, consistent with showing some clearly significant effect. Depending on your calorimetry, 105% might be enough, it certainly was enough to show cold fusion with skilled calorimetry. Then keep varying it, a series of experiments that change only one variable, the more the better within one series. All the data is valuable, there are no "failures" in an approach like this.

As data like this becomes available, from those who choose to publish it, finding adequate theories will become easier. It will still be one of the most difficult puzzles in theoretical physics to come along for a long time, I predict. There are probably two miracles involved: how fusion or other LENR happens in the first place, and then how is the energy converted into heat, what happens to the expected gammas, etc.? Maybe someone will get lucky and propose a mechanism that, all by itself, causes the great forehead slap, and numbers will fall out. But I'm not counting on it.

Added on May 14, 2011

Intense theoretical discussion, involving several people, has been going on at the private Internet website for CMNS researchers. Let me show two interesting generalizations formulated by Ed Storms and John Fisher. They are addressed to those who speculate about mechanisms of nuclear processes responsible for the reported experimental data.

In one of his messages, **Ed Storms wrote:** *We have two entirely different kinds of reactions to explain; fusion and transmutation. The questions is, "Is one or more than one mechanism in play"? Regardless of how many mechanisms are operating, the same consequence is produced, i.e. the barrier is overcome by a process other than brute force and the energy is released in small increments, generally too small to detect.*

I think we have good evidence that fusion between two D takes place and produces the expected ^{4}He. Tritium is a problem because it can not result simply from d-d fusion and produce the observed consequences. Tritium has been produced when deuterium is present but also in H_2O. The evidence suggests both d and p must be present. In both cases, radiation is seldom detected. So, we need a mechanism that addresses these conditions and consequences.

Transmutation has been shown to involve clusters as well as single d or p. In both cases, radioactive isotopes are very seldom produced. In addition, radiation is seldom produced. The rate of the reaction does not seem to be sensitive to the charge on the target nuclei. This means the mechanism hides the charge on the p or d, even to the extent when a cluster contains 6d, but does not affect the charge on the target. When transmutation occurs in Pd+D, the Pd atoms forming the lattice are not the main target. The situation in the hydrogen system, according to Rossi, is different. Does this mean that several mechanisms are operating, which are sensitive to whether d or p is used?

I suggest the first approach is to see if a mechanism can be found that can produce all the observations without making ad hoc assumptions. None of the propose mechanisms can do this although some make that false claim. The erzion and polyneutron ideas do not fit the bill on many levels even though they are clever and address limited observations very well. The deflated electron idea of Horace, although possible as a basic concept, is much too complicated and filled with arbitrary assumptions and vocabulary to be plausible. The BEC ideas have no observational support and have

limited application. If a BEC were found to form in a lattice at RT, this observation alone would warrant a serious prize, regardless of CF. I have addressed the W/L theory before and shown that it is not worth discussing. The idea suggested by Andrew is getting close to what is required, but it also needs to be explained better. So, I hope people who have made theoretical suggestions will take these comments seriously and try to fix the problems so that we can get something to guide experiment.

In one of his messages, **John Fisher wrote:** *The comment by Ed Storms regarding X-rays associated with LENR reminded me again of the beauty and utility of the experiments done by Iwamura and his associates. Their reactor is conceptually simple: a specially prepared palladium foil with deuterium gas on one side and vacuum on the other. The Pd foil is special by having very thin layers of CaO interleaved with Pd layers near the surface facing the gas. With this reactor they have performed a number of critical experiments. They observed excess heat and X-ray emissions when using Pd foils containing CaO, but not when using plain Pd foils. They observed transmutation of target elements deposited on the deuterium-facing surfaces of foils, but there was no transmutation when H was substituted for D or when MgO was substituted for CaO. These experiments raise clear-cut questions for theory:*

(1) How does theory account for the X-rays?

(2) Why is there excess heat with D gas but not with H gas?

(3) What is the role of CaO in this reactor?

(4) Why doesn't MgO support nuclear reaction like CaO?

(5) How does theory explain the observed transmutations?

We theoreticians owe a substantial debt of gratitude to the Iwamura team for raising these challenging questions against which to test our theories.

400) An Abandoned Line of Research

Ludwik Kowalski, <kowalskiL@mail.montclair.edu>

Montclair State University, Upper Montclair, N.J.

I have just reread a ten years old article (1), signed by nine authors. The main authors were probably Cecil and Jones. They loaded deuterium into titanium foils--by placing them into the hot and compressed deuterium gas--and detected energetic charged particles, emitted form foils. Presence of such particles has been reported by other researchers, as summarized in (2). But detectors used by Keeney et al. were more advanced. The authors were able to distinguish different kinds of charged particles, and to measure their energies.

Here is the abstract of their article: *"We present evidence for energetic charged particles emanating from partiallydeuterided titanium foils (TiDx) subjected to non-equilibrium conditions. To scrutinize emerging evidence for low-temperature nuclear reactions, we investigated particle yields employing three independent types of highly-sensitive, segmented particle detectors over a six-year period. One experiment measuring neutron emission from TiDx foils showed a background-subtracted yield of 57 ± 13 counts per hour. (The neutron experiments are discussed in a separate paper in this proceedings.) A second experiment, using a photo-multiplier tube with plastic and glass scintillators and TiDx registered charged particle emissions at 2,171 ± 93 counts/hour, over 400 times the background rate. Moreover, these particles were identified as protons having 2.6 MeV after exiting the TiDx foil array. In a third experiment, coincident charged particles consistent with protons and tritons were observed with high reproducibility in two energy-dispersive ion-implanted detectors located on either side of 25-micron thick Ti foils loaded with deuterium.*

Our overall data therefore strongly suggest low-level nuclear fusion in deuterided metals under these conditions according to the fusion reactions d + d _ n(2.45 MeV) + 3He(0.82 MeV) and d + d _ p(3.02 MeV) + t(1.01 MeV), with possibly other nuclear reactions occurring. Important advances were particle identifications, and repeatability approaching 80% for coincident charged particle emissions. Metal processing and establishing non-equilibrium conditions appear to be important keys to achieving significant nuclear-particle yields and repeatability."

Their detector was a plastic scintillator, mounted of a glass and on the photomultiplier tube (PMT), as shown in Figure 1. That tube was connected to a multichannel analyzer. I am familiar with this method of detection. In fact, my very first original scientific contribution (3) was a thin layer of CsI, evaporated on glass. I wanted to use it in my doctoral dissertation studies. But silicon detectors became commercially available. They offered a better solution to a problem I solved, and I used them instead. My setup, for simultaneous detection of two fission fragments, with two solid state detectors, was also the same as shown in Figure 10. The fragments were emitted from a very thin uranium target and the whole setup was inside a vacuum chamber. What I did not know, however, was that the shape of the electric pulse, produced by the PMT, provides information about the origin of light (plastic scintillator versus glass, as shown in Figure 8).

Note that the labels "Light output" along the horizontal axis (Figure 3 etc.) is most likely the channel number of the analyzer; it is particle energy in arbitrary units. The background was 400 times lower than the signal, according to the abstract. The lines in Figure 2, on the other hand, are not experimental data, except the Am-241 calibration point. They show where the data points were expected. The vertical axis numbers, in Figure 2, should probably be multiplied by the factor of 10, in order to agree with the energy spectrum in Figure 3. (The amplifier gain was probably not the same in each experiment.) It would be more useful if all Light Outputs were expressed in terms of MeV, not in arbitrary units.

The emission of charged particles is apparently influenced by the "non-equilibrium conditions," as stated in the abstract. That refers to the 3 A current flowing through the foils, as illustrated on the right side of Figure 1. Figure 9

shows that the dependence of the rate of emission on time, after the end of loading, was not exponential. The maximum counting rate, at t=100 minutes, was close to one charged particle (mostly a proton with the energy close to 3 MeV) every 1.6 seconds. This amounts to 2200 cnts/hr. The counting rate at t=2 weeks was only 30 cnts/hour.

How reproducible is the shape of the distribution shown in Figure 9? How can such bell-shaped distribution be explained? Unfortunately, no answers to these questions can be found in the article. Even more surprising is the total absence of the follow-up publications; this article was published in 2002, at the 10th International Cold Fusion Conference, Cambridge, MA. How can absence of the follow-up publications be explained?

401) A Refutation and a Replication

Ludwik Kowalski, <kowalskiL@mail.montclair.edu>
Montclair State University, Upper Montclair, N.J. 07043

Introduction
In closing sections of Chapter 4 (1), Ed Storms focuses on various aspects of replication experiments. Let me address some of these issues, in the context of two projects: our Curie Project and SPAWAR project.

Curie Project
Our purpose (2) was not to either accept or reject Oriani's claim; it was to either confirm or not confirm it. The so called "burden of proof," as always, is on the author of a claim. The burden of rejection, on the other hand, is on all of us, not on authors of individual reports. I agree with Storms that "deciding whether sufficient replication has been achieved to justify accepting the effect as real phenomena is a complex problem." That is why a decision about accepting or not accepting belongs to the entire scientific community, in any given discipline. Unfortunately, a large fraction of nuclear scientists have already decided that all CMNS claims are pseudoscientific. That conclusion, accepted in the early 1990's, prevents constructive evaluation of new experimental data.

As stated in the Introduction, our goal was to either confirm or refute the claimed reproducibility of the Oriani effect. According to Storms, "repetitive failure [to replicate results] generally means the parameter space in which critical conditions fall is too small to be entered very often by accident using the available methods." This is certainly a possibility; our individual conditions were not exactly the same as in Oriani's lab. What exactly was responsible for our failure to replicate the originally reported results? That question can be answered, at least in principle, via a very complex investigation. I am thinking about changing places, for example, Oriani performing experiments in our laboratories using distilled water and us performing experiments in his laboratory, using tap water. I am also thinking about the use of teflon by Richard, about the use of spot-welded contacts by each of us, etc. A systematic investigation of this type would be practically impossible, under our working conditions.

SPAWAR project
The idea of organizing a collective attempt to replicate Oriani's results, The Curie Project, was a logical consequence of my participation in The Galileo Project, an attempt to confirm the effect discovered by SPAWAR team. Like other participants I observed the same copious pits as those observed by scientists who discovered them. After confirming their experimental results I addressed the issue of interpretation. Are the observed pits due to alpha particles, as claimed by SPAWAR scientists, or are they due to something else, as suspected by Richard Oriani? My answer to this question, based on measured sizes of copious pits, was that they cannot be due to common alpha particles, as described in (3). This conclusion was rebutted in (4). The issue the interpretation of reproducible results remains unresolved (5).

Unfortunately, this line of research--investigation of copious pits, on both CR-39 surfaces--was apparently abandoned in favor of the investigation of rare triple tracks (6), presumably due to fast neutrons. Why unfortunately? Because spectacular results whose reproducibility has been independently confirmed are rare. Such results should be studied, not abandoned. The first task should be to identify parameters, or combinations of parameters on which the effect depends or does not depend, as described in (1). For example, what happens when the magnetic field is either increased or decreased, when different cathodes, codeposition rates and laser illuminations are used, when ... etc. etc. Changing one parameter at a time, and publishing the results, preferably in different journals, would be highly desirable.

Conclusion

As stated in (7), each of us "is a citizen of the community of science. Each shares responsibility for the welfare of this community," and for the society at large. Attempting to objectively confirm or refute various scientific claims is our professional obligation.

Nuclear transmutation of radioactive isotopes and reactor waste deactivation in biological systems

Prof. Vladimir Vysotskii
Kiev National Shevchenko University,
Kiev, Ukraine

Dr. Alla Kornilova
Moscow State University,
Moscow, Russia

28 August 2011

Experimental investigation of fusion of iron-region stable isotopes in "one-line" growing microbiological cultures (1994-2000)

A typical series of experiments concerning nuclear transmutation of elements consisted in growing of microbiological culture in 3 disks

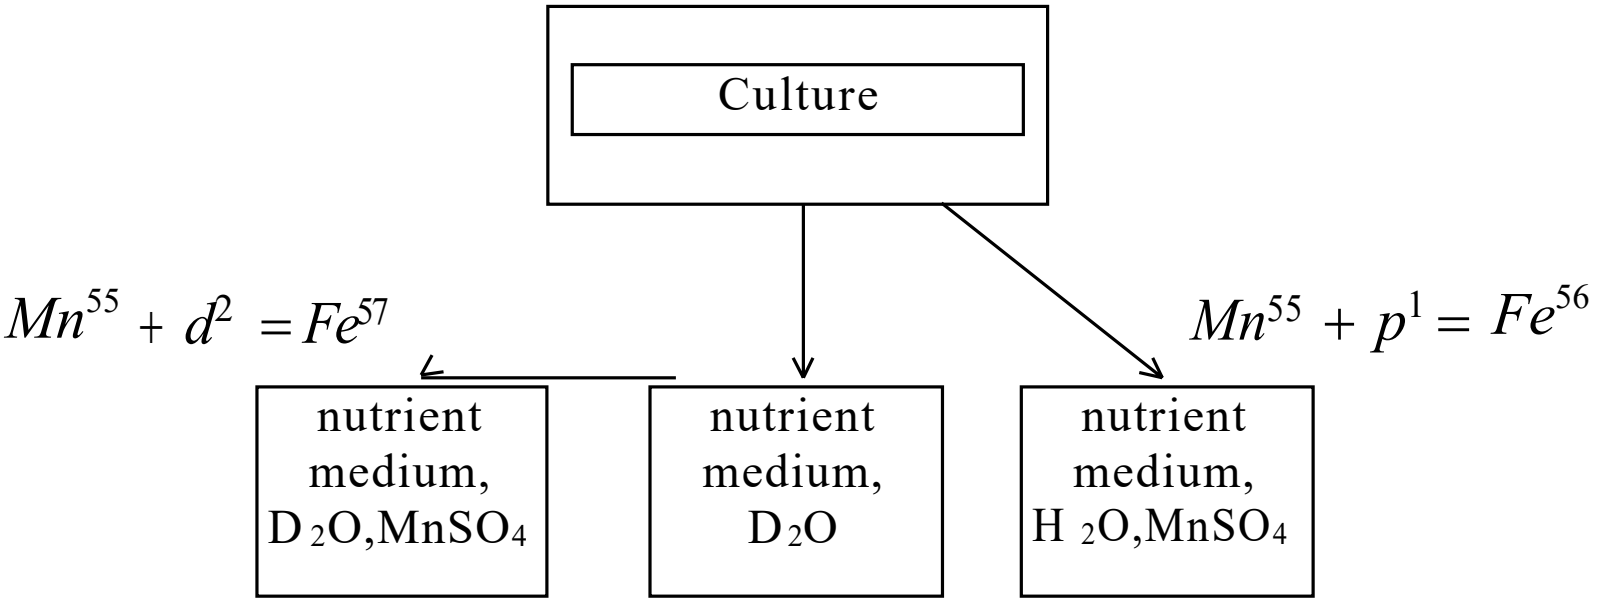

Fig.1 The scheme of experiment.

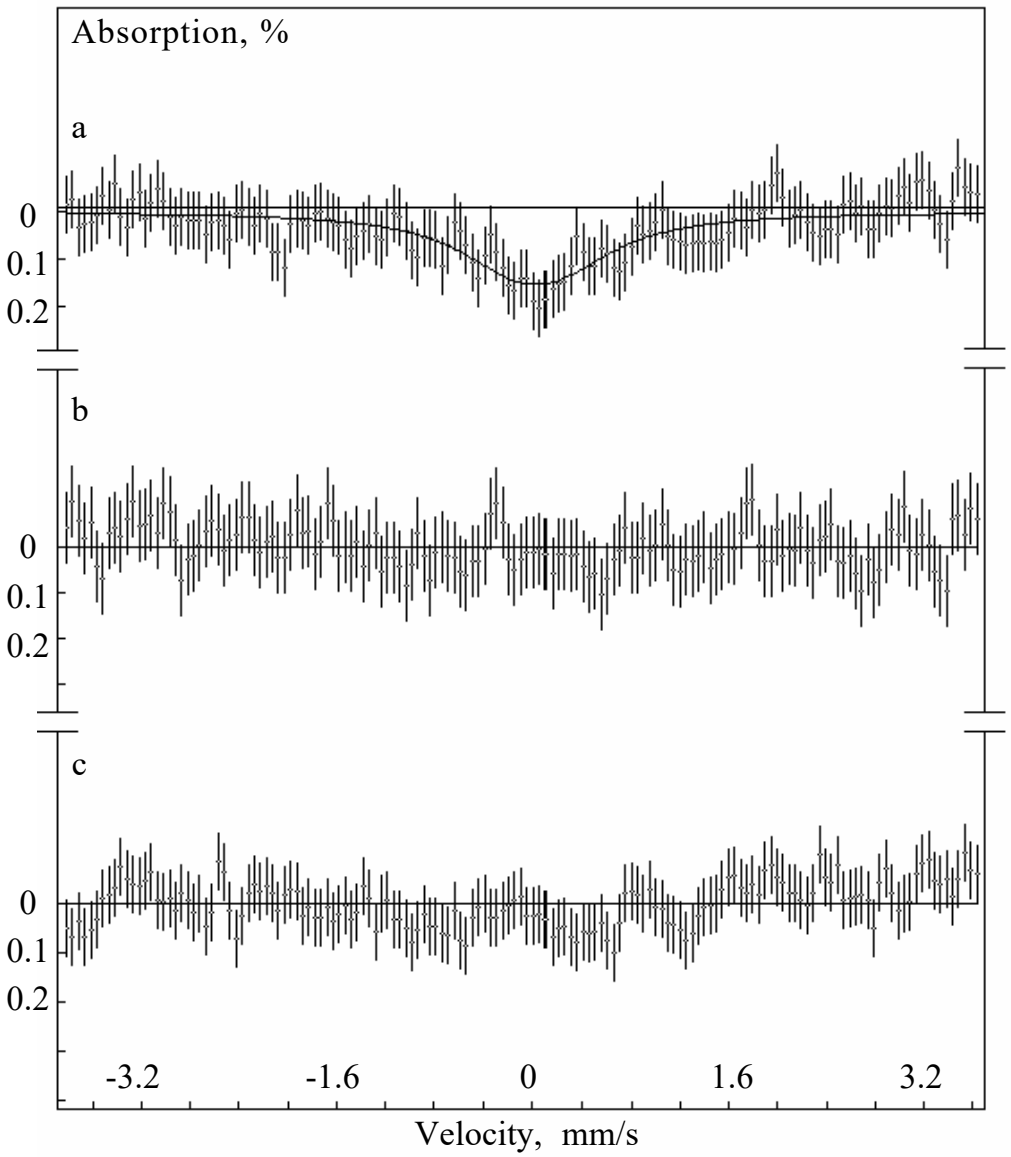
Such series of experiments was held for different cultures, different time of growth Δt (24, 48 and 72 hours) and different growth modes (in still disks and media and in suspension stirring mode using magnet stirring device).

Bacteria and yeast were grown in a thermostat at optimal temperature 32 C.



Mossbauer investigation of isotope transmutation

It was shown that the transmutation process during the growth of such microbiological cultures had taken place, but its effectiveness had been low:

$$t = \frac{\Delta N(Fe^{57})}{N(Mn^{55})\Delta t} \approx 10^{-8}$$

synthesized Fe^{57} nuclei per s and per single Mn^{55} isotope

The Mossbauer specter for the grown culture S*accharomyces cerevisiae T-8:* *a*) in D_2O with Mn^{55}; *b*) in H_2O with Mn^{55}; *c*) in D_2O without Mn^{55}

Studying of a transmutation of light and intermediate isotopes in growing microbiological culture by laser time-of-flight mass spectrometer

$$Mn^{55} + d^{2} = Fe^{57}$$

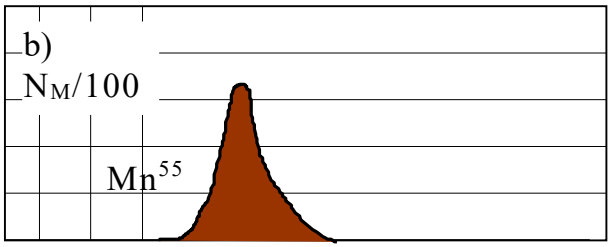
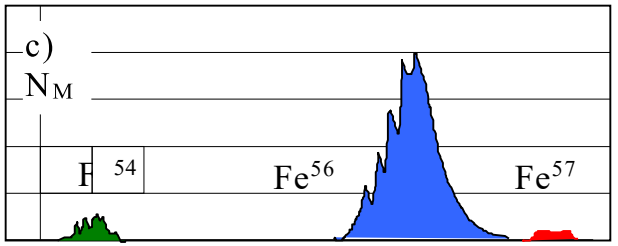
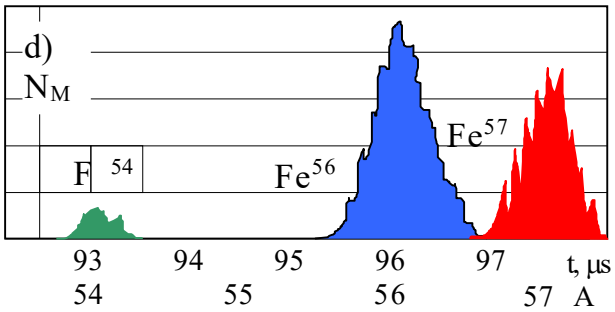
Nature Fe



Nature Mn



Culture grown in D_2O without Mn



Culture grown in D_2O with Mn

Fusion of iron-region stable isotopes in optimal growing microbiological associations (2000-2006)

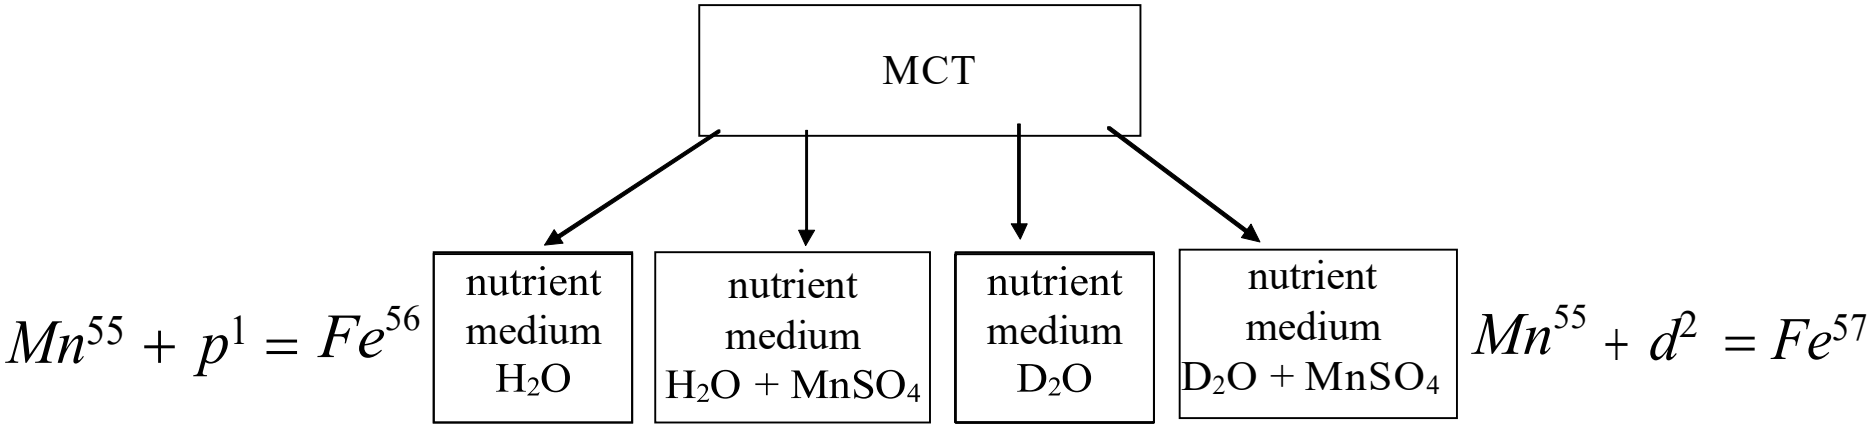
The relatively low efficiency of these reactions is the result of the relative narrow interval of optimal functional individual characteristics for supporting of nuclear activity in any "one-line" type of culture. During the growth of a "one-line" culture, we hypothesize that processes involving forms of auto-intoxication of nutrient media by metabolic products take place.

In a contrast to these "one-line" cultures, we have investigated microbe syntrophin associations that include great numbers of types of different cultures that are in the state of complete symbiosis.

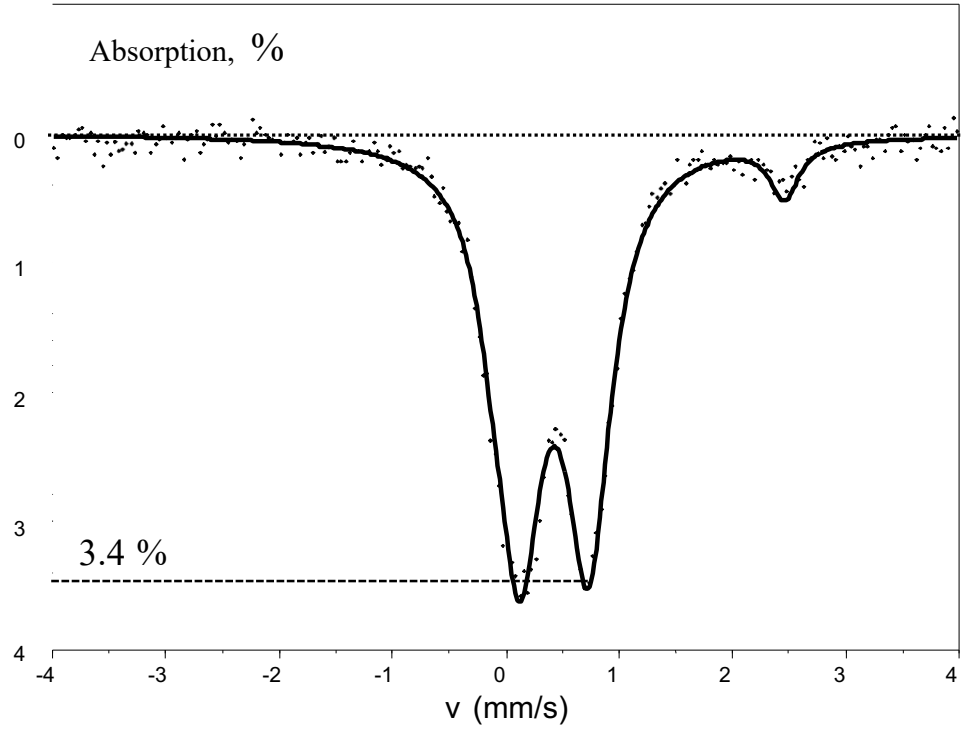
The ***MCT*** (microbial catalyst-transmutator) compound is the special granules that include:

1. concentrated biomass of metabolically active microorganisms (microbe syntrophin associations);
2. sources of carbon and energy, phosphorus, nitrogen, etc.;
3. gluing substances.

Investigation of nuclear reaction $Mn^{55} + d^{2} = Fe^{57}$ with MCT

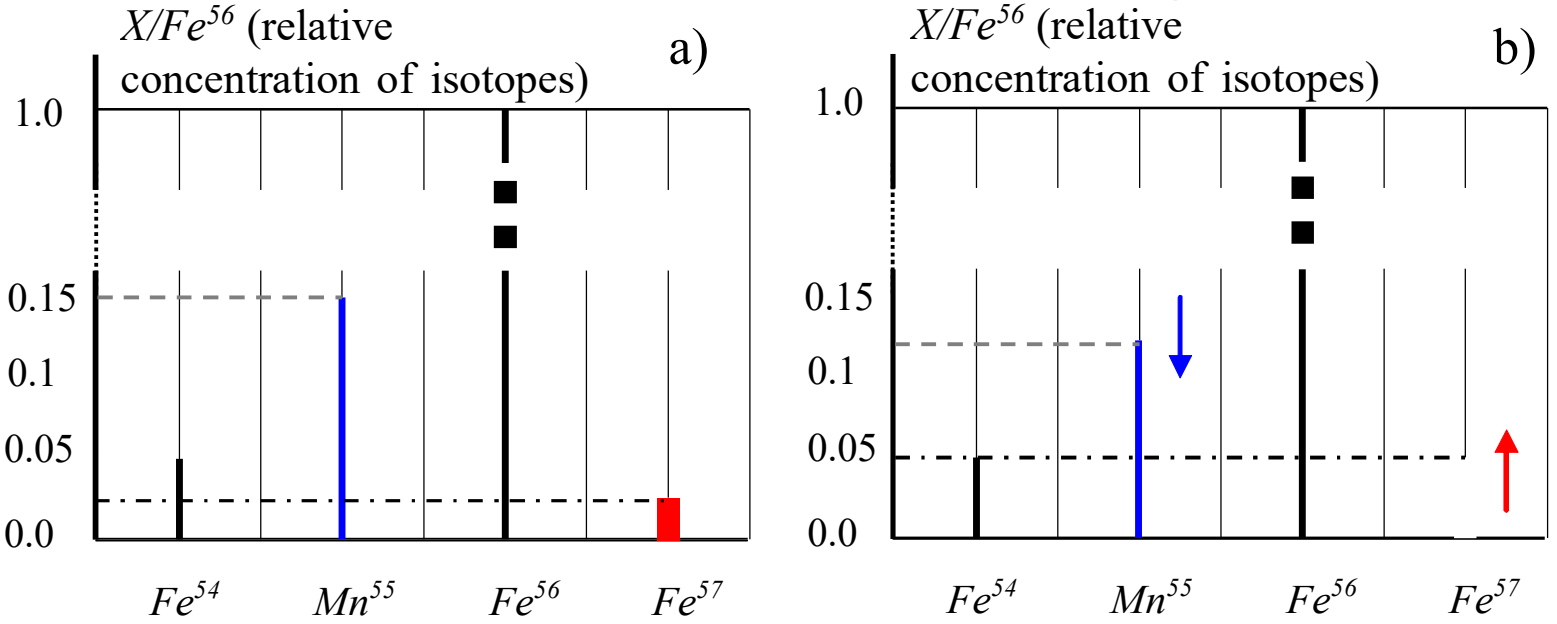


In these experiments the very large increasing of transmutation efficiency (by 100 times) was observed!



The Mossbauer specter for **growing microbiological associations** in D_2O with Mn55

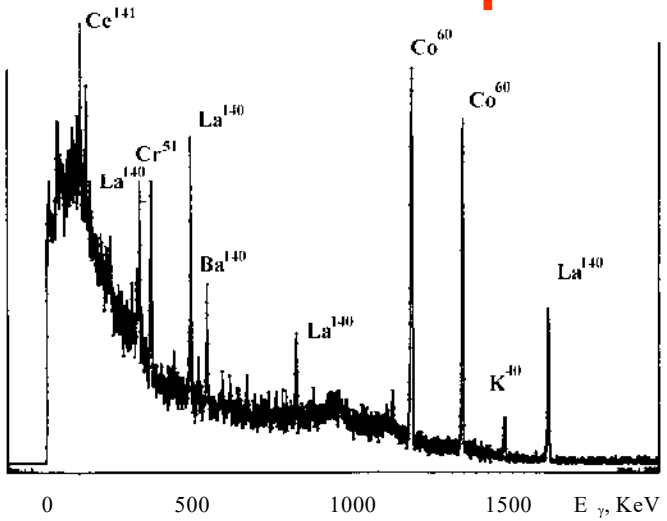
For verification of these results, additional examinations of the isotopic ratio of the same dried biological substances (both control and transmutated) were conducted by TIMS (**Thermal Ion Mass Spectroscopy**, «Finnigan» MAT-262.
The results of TIMS measurements presented in Figure



$$Mn^{55} + d^2 = Fe^{57}$$

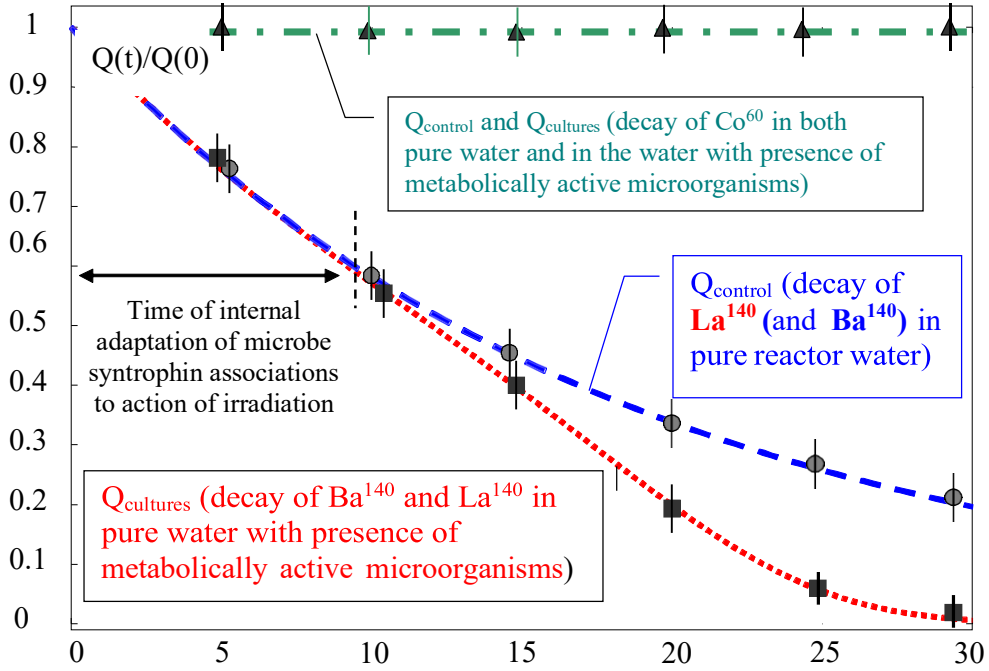
Mass-spectrum of iron-region of microbiological associations (dried biological substances) that were grown in control nutrient medium with H_2O and Mn^{55} (case a)) and in experimental nutrient medium with D_2O and the same quantity of Mn^{55} isotope (case b)) .Here $X=Fe^{54};Mn^{55};Fe^{57}$ ***The process of increasing (−) of concentration of Fe^{57} isotope is accompanied by decreasing (−) of concentration of Mn^{55} isotope***

Experiments on controlled decontamination of active isotopes in biological cells (2003-2010)



a) Deactivation of reactor water in biological cells

Spectrum of gamma-radiation of distilled water from first contour of water-water atomic reactor of Kiev Institute for Nuclear Research (10th day after extraction from the active zone).



t, days after extraction of water from the active zone of nuclear reactor

Change of activity Q(t) of the same reactor Ba^{140}, La^{140} and Co^{60} isotopes in the experiment on transmutation (activity $Q_{cultures}$ in pure reactor water with presence of metabolically active microorganisms) and in the control one (activity $Q_{control}$ in the same pure reactor water without microorganisms)

Studied La-140 isotope has short life-time 40.3 hours and is nonstable daughter isotope of Ba-140 radioactive isotope that has life-time about τ_{Ba140}= 12.7 days: Ba-140 $\rightarrow$ La-140 + β- + ν^* $\rightarrow$ Ce-140 (stable) + β- + $\tilde{\nu}$

Initial activities of the Ba-140 and La-140 isotopes (on the 10th day after extraction of water from the active zone of the nuclear reactor) were

$$Q_{Ba-140} = 1.46.10^{-6} Curie / l$$

$$Q_{La-140} = 2.31.10^{-7} Curie / l$$

The possible way of radioactive Ba^{140} isotope transmutation to the stable state is

$Ba^{140} + C^{12} = Sm^{152} + \Delta E$

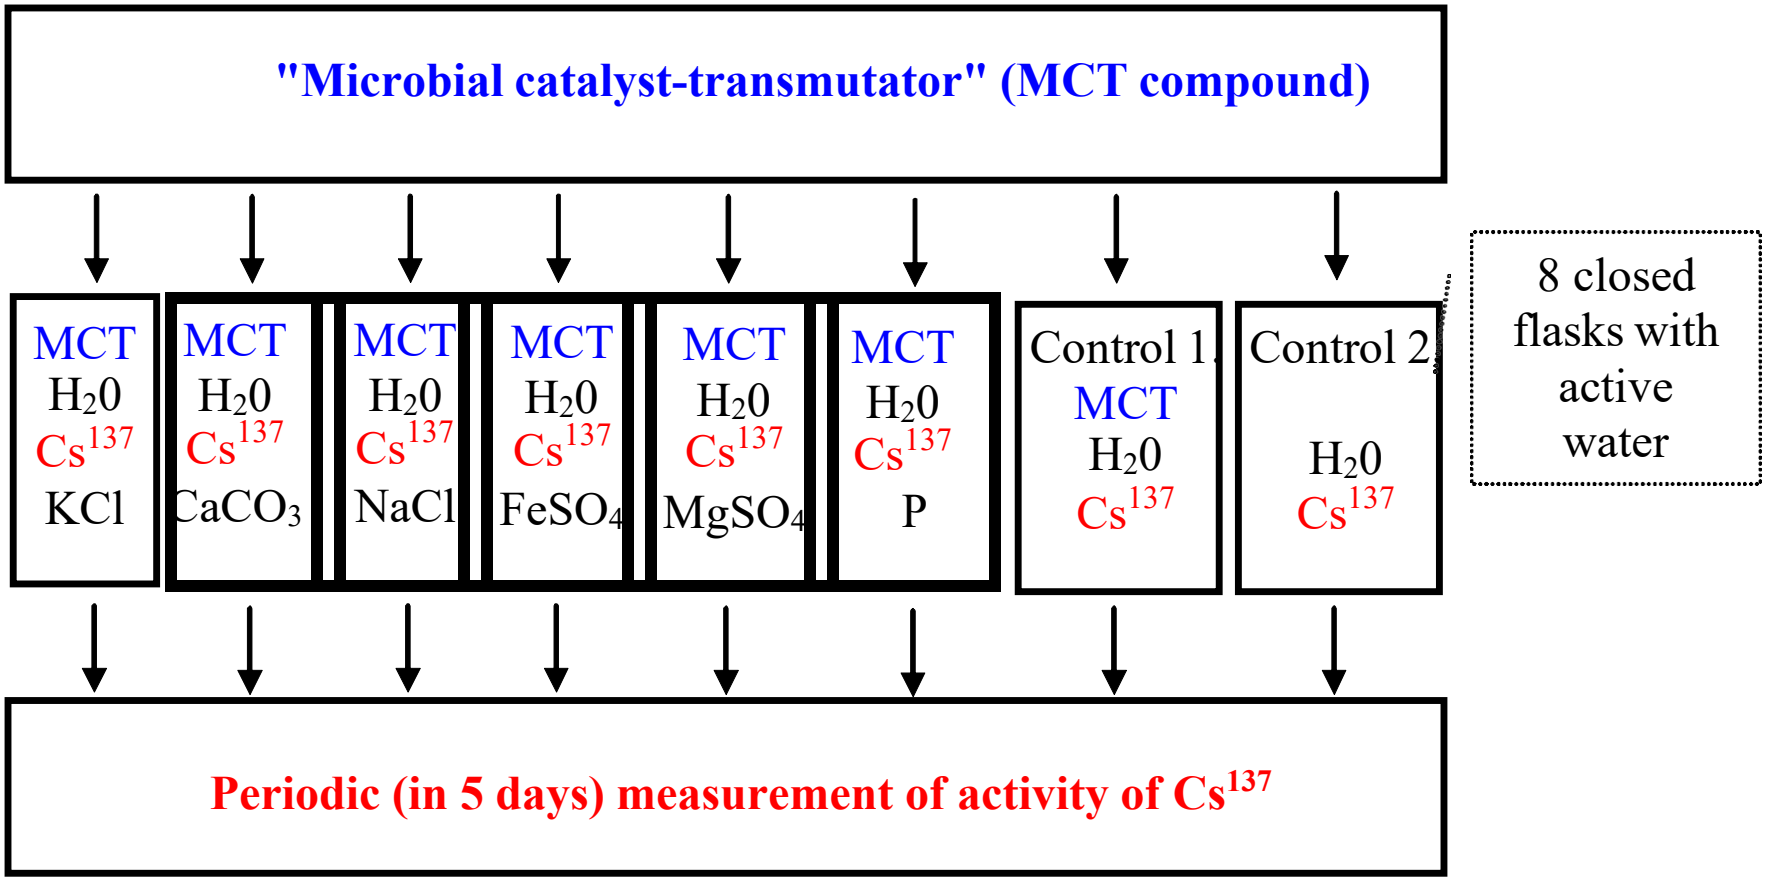
These reactions are energy favourable and

$\Delta E = E(A_{Ba}, Z_{Ba}) + E(A_C, Z_C) - E(A_{Sm}, Z_{Sm}) = 8.5$ MeV is positive.

The Sm(2+) and Ca(2+) ions are chemically alike and have the approximately same ionic radiuses of divalent state (R_{Sm} » 1.2 A, R_{Ca} » 1.06 A). Substituted element Ca is among several vitally necessary elements. Ions of created Sm(2+) elements can substitute Ca(2+) ions while microbiological cultures are growing.

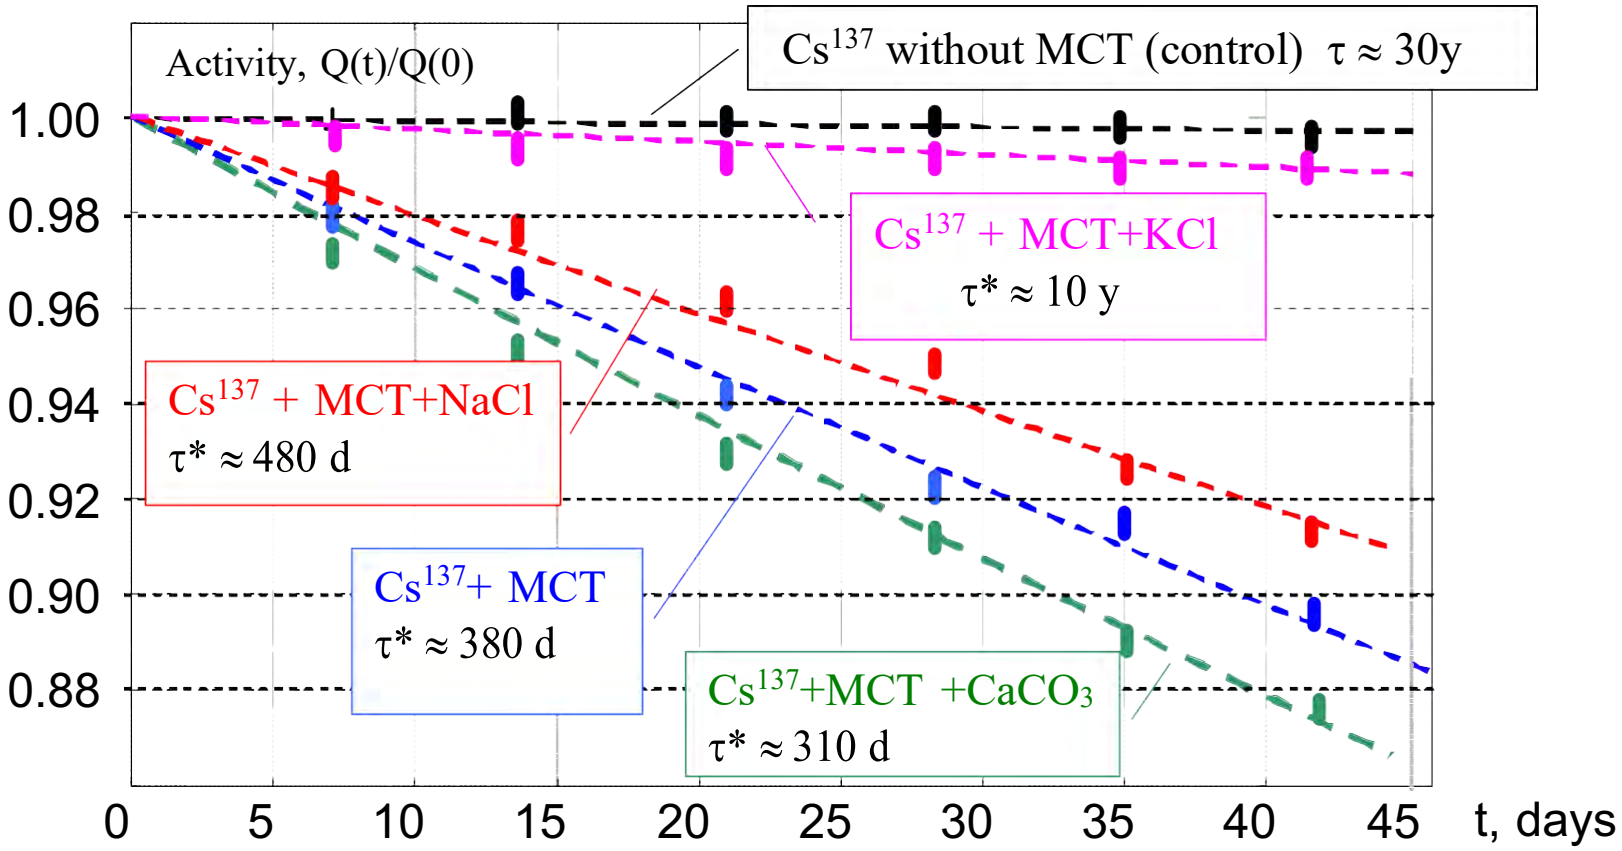
b) Deactivation of reactor Cs^{137} isotope in biological cells

The research has been carried out on the basis of the same distilled water that contained long-lived reactor isotope Cs^{137} (activity $\approx 2.10^4$ bq), In our experiments 8 identical closed glass flasks with very thin walls and with 10 ml of the same active water in each were used. The MCT was placed in 7 glass flasks.



Study of utilization of active isotopes at different conditions

Results of experiments on accelerated deactivation (decontamination) of Cs137 isotope in "hot" water



During 100 days we have observed speeded up decay of Cs^{137} isotope (by transmutation to different stable isotope) in all experiments with MCT and with the presence of different additional salts.

The most speeded up decay with t* » 310 days (accelerated by 35 times) was observed at the presence of Ca salt - Cs^{137}+MCT +$CaCO_3$.

Deactivation of different active isotopes in most optimal experiment

(MCT + active water with presence of Cs^{137}+ $CaCO_3$ salt)

		Start of experiments	Intermediate finish (100 d)			
Isotope	Energy, keV	N_1, registered events per 10^3 s	N_2, registered events per 10^3 s	Error (absolute/ relative)	Natural decay per 100 d	Change $(N_2-N_1)/N_2$
Cs^{137}	661.7	266900	216800	±478(±0.2%)	-0.6 %	-24 %

The possible reaction of Cs^{137} isotope utilization is $Cs^{137} + p^1 = Ba^{138}$ (stable) + ΔE. The result of this reaction is the creation of stable Ba^{138} isotope. This reaction is energy favourable (ΔE = 5.58 MeV is positive).

The Ba^{2+} and K^+ ions are chemically alike and have the approximately same ionic radiuses of divalent state (R_{Ba} » 1.4 A, R_K » 1.33 A). Substituted element K is among several vitally necessary elements. Ions of created Ba^{2+} elements can substitute K^+ ions in metabolic process while microbiological cultures are growing.

The presented results show perspectives of use of the effect of stable and radioactive isotopes transmutation in biological systems for natural and industrial applications.

These results can give the answer to the question of the reasons of abnormal accelerated decrease of environmental radioactivity in some isolated areas inside Chernobyl NPS accident zone and after bombing of Hiroshima and Nagasaki with initial high level of radiation pollution.

Biophysical reasons and possible physical mechanisms of isotope transmutation in biological systems are described in our books:

1) Introduction

As a retiree I participate in a memoir-writing workshop for senior citizens, directed by Lucile Lichtblau. About eight of us meet each month to read and discuss our compositions. My first two memoirs were based on WWII events; the third was about Cold Fusion (CF). What is CF? I am not ready to answer this question at this point; the answer will emerge from subsequent chapters. For the time being let me say that CF is a highly controversial field of physical science research. It is also known as Condensed Matter Nuclear Science (CMNS), and Low Energy Nuclear Reactions (LENR). These acronyms might be useful to those who are impatient and want to start Googling for answers immediately. These three names will be used interchangeably below.

The controversy started in March 1989, when two university professors in Salt Lake City announced a totally unexpected discovery. Some people think that this was the greatest fiasco of the last century; others believe that this discovery was an important step toward future technology of pollution-free nuclear energy. My short memoir was read at one of our monthly meetings. But it was not well received. Most participants were confused by technical terms. I was advised to focus the essay on personal experience, rather than on science. That is what I did. But what started as a short essay turned into a book.

Seeking a model of clear writing about the topic, I consulted the book "Cold Fusion And The Future." The author Jed Rothwell is a friend. He wrote: *"many nightmare problems that seem beyond any present solution, such as global warming, invasive species, and providing clean drinking water and sanitation to billions of poor people, may be remedied with cold fusion combined with other technologies. The future might be better than you think."* Jed is not a professional scientist. But he knows enough science to describe it clearly to lay people. His book is freely available online.

Yes, abundant and pollution-free energy would make life on earth better for billions of people, especially in underdeveloped countries. Unfortunately, the world is still waiting for a reproducible-on-demand demonstration of a CMNS effect. The essence of the CF controversy is whether or not a chemical process can trigger a nuclear reaction. Most scientists think that this is impossible. But a small fraction of them, perhaps 100 people worldwide, including myself, continue to conduct experiments whose purpose is to investigate LENR effects.

2) What Is Cold Fusion?

The best way to start explaining CMNS is to refer to so-called "hot fusion," a process in which two atomic nuclei of hydrogen fuse at temperatures exceeding several million degrees. This process generates thermal energy (heat) in hydrogen bombs, and in stars. In the last five decades numerous attempts have been made to turn a hydrogen bomb explosion into a "slowly burning" controllable process. This line of technological research, costing tens of billions of dollars, has not yet produced anything of practical use.

Fusion of atomic nuclei has been studied by physicists since 1930s. We know that such fusion is only possible at extremely high temperatures. Its probability at ordinary temperatures-- that is below ten thousand degrees or so--is practically zero, due to mutual electric repulsion of atomic nuclei.

That is why physicists were so surprised, in 1989, when two chemists, Fleischmann and Pons (F&P), announced the discovery of cold fusion, presumably similar to hot fusion but taking place at room temperature. The announcement made at the University of Utah press conference created a lot of excitement. The cover page of the Business Week magazine was "Miracle or Mistake: Fusion in a Bottle." Similarly, Times magazine's front page question was "Fusion or Illusion?" Newsweek's front page was also devoted to cold fusion; the title was "The Race for Fusion." F&P had no evidence that measured heat was due to a nuclear process; that was only their assumption.

At that time I participated in a research project at Brookhaven National Laboratory. My work had nothing to do with nuclear fusion. But we debated the F&P's discovery constantly. A chart on a wall was updated each morning, showing how many teams of scientists, worldwide, confirmed the announced discovery and how many reported negative results. Similar debates were taking place in other labs, as I learned later. Most of them were focused on the "theoretical impossibility" of CF, rather than on possible experimental errors. Needless to say, I followed the debates with great interest. But, like most scientists, I came to the conclusion (in 1992) that the F&P claim was not justified.

My renewed interest in CMNS was rather coincidental. In the summer of 2002, I went to a scientific conference in Albuquerque, NM, to hear what nuclear scientists had to say about new ways of dealing with radioactive waste produced in existing nuclear reactors. My wife joined me after the conference. We rented a car and had a wonderful week in New Mexico. Naturally, we stayed in Santa Fe--how could one skip this wonderful place. We also visited the WWII museum in Los Alamos, and Alamogordo, site of the first nuclear explosion, several months before Hiroshima

and Nagasaki. But the conference had a most remarkable and totally unexpected consequence for me--the renewal of interest in cold fusion (CF).

Why unexpected? Because the conference was not about CF. Several reports, however, were devoted to CF topics. I listened to them very carefully and talked with scientists who described new results. I was very impressed by their credentials, and by the fact that they were debating experiments, not interpretations. That is why I decided to get re-acquainted with developments in the field, 13 years after the controversy started. The purpose of this book is to describe my CMNS-related activities since the Albuquerque conference. I have met many interesting scientists, attended four international CF conferences, participated in several research projects and published several papers in that field. This has been chronologically recorded, more or less regularly, at a dedicated website:

http://pages.csam.montclair.edu/~kowalski/cf/

Some items at this website are more technical than others. But most of them can be comprehended by people who studied physics and chemistry in high school.The readers of this book are also expected to be familiar with elementary science.

3) Meeting a Russian Scientist, Alexander Karabut

The scientist who impressed me the most in Albuquerque was Alexander Borisovich Karabut, from Russia. F&P, as mentioned in Chapter 2, had no evidence that their excess heat was due to a nuclear process. They suspected that excess heat was nuclear because it was too large to be due to a known chemical reaction. Karabut, and his team, by contrast, reported not only excess heat, generated at the rate of about 9 watts, for 120 hours, but also the presence of several nuclear effects. This was a revelation to me.

The team spent ten years studying nuclear processes associated with generation of excess heat at ordinary temperarures. His talk at Albuquerque was the summary of findings; some of them had been reported as early as 1990. As a Russian speaker I was able to help the author improve his presentation in English, a language in which he is far from fluent. We talked about his paper before it was formally presented, and we discussed it afterwards. What I heard in Russian was much clearer than in his English text. The link to my translation is:

http://csam.montclair.edu/~kowalski/cf/13karabut.html

One of the effects, reportedly observed by Russians, was emission of high-energy alpha particles from the palladium foil saturated with heavy hydrogen. This effect alone, if independently confirmed by other scientists, would be sufficient to validate the idea that a nuclear process can be triggered by a chemical process at low temperature. Why had no one tried to replicate experiments described by Karabut? That question still puzzles me. Whose moral obligation was to it to verify such extraordinary results? The most obvious people were other CMNS experimentalists. But each of them worked on his or her own project, usually without any financial support. Furthermore, confirming a discovery made by someone else is not as rewarding as being recognized as the discoverer of something unknown and important.

I can only imagine how Karabut's discoveries would have been treated in Stalin's USSR. The Academy of Sciences would at once have organized several replications. Confirmation of results would turn Karabut into a famous scientist. Rebuttal of the results, on the other hand, would have led to immediate disqualification, or much worse. But that is not what happed in post-USSR Russia. The scientific establishment, associated with the Academy of Sciences, declared Karabut a pseudo-scientist. This was not based on new experimental results; it was based on theoretical grounds--the reported facts conflicted with the already-accepted theory of hot fusion reactions.

The main accuser, according to Karabut, was the Academician E.P. Kruglakov, the author of "The Highwaymen of

Science." This book, published in 2001, is indeed very interesting; Karabut sent it to me, after returning to Moscow. The Russian scientific establishment, according to Dr. Karabut, considers cold fusion to be voodoo science. In fact, Dr. Kruglakov heads the "Commission to Oppose Pseudo-Science and Falsifications in Scientific Research." I had no idea that such a commission had been created by Russian Academy of Sciences. The book ranks cold fusion at the same level as N rays (a well known case of either fraud or self-delusion in France), astrology, extrasensory perception, and magic. Karabut hinted that the antagonism against CMNS in Russia has more to do with the competition for very limited financial support than with objectivity.

I can also imagine how our own government would have reacted to CMNS discoveries published by Russian scientists during the Cold War. The DOE (Department of Energy) would have quickly organized several replications, in order not to be left behind. Successful replications would probably have been classified and additional research would have been sponsored by the DOE, at various laboratories. Refutations, on the other hand, would provide evidence that results reported by Karabut should not be taken seriously. It is interesting that a book similar to Kruglakov's was published in the US: "Voodoo Science: The Road From Foolishness to Fraud" by a physicist, Dr. Robert Park.

4) Meeting George Miley

Dr. George H. Miley, a chemical and nuclear engineering professor from the University of Illinois, was another scientist I met at Albuquerque. His conference paper made me aware of how much I had missed since I had stopped paying attention to the CMNS field. A very impressive summary of Miley's professional accomplishments can be found in Wikipedia. Before 1989 he was a hot fusion researcher; afterward he became a CF researcher as well. In 1990 he published a paper, in cooperation with another researcher, about production of chemical elements in thin layers of metallic films saturated with hydrogen. They wrote: " the Ni film [removed from our experimental cell] was found to contain Fe, Ag, Cu, Mg and Cr." Concentration of these elements, after the experiment, was found to be much higher than before. If confirmed this would be undeniable evidence for nuclear reactions taking place at low temperatures.

But the most interesting Miley paper, as far as I am concerned, was published in 2002, the year I met him. The title was "Some Personal Reflections on Scientific Ethics and the Cold Fusion 'Episode' ". Unfortunately, he did not tell me about this paper in Albuquerque. I read it several years later; it is now available online. The link is:

http://www.lenr-canr.org/acrobat/MileyGHsomeperson.pdf

Most papers written by CMNS researchers are devoted to scientific and technical topics, as one can verify by going to the online library at

www.lenr-canr.org

That library, by the way, was created by Jed Rothwell. George Miley's long paper is devoted to political aspects of the controversy. Here is a brief summary. My encounter with CF, he wrote, *"was at the initial congressional hearing in Washington D.C. on the topic. I was selected to provide input from a fusion researcher known for innovative research who might comment on CF from a 'neutral position'. Thus, I was 'squeezed' into the testimony order between the originators of the field, Pons and Fleischmann, and a strong opponent of CF, Harold Furth, the then director of the Princeton Plasma Physics* [hot fusion] *Laboratory."*

In his talk Miley speculated about possible future CF developments. After the hearing, he said that *"a CIA agent caught me in the hall and warned that someone like myself with a 'Q clearance' should not publicly air such sensitive speculation. As it turns out, my speculation had some validity*. Describing other 1989 meetings, Miley wrote that *"almost 'carnival atmosphere' was created by the combination of reporters, entrepreneurs, garage inventors, curious on-lookers, politicians, financial brokers, and scientists at the initial Los Alamos National Laboratory [...]*

Then there was the 'famous' NSF-EPRI meeting in Washington DC where the NSF ended up withdrawing 'official' sponsorship at the last moment due to the swing in opinion against CF. Despite this controversy, Edward Teller [known as the father of the first hydrogen bomb] attended this meeting in a wheel chair (due to a recent operation) and provided a guiding example of an open scientific mind by freely entering the discussion. Instead of ruling CF out due to lack of theoretical explanation, he suggested that a new particle, dubbed "meshuganon," would be needed (and might actually exist) to explain the observations reported by Pons and Fleischmann. [...].

Looking back, he continues, *"the CF field has caused grief for many key persons who became 'too' strongly involved. Pons and Fleischmann left the US for France [...]; the President of the University of Utah was forced to resign as a result of issues raised about CF funding procedures [...], John Bockris at Texas A&M, was bombarded with University-appointed investigating committees and, as a 'crowning blow' was forced off-campus with the second International Meeting on Low Energy Nuclear Reactions that he hosted. Gene Mallove found it necessary to step down from his scientific information post at MIT following publication of his book, Fire from Ice. Peter Hagelstein faced a hostile promotion committee at MIT after his early theoretical work on CF; [...] Why should such intense controversy and drastic personal repercussions develop over a scientific field?*

Certainly the unconventional manner in which Pons and Fleischmann introduced CF by announcing it to the press initiated the controversy which eventually polarized the field into camps of 'believers' and 'non-believers'. The fundamental reason behind this emotional approach to CF was, in my view, the tremendous impact that CF, if proven true, could have. Consequently, the vast amount of money and the prestige at stake brought out the 'best' and the 'worst' in people. [...]

5) Beginning Of Censorship: Also From Miley's Paper

The paper from which I am quoting is worth reading in its entirety. It is a rather unique testimony from an open-minded researcher and editor, caught in the middle of the 1989 CF controversy. In one section he writes: " *Another criticism of my editorial policy on CF has been that since I have done research on the topic, I must be biased in favor of it. It's true that I have had papers in most ICCF meetings, starting from the original LANL meeting in Santa Fe. This criticism, in my view, amounts to a double standard. My initial selection as FT's* [FusionTechnology] *editor, and the other two journals, was based on my recognized research on fusion, lasers, and plasma physics.*

This track record was assumed to provide me with better insight into the technical content of the papers, and allow me to select top reviewers. In universities, teaching and research are well recognized as reinforcing each other. The same is certainly true for editing and research. Why wouldn't the same be true for CF? [...]

In conclusion, the issue of whether my FT position, as opposed to Nature's closed-door policy, is proper for a scientific journal must be left to the reader. The question to be answered, in my opinion, is which policy will advance science best in the long run? To rephrase the question, we might ask if the publications in FT have communicated new scientific information or have they mislead readers? [...]"

In March of 2012, George Miley was again at the center of the CMNS controversy. This time he appeared as a designer of something very practical--a CF nuclear battery. Chemical batteries do not last long enough to power electrical equipment in a spaceship. That is why nuclear batteries, containing highly radioactive plutonium, have been used in long-lasting NASA missions. Miley is developing a battery based on a CF effect. Such battery, using non-radioactiv and less expensive hydrogen and palladium instead of plutonium, would indeed be highly desirable. A brief announcement of his invention can be found at:

http://nextbigfuture.com/2012/03/george-miley-upcoming-presentation-game.htm

6) Theories Guide But Experiments Decide

Scientific methodology of validation of claims, a set of rules developed to deal with difficulties, mistakes and controversies is well known. Most scientific mistakes are recognized when new results are discussed with colleagues, or via the peer review process. Occasional errors in published papers are subsequently discovered during replications conducted by other scientists. Our results, if valid, wrote one scientist, John Huizenga, must be reproducible on demand. *"When errors are discovered, acknowledged and corrected, the scientific process moves quickly back on track, usually without either notice or comment in the public press."* The scientific process, in other words, is self-corrective. The process might be slow but it works, more often than not.

Why is the CMNS controversy unresolved since its beginning in 1989? Because the claims are still not reproducible on demand, and because experimental results conflict with the accepted theory of nuclear fusion. A theory, in this context, is not just a hypothesis, it is a logical structure that is known to agree with a wide range of already verified experimental data. Scientists know the rule--theories guide but experiments decide. But they are very reluctant to abandon accepted theories. To be reluctant means to insist on additional verifications of new experimental results.

Referring to such situations, Huizenga wrote: "There are occasionally surprises in science and one must be prepared for them." Theories are not carved in stone; scientists do not hesitate to modify or reject theories when necessary. Rejecting a highly reproducible experimental result "on theoretical grounds," which is quite common, is not consistent with scientific methodology. But that is exactly what often happens when CMNS claims are criticized.

John Huizenga, one of recognised leaders of the field known as Nuclear Chemistry, was a senior colleague, when I was a post-doctoral researcher at Columbia University. He often visited us and I had the priviledge of discussing topics of common interest with him. His book about CMNS, "Cold Fusion: The Scientific Fiasco of the Century," persuaded me that F&P claims were not valid. This was nearly ten years before the 2002 Albuquerque conference.

My comments on the process of scientific development in general, and on the CMNS field in particular, can be found in Chapter 23.

7) First US Government_Investigation

The significance of CF, if real, was immediately recognized. Some believed that ongoing research on high-temperature fusion, costing billions of dollars, should be stopped to promote research on CF. Others concluded, also prematurely, that such a move would be opposed by “vested interests” of mainstream scientists. Responding to such considerations, the US government quickly ordered a formal investigation. A panel of scientists, named ERAB (Energy Research Advisory Board), and headed by John Huizenga, was formed to investigate CF in 1989. The final report, submitted to the DOE several months later, interfered with the normal development of the field.

I was later disappointed to learn that ERAB scientists investigating the CF claims were not personally involved in replications of experiments. Conclusions and recommendations from their report, based on visits to several laboratories rather than participation in experiments, are summarized in a paper I published recently

http://www.ptep-online.com/index_files/2012/PP-29-L2.PDF

Only one of their six conclusions refered to CF experiments; the remaining five conclusions were about anticipated practical uses of CF, and about various aspects of the suggested interpretation of results. Instead of focusing on reality of excess heat, critics focused on the fact that the hypothesis was not consistent with what was known about hot nuclear fusion. The same observation can be made about the six ERAB recommendations. Only one of them referred

to possible experimental mistakes. It is clear that the ERAB observations were based mostly on ”theoretical grounds,” and not on identified laboratory mistakes. Support for CF research in the US practically stopped in 1989.

Another result of the first DOE investigation, as described by Miley, was that editors of some scientific journals started rejecting manuscripts writen by CF scientists, bypassing peer review. This kind of discrimination, directed against PhD-level scientists, is totally inconsistent with scientific norms. Illustrations of such descrimination are to be found in chapters 17 and 18.

Inserted on 5/24/2012

Here is message about CF that I posted last night at our university forum.

"As shown in < http://www.ptep-online.com/index_files/2012/PP-29-L2.PDF> , the first two DOE investigations of CF claims failed to focus on what was the most important--promotion of experiments designed to verify reality of excess heat. The DOE refuted F&P claims on the “theoretical basis,” that is on the conflict between the reported fact and the hot fusion theory.

What would I do if I were appointed to organize the first DOE investigation, in 1989? Familiar with Fleischmann’s undeniable reputation I would offer him a generous research grant, for two or three years, to continue CF research. I do not think that F&P’s motivation was anything else but desire to be recognized as discoverers of something new and important. They would probably welcome the grant and cooperated with the government. Unwillingness to cooperate (in order to protect secrets, pending patent applications, etc.) would show that the claim is commercial and does not justify the grant."

Knowing that the government grant was accepted, I would find two knowledgeable electrochemists and made them responsible for cooperation with F@P. The purpose of cooperation would be to help them to clearly describe the protocol, and to publish it in a peer reviewed journal. A year or two later (if the controversy were still not resolved via the normal self-correcting process) I would select ten other reputable electrochemists (Energy Research Advisory Board), working in government laboratories, and asked them to replicate the F&P experiment, using the published protocol. The formal report, prepared by ERAB chairman, would be mostly based on available experimental data, not on the fact that results conflict with our model of thermo-nuclear reactions.

P.S. Yes, I know that no one will ask me for something like this. It is only a speculation, based on past mistakes."

Responding on the forum a prominant CF researcher wrote:

"Of course Ludwik, any one who was interested in benefitting from LENR would have treated the situation the way you describe. The people at the DOE are not stupid or ignorant. They know how to do a proper review. The fact that the DOE did not act this way reveals that they were not interested in finding out the truth. They wanted the possibility of LENR being real to be eliminated. This phenomenon is a threat to all that the DOE values. When the DOE wants a program to be supported, they work very hard and ruthlessly to see that this happens. They did just the opposite with respect to LENR. This was a result of well considered policy. That is why an attempt to contact Sec. Chu or anyone in the DOE who has authority will not change their approach. They want LENR to fail for obvious reasons. They just don't want to appear to reject the idea, so they created these sham reviews. "

Some one could say that this is a conspiracy theory. Saying "a reasonable hypothesis," rather than "a theory" would probably be more appropriate. A formal theory should be based on specific assumptions--for example, already accepted theories or data--and a logical derivation of the final statement.

Go to the next chapter
Go to the Table of Contents

8) Second US Government_Investigation

The second DOE investigation of CF was announced in March 2004, nearly 15 years after the first one. The six most important scientific questions, based on new experimental CMNS claims, were:

(a) Is it true that unexpected protons, tritons, and alpha particles are emitted in some CF experiments?

(b) Is it true that generation of heat in some CF experiments is linearly correlated with the accumulation of ^{4}He, and that the rate of generation of excess heat is close to the expected value of the 24 MeV per atom of 4He?

(c) Is it true that highly unusual isotopic ratios have been observed among the reaction products?

(d) Is it true that radioactive isotopes have been found among reaction products?

(e) Is it true that transmutation of elements has occurred?

(f) Is the research methodology of CF scientists the same as that used by other scientists? In other words, is it consistent with the generally accepted norms of the so-called "scientific method?

A positive answer to even one of these questions would be sufficient to justify an official declaration that cold fusion, in light of recent data, should be treated as a legitimate area of research. But only the (b) question was addressed by the selected referees. They were asked to review the available evidence of correlation between the reported excess heat and production of fusion products. One third of these referees stated that the evidence for such correlation was conclusive. That was not sufficient; the attitude of the scientific establishment toward cold fusion research did not change.

Scientific disagreements are not supposed to be resolved by voting. Why was the reconized methodology of validation of claims--theories guide but experiments decide--not followed by the DOE-appointed scientists? Why did “rejections on theoretical grounds” prevail? The only answer I have is that scientists are not ideal; competition among them, as among people in other social groups, has both positive and negative effects.

Cold fusion will certainly be viewed as an interesting episode in the history of science, regardless of verdicts about validity of numerous CMNS claims. More specifically, the long-lasting CF episode will be remembered as a social situation in which the self-correcting process of scientific development was not allowed to flourish. To what extent was this due to extreme difficulties in making progress in the new area (without financial support from the DOE, NSF, etc.), rather than to negative effects of competition, greed, jealousy, and other "human nature" factors?

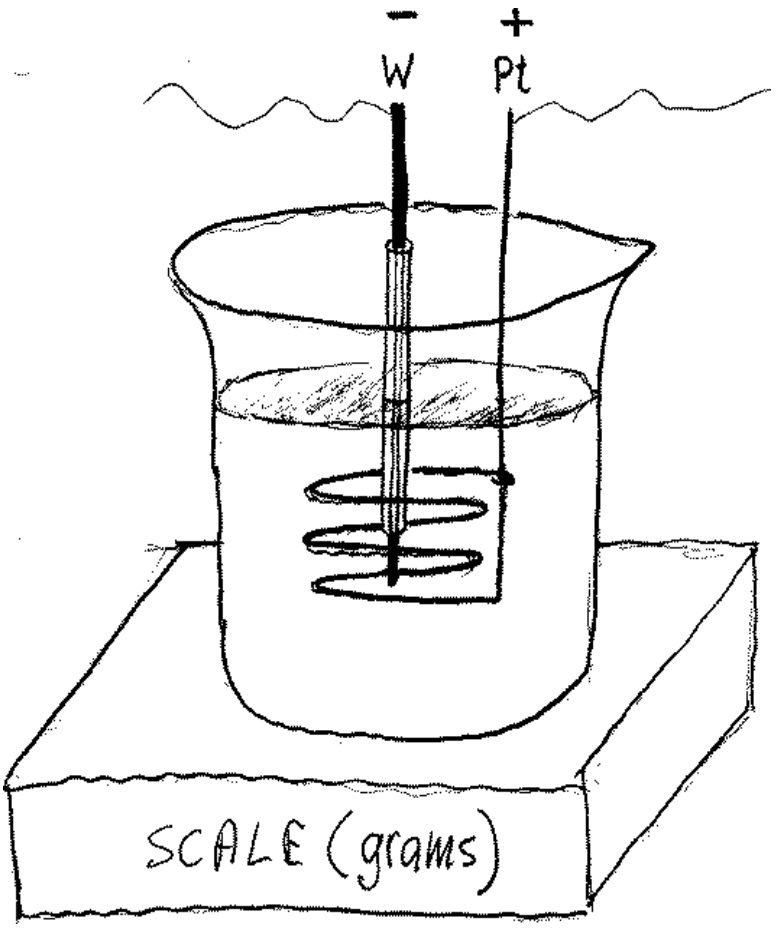
9) Excess Heat, Real Or Apparent?

The 2005 scientific conference in Japan (ICCF12), in which I participated, was devoted to CF. One French scientist, Pierre Clauson, described a high voltage electrolysis process in which excess heat was said to be generated at the rate of about 100 watts. After some hesitation I decided to verify this claim, with a colleague from Texas, Scott Little. The experiment turned out to be more difficult than I expected; we were not able to confirm or refute reality of excess heat.

But in a subsequent 2007 experiment, conducted with Richard Slaughter in Colorado, and Pierre who came to guide us, the excess heat was apparently detected. Why do I say "apparently"? Because the wattmeter we used, brought by Pierre from Paris, was later found to be inappropriate for our setup. The excess heat turned out to be zero when a more sophisticated wattmeter was used (in Paris, by Pierre and his partners.)



The diagram of our cell is shown above. Here is how the setup was described in my later conference presentation: *"[... Our] cell operating under such conditions is shown in Figure 1. The cathode was a tungsten rod while the anode was a large platinum wire spiral, or a platinized niobium cylinder. The electrolyte was potassium carbonate (K_2CO_3) dissolved in distilled water. The concentration was 20 grams per liter. Decomposition of water, at high current, was so intense that yellow glow discharge and arcing was taking place in the layer of gas-plasma surrounding the cathode."*

The scale supporting the cell was used to measure the amount of water evaporated in each experiment. That allowed us to calculate the amount of heat generated. Instruments used to measure electric energy are not shown in the figure.

Let me mention that Clauson's results presented at the conference were a confirmation of similar results reported by a Japanese scientist, Tadahiko Mizuno, two years earlier. In 1997 Mizuno wrote a book entitled "Nuclear Transmutations: The Reality Of Cold Fusion." It was translated into English by Jed Rothwell, our mutual CMNS friend. Detecting excess heat generated at the rate of 100 W was rather unprecedented; most often measured rates, in F&P type of cells, are 1 W and less. Before going to the conference in Japan--during a sabbatical leave-- I made an arrangement for working with Mizuno. But the plan had to be canceled, due to some administrative complications. Instead of working with Mizuno I was able to work with another top Japanese scientist, J. Kasagi. But this was not a CF project.

Many people reported generation of excess heat. But non of them claimed that excess heat experiments are reproducible on demand. The situation facing researchers in this area is well described by Mike McKubre, at a cold fusion conference-ICCF15 in Rome. The link to his report is

www.enea.it/it/produzione-scientifica/pdf-volumi/introduction-iccf15-proceedings-2.pdf

Mike is an electrochemist. I know him personally and I have no doubt that he is honest. In fact, he is a hero, in my view. How many people would be willing to continue studying CF for more that two decades under showers of insults.

I think that he is motivated by the noble desire to help society. Unfortunately, I did not attend ICCF15 in Rome in 2009. But I did participate in, and contributed to, four other conferences (USA-2003, France-2004, Japan-2005 and USA-2006). My impression was, and still is, that most CF researchers (not all) are like Mike, and that their methodology of validation is scientific.

Great scientists I have met, including Joliot-Curie, who introduced me to research, would agree. The difficulties described by Mike are real. What do I mean by showers of insults? I will explain this in a later chapter. Download Mike's paper and read it carefully; scientists among you will probably agree that there is nothing unscientific in it.

Speaking about irreproducibility I often refer to the following personal experience. I was heating milk in a microwave oven for two minutes. Then I removed the cup and inserted a cold spoon into it. At that moment I observed sudden "explosive boiling;" It was a clear indication that superheated milk was created. I tried to reproduce this next day, and several days later, using the same oven, the same cup, the same amount of milk, etc. but without success. Does it mean that my observation was not real? I do not think so. It only means that some important factors, perhaps the air temperature or pressure were different in subsequent experiments. Or perhaps the rate and angle at which the spoon was inserted into the cup were not exactly the same. Cold fusion phenomena seem to depend on factors which are hard to identify.

10) Robert Park, A Scientist Writer

George Miley's observations can be contrasted with those of Robert Park, whose book "Voodo Science: The Road from Foolishness to Fraud," published in 2000, has already been mentioned. Referring to this book, one reviewer wrote: *, "Professor Park does more than debunk, he crucifies. .... You'll never again waste time or your money on astrologers, quantum healers, homeopaths, spoon benders, perpetual motion merchants, or alien-abduction fantasists."* But isn't CF different from the above? I don't exclude the possibility that some CMNS claims may have been fraudulent; con artists are naturally attracted to scientific controversies, as illustrated in:

http://csam.montclair.edu/~kowalski/cf/16voodoo.html

George Miley told me about the 9th International Connference on Cold Fusion, ICCF9. It took place in China, where many new discoveries were presented and discussed. The next conference, ICCF10, was to take place in Cambridge, Massachusetts and I decided to attend. One of the organizers of this conference told me that Robert Park was personally invited but decided not to come. That was an insult, in my opinion. What I would do in his place? I would welcome the chance to meet the authors of questionable claims, to discuss controversial topics and to ask for evidence. Dr. Park's refusal to participate disqualified him in my eyes. Those who accuse others of being pseudo-scientsts should have the courage to face their opponents.

In a review of Park's book at: http://home.netcom.com/~storms2/park.html

Edmund Stoirms wrote:

[...But to Park] *the explanation becomes more important than the observation. Because this particular explanation can not be believed, the observation must also be rejected. Thus, a major flaw in modern science is revealed - a Theory is more important than an Observation. The behavior of nature is not real unless it can be explained, especially using conventional concepts. This flaw in logic is at the heart of the book and provides an explanation for rejection of these and other subjects by many scientists.*

__New discoveries always conflict with some dearly held belief. This conflict when used to reject the claims, prevents new discoveries from being explored and properly explained. This is not to say that all 'strange' ideas are correct or

that all have a new and worthwhile explanation. Clearly, some should be rejected as being caused by obvious error, fraud, or simple insanity. The problem comes in deciding how much time and resource should be devoted to a search for an explanation and how the resulting facts should be evaluated..... If science is to clean up its act, this defect in the approach scientists use needs to be addressed. A clear and extensive discussion of this general problem can be found in the book "Revolution in Science" by J. Bernard Cohen (1985) or "Forbidden Science" by Richard Milton (1994)."

Robert Park is not alone in his bias against CF scientists on the basis of authoritarian pronouncements made by DOE investigators. He apparently does not need to hear the CF reports, or perform his own experiments. Fortunately, such an attitude does not prevail among mainstream scientists, but it is common. Aggressive discrimination against CMNS reminds me of something else. Long ago, when I was a communist student in Poland, I believed that genetics was pseudoscience. That was the official party line, supporting Lysenko's teaching. The same was true about cybernetics; it was defined for us as "bourgeois pseudo-science serving American imperialism." Naturally, no one is takes such statements seriousey today, even in Russia. But disagreeing with them could have been dangerous, when Stalin was alive.

11) Three Professional Biographies

These short professional biographies of Fleischmann, Pons (chemists) and Jones (physicist) appear on pages 46-49 of E.F. Mallove's book : "Fire from Ice; Searching for Truth Behind the Cold Fusion Furror," John Wiley & Sons, New York, 1991. I strongly recommend this book.

***Martin Fleischmann**, now a naturalized British subject, was born March 29, 1927. [...] Since 1986, Fleischmann has been a Fellow of the Royal Society, an honor given only to the most distinguished of scientists. The author of over 200 scientific papers [...], Fleischmann won the Royal Society of Chemistry's medal for Electrochemistry and Thermodynamics in 1979. He was president of the International Society of Electrochemistry (1970-1972). In 1985 he was awarded the Palladium Medal by the U.S. Electrochemical Society.*

***Stanley Pons**, born in 1943, attended Wake Forest University in Winston-Salem, North Carolina, graduating in 1965, and began advanced studies at the University of Michigan at Ann Arbor. But with his doctorate almost in hand in 1967, he, the eldest of three brothers, left school to work in his father's prosperous textile mills and to manage a family restaurant in North Palm Beach, Florida. Eventually, his love for chemistry drew him back to active science.*

With the encouragement of faculty at University of Southampton in England, he entered its graduate program in chemistry and received his Ph.D. there in 1978. Martin Fleischmann was one of his professors. After being on the faculty at Oakland University in Rochester, Michigan, and the University of Alberta in Edmonton, Pons came to the University of Utah in 1983 as an associate professor, becoming a full professor in 1986, and Chairman of the Department in 1988. He has authored or coauthored over 150 scientific publications.

***Steven Jones** was well known to physicists and the hot fusion community, which gave him a credibility that Fleischmann and Pons could not match. That Jones came out with a dissimilar but closely related item of cold fusion news at about the same time, ironically, may have boosted the credibility of Fleischmann and Pons in their claims. But there was initial confusion about what Jones was asserting, because of his well-known earlier work on cold fusion of a different sort -- the concept called muon-catalyzed fusion.*

Much of the difficulty that ensued between Fleischmann and Pons on one side and Jones on the other -- a friction that has now lessened considerably -- can be understood in part from a chasm of personality differences. [...] Jones pursues his science with religious fervor, almost literally. His University stationery bears witness, inscribed as it is with the Brigham Young University motto, 'The Glory of God Is Intelligence.' " Yes, Jones' research was focused on nuclear reactions, not on excess heat. He was fully aware that excess heat associated with reactions he was studying

was too small to measure. The discovery of excess heat was announced by F&P only.

In my opinion that discovery, after being verified several times, should have been announced, more or less, in this way: 'we know that the excess heat is produced in our cells but we have no idea what process is responsible for it.' The approach would be --'let us agree on facts before discussing conceivable interpretations.'

Some think that discovering an experimental fact without giving some kind of explanation is not a scientific event. I cannot agree with this. Electric batteries, for example, invented in the early 1800s by Alexander Volta (Italy), became valuable long before their operation was theoretically explained. The same can be said about the accidental discovery of X rays, in 1895 by Wilhelm Roentgen (Germany). And who would believe that radioactivity of uranium, discovered in 1897 by Henry Bequerel (France), would lead to atomic bombs and to electric power plants, half a century later? Will CF lead mankind to new technologies in the next century? It's possible but not certain.

12) The First CF Conference I Attended

One year after the Albuquerque conference I attended the conference devoted to CMNS topics only. Such conferences have been taking place each year, in different countries, since 1990. This was the tenth one (ICCF10); it took place in Cambridge, USA. I did not come to the conference empty handed. But my presentation, entitled "The Dilemma of a Physics Teacher," had nothing to do with specific CMNS claims; it was about how to deal with CF claims in classroom situations.

In the first half of my talk I said: *"This presentation is dedicated to a high school chemistry student who sent me an e-mail message last spring. She wrote: 'Help! My name is Maggie Johnson and I am a sophomore at Saratoga High School. In my chemistry class, I am doing a project on Cold Fusion. I was looking on the Internet for websites on Cold Fusion, and I came across links to your Cold Fusion items. I was wondering if you could give me some advice or information?'*

A year ago I would have replied that cold fusion is pseudoscience. But I am no longer comfortable with this kind of reply. Why am I not comfortable? My first opinion was based on Huizenga's famous ERAB report. I knew the author personally and I respected him. His criticism of cold fusion was convincing because it was based on the idea that cold fusion is a thermonuclear reaction between only two colliding hydrogen ions. Experimental data certainly do not support such an idea. [... They seem to indicate that a much larger number of atoms, in a crytal, participate in each CF event]

Two other factors helped to discredit the cold fusion field in many minds: (a) the claim that experiments in this area are extremely simple, and (b) that practical applications are going to be possible very soon. Again, I do not know who the authors of such claims were. Those who criticize cold fusion today, Park in the US and Kruglyakov in Russia, essentially repeat Huizenga's arguments. What was convincing in 1989 is no longer convincing today. Why do they ignore generation of helium? Why do they ignore more sophisticated calorimetry? Why do they ignore unnatural isotopic ratios? Why are they not at this conference listening to presentation of new data and defending their own ideas? That is another set of questions that I am not able to answer. Ignoring experimental data is not an acceptable method of addressing a scientific controversy. I am still not convinced that cold fusion is real. But I no longer say that it is voodoo science.

Why am I still puzzled? Because everything I know about nuclear science goes against the idea that nuclear reactions can be induced by chemical processes at ordinary temperatures. I wish I had a chance to personally participate in experiments generating extraordinary results. But, like most teachers, I have no access to a sophisticated laboratory which would be needed to verify accumulation of helium and heavier reaction products. I read about such phenomena and I am impressed. But I would be more comfortable if the reported results were examined and officially confirmed by an appointed panel of open-minded experts.

I am also puzzled by the fact that hundreds of sophisticated research scientists exploring cold fusion over the past 13 years have not yet developed a reliable demo for teachers; windows of opportunity did exist in several countries. Teachers need experiments that can be performed with simple instruments available in colleges and universities, such as Geiger counters and gamma ray spectrometers. Excess heat generated at a rate of about one watt is not convincing unless one is able to deal quantitatively with all possible chemical reactions taking place in the apparatus. I am not a chemist.

Reproducible generation of excess heat at the level of twenty watts, or higher, for a long period of time, would be much more convincing to a physics teacher, especially if it could be correlated with emission of nuclear particles or gamma rays. Even a 70% reproducible demo would be useful; teachers know that some experiments, for example in electrostatics, do not succeed when humidity is too high. Cold fusion seems to depend on factors which have not yet been identified. Abnormal isotopic ratios, reported by many independent researchers, are extremely convincing but a typical teacher can not verify such data. [...]

I am optimistic that the cold fusion controversy will be resolved, one way or another. The optimism is based on the following quotation from what John Huizenga, the author of the ERAB report, wrote in 1989. 'The scientific process is self-corrective. This unique attribute sets science apart from most other activities. The scientific process may on some occasions move slowly, sometimes even along a circuitous path. The significant characteristic of the scientific method, however, is that in the end it can be relied upon to sort out the valid experimental results from background noise and error.'

And here is another quote from the panel of appointed scientists responsible for the first national investigation of cold fusion. 'The Panel recommends against the establishment of special programs or research centers to develop cold fusion. However, there remain unresolved issues which may have interesting implications. The Panel is, therefore, sympathetic toward modest support for carefully focused and cooperative experiments within the present funding system.' Sympathetic attitude toward unresolved issues is worth emphasizing.

What will the verdict of history be? Sooner or later, perhaps in 50 years, the cold fusion puzzle will be resolved (like the 'puzzle of cybernetics,' or the 'puzzle of genetics,' both in USSR). Only two outcomes are possible: (a) CF phenomena will finally be confirmed or (b) CF phenomena will not be confirmed. In each case one will have to deal with important social issues. Suppose that CF is confirmed. Then one would have to explain causes of a long-lasting conflict between scientists and administration. Suppose that CF is not confirmed. Then one would have to explain a phenomenon of massive self-deception involving hundreds of top scientists in many countries. In either case you will be recognized as participants of an important and unique event in the history of science.

Keep working to clarify the most intriguing scientific and social puzzle of the 20th century. I am certainly not the only physics teacher waiting for a consensus on cold fusion. Keep submitting good papers to traditional refereed journals, such as Physical Review, etc. Do not be discouraged by frequently unjustified rejections of your papers. Document such rejections and make them known to mainstream scientists. Deplorable confrontations with overly-bureaucratic editors should also be exposed. Take advantage of the new electronic journal devoted to cold fusion. Dissociate yourself from voodoo scientists and openly criticize them. Keep bringing cold fusion topics to scientific conferences devoted to areas overlapping with your activities. My own interest in cold fusion was reawakened at such a conference one year ago. Try to seek contacts with students, and with the general public. But focus on puzzling scientific results; it is too early to speculate about practical applications."

13) The Editor Of Physics Today Rejected My Letter

Discrimination against CF manuscripts, by editors of major scientific journals, has been described by George Miley, in Chapter 5 above. Let me describe my own experience with this kind of unjustified bias. It is also a long quote from my

ICCF10 talk. In the second half of that presentation I said:

"About half a year ago I wrote a letter to the editor of Physics Today. In that letter I described my own dilemma, as a teacher, in dealing with cold fusion, and asked for help. Why was my short letter rejected? Why was I not allowed to see what the referees wrote about it? Ironically, that letter was triggered by the article entitled 'New American Physical Society's Ethics Guidelines.' That article by Jim Dawson was published in the January 2003 issue of Physics Today." Why "ironically? Because what they did was an example of behavior inconsistent with the article they published.

"I welcomed the new guidelines and asked how a physics teacher can make sense of 'cold fusion?' Was the research conducted in that area, in the last ten years, a 'departure from the expected norms of scientific conduct'? Did it 'lead other scientists along fruitless paths?' I see no evidence that the data were 'fabricated.' As a physics teacher I am confused by the situation. Some say CF was 'a fiasco' while others say it was an 'important discovery.' How should teachers address this topic in the context of 'public affairs between science and society,' or in the context of discussing 'institutional support for new ideas and innovations?'

After waiting several months I sent an e-mail message asking about the status of my letter. On Thursday, June 12, 2003, I received a reply from Letters Editor at Physics Today. He wrote: *"So far, I have a split decision on the possible publication of your letter. I expect soon to have a tie-breaking input from a third reviewer. I will let you know as soon as I have a firm decision. Thank you for your patience*." On Thursday, July 3 Dr. Hanna wrote "*We have completed our review of your letter commenting on the APS ethics guidelines story in our January 2003 issue. Our decision, after some valuable discussion, is not to publish your letter. Thank you for writing and for your interest in Physics Today."*

Unhappy about this I wrote *"I would very much appreciate if you could send me the reports of the referees evaluating my letter to the editor."* The immediate reply was: *"Please let me explain. I know that scientists who submit articles to peer-reviewed scientific journals expect reviewers to give them a critique of their letters. Physics Today is not, in the strictest sense, a peer-reviewed scientific journal; it is, instead, a special-interest magazine for physicists. Generally, my reviewers are staff writers and editors (all physicists) who may give me little more than 'thumbs up' or 'thumbs down' on a letter. As a rule, we do not give out the specific comments of the reviewers, because we consider them to be internal business. Thank you for your inquiry. I hope my explanation has helped."*

That was the end of our correspondence. Why was it not obvious to them that my letter to the editor was not about specific CMNS claims. I hoped that readers of the journal will comment on my 'special-interest" plea, advising me how to resolve the dilemma. That what Letters To The Editor are for. I often benefit from reading that section each month. Why did the editor decide to deprive me of this valuable resource? How can this censorship be justified in the context of 'New American Physical Society's Ethics Guidelines'? Something was not right. My experience was consistent with George Miley's observations.

14) Meeting Fleischmann And Jones

I was lucky to personally meet Martin Fleischmann and Steven Jones, whose research triggered the CMNS controversy. Fleischmann's presentation at ICCF10 (the first CF conference I attended) was based on what happened in the past. I was surprised to hear that he was motivated by profound theoretical consideration, and by results of experiments performed half a century earlier. At the end of the talk he said: *"I believe that the work carried out thus far amply illustrates that there is a new richly varied field of research waiting to be explored."* Jones made three presentations based on work in progress. Fleischmann was kind enough to allow me to be photographed in with him. He is wearing glasses on the photo shown below.

Jones and his coworkers presented two papers devoted to detection of nuclear projectiles from titanium foils saturated with heavy hydrogen. The first presentation was devoted to energetic protons, the second to emission of energetic neutrons. Instruments they used were similar to those I used in my post-doctoral studies. That is why I approached Jones and asked for numerous details. At the end of this conversation Jones invited me to visit his laboratory at Brigham Young University. I visited him several months later and he gave me a sample of titanium to investigate at home. I hoped to discover delayed emission of protons and alpha particles.

15) New CF Results Reported By Other Researchers

The most impressive ICCF10 presentations, from my point of view, were those of Yasuhiro Iwamura, from Japan, and Dennis Letts, from Texas. Iwamura and his coworkers diffused heavy hydrogen through a thin palladium foil. The surface where hydrogen entered was covered with a chemical element Sr. The experiment lasted 400 hours. During that time the amount of strontium was progressively decreasing. This was accompanied by the appearance of the element Mn (molybdenum) on the other side of the foil. The number of atoms of Sr that disappeared was about the same as the number of atoms of Mo detected on the other side of the foil.

The provided interpretation was that atoms of strontium are turned into atoms of molybdenum. Instuments used in this investigations were totally unknown to me. But I was fully aware of the significance of the reported results. It was alchemy--a change of one element into another. The obvious question, which I did not ask, was about a possibilty of Mo contamination--how do you know that the detected molybdenum was not originally present in the setup? Anticipating such questions, Iwamura provided an answer. The isotopic composition of molybdenum was very different from that found in nature.

Alchemy, by the way, is known to be impossible unless nuclear reactions are involved. Production of plutonium from uranium, to make atomic bombs, is an example of "nuclear alchemy." Turning atoms of one element into another, by means of nuclear reactions, is usually called transmutation. Even turning mercury into gold is now possible; but one gram of gold produced via transmutations would cost more than one billion dollars. Presence of transmutation products in a reproducible-on-demand CMNS process would be a very strong indication that nuclear reactions do indeed take place at a low temperature.

Letts' setup was much less sophisticated than that of the Japanese scientists. It was an F&P type of experiment, designed to demonstrate production of excess heat. What impressed me was the fact that results--generation of excess

heat at the rate of about one watt--became reproducible when the cell was irradiated with a beam of laser light. Absence of reproducibility was the Achilles' heel for this kind of experiment.

16) Cooperation With Oriani

I was also impressed by Richard Oriani's ICCF10 presentation. He reported emission of alpha particles during electrolysis. These particles were detected in a plastic material known as CR-39. Most eyeglasses are now made from that transparent material. It turns out that an alpha particle, stopped in CR-39, creates an invisible track. Such tracks become microscopically visible after the material is chemically processed. I learned about this method of detection of nuclear particles in Europe, about four years before coming to the US. But the material I used was natural mica, not CR-39.

Let me digress and describe how I became one of the first Europeans to use mica to detect fission fragments (not alpha particles). I was working on my Ph.D. project, in Orsay, near Paris. At that time I was already an expert in using several kinds of detectors of nuclear particles. One afternoon I received a telephone call from our librarian. She told me that she had an American guest interested in fission. "Please come and take him with you," she said, "I am too busy with other things." That is how I met John Walker, who invented the method of detection of fission fragments with common mica. He wanted to demonstrate the method to people who might be interested. I had everything he needed and two days later we observed tracks of fission fragments.

I did not use mica in my dissertation project but I used it in the US, when I became a postdoc at Columbia University, several years later. My most important scientific contribution to nuclear physics, during that time, was made by using mica detectors. CR-39 is used in the same way as mica, except that turning invisible tracks into visible tracks is slightly different. Learning how to detect alpha particles with CR-39 presented no difficulty to me; I mastered that skill very quickly. I was lucky to be invited to Oriani's laboratory, at the University of Minnesota. Two of our replications of his results, which had been reported at the conference, turned out to be highly successful.

After each replication we examined the CR-39 chip removed from the electrolytic cell and a control chip that was not in the cell during the experiment. The second chip was chemically etched in exactly the same way as the first one. Then pits on each chip were counted under the microscope. The control chip was used to measure the unavoidable background, such as alpha particles from cosmic rays, radon, etc. In each case tracks on the control chip were much less numerous than tracks on the experimental chip. The next step for me was to perform similar experiments independently. To be sure that my cell was exactly the same as his I ordered it to be made in the shop in which Oriani cells were made. I returned home and started experimenting immediately.

Unfortunately, my results were not as reproducible as our results in Minneapolis. In the first experiment I saw nothing except the natural background, on both chips. In the second experiment the number of observed alpha particls on the experimental chip was much higher that on the control chip. But the third experiment's result were essentially the same as the first one. Subsequent experimental results were also not reproducible. In other words, I was not able to either confirm or refute the results described by Oriani. This, however, was not the end of the story; I will return to this topic on Chapter 22. Results from my cooperation with Letts and Jones are described in the next chapter.

Go to the Table of Contents

17) Next CMNS Conference: My Three Presentations

The next CF conference, ICCF11, took place in Marseille, France. This time I did have some experimental results to share, plus two 'philosophically-oriented' presentations. Jones, Letts and Cravens were coauthors of my experimental

report, entitled "Charged Particles from Ti and Pd Foils." Referring to my cooperation with Jones I said that his Ti foil was *"sandwiched between two CR-39 detectors for the period of 55 days. [...] The number of tracks on the experimental chip was 225; the number of tracks on the control chip was 132. Such results, if generated by a Geiger counter, for example, could be used as evidence of nuclear particles being emitted from the foil."*

Then I explained why the difference, 225-132=92 was not sufficiently large to draw the same conclusion from our CR-39 experiment. Additional experiments, I said, will be performed. Unfortunately, such experiments were not performed; Jones was apparently distracted by other matters. According to Wikipedia, "he retired on October 20, 2006 with the status of Professor Emeritus." Fortunately, the low-numbers-of-counts problem did not exist in my analysis of palladium foils from Texas. Here is how my cooperation with Letts was presented in the conference report:

"[... L.K.] asked for a chance to look at a possible 'nuclear signature.' Three palladium cathodes: Pd-613, Pd-616, and Pd-615 were sent to L.K. and he exposed them to the CR-39 detectors. [...] The tracks were counted, under the microscope. The results were: (a) about 500,000 tracks on the two detectors sandwiching the Pd-613 cathode, (b) about 11,000 tracks on two detectors sandwiching the Pd-616 cathode, and (c) no tracks above the background on the detectors sandwiching the Pd-615 cathode. ....Only then was L.K. informed that the Pd-613 generated an unusually high amount of excess heat, the Pd-616 generated much less excess heat, and Pd-615 generated no excess heat at all. He was also informed that all three cathodes were cut from the same sheet of pure palladium, and that the electrolyte from the Pd-13 was known to be contaminated with uranium."

In other words, the huge number of tracks from the Pd-613 was most likely due to uranium. The Pd-616 and Pd-615 results, on the other hand, were highly significant. They demonstrated a correlation between the amount of excess heat generated and the number of alpha particles produced. [.] In the same presentation I said that cooperation with Letts also did not have a happy ending. To establish a correlation between the excess heat and emission of alpha particles one needs more than two samples. But new samples were not sent to me. In 2005, alarmed by the situation, I sent the following e-mail message to Dennis Letts.

"I am going to galley proof our Marseilles presentation. This puts me in an awkward situation. If I were reporting on my own work I would add a short paragraph, something like this: 'No additional experiments were conducted to confirm observations made 6 months ago. The unexpected delay is due to [.]' or something like this. But in this case I was only a messenger; you are the real player. A reader is likely to be interested in the current status of our investigation. I think that it is not right to report positive results only and keep negative results hidden. Do you agree? [.]," The following reply was received several hours later.

"No additional experiments were conducted to confirm observations made 6 months ago. The unexpected delay is due to the fact that experiments seldom work on a schedule. The calorimeter had to be modified slightly to re-store design stability and precision. Also, we have not observed laser-triggered excess power since August 2003. Of course I agree [with your last statement] - since changing metals at the end of 2004, my success rate has been zero. This is compared to a success rate of 87% during the years of 2000-2004. Other than changing Palladium stock, I don't know what has caused the sudden loss of the laser effect. Experiments have been conducted in a high quality calorimeter, in a moderate quality calorimeter (my Avanti) and on the open bench. The laser effect has not re-appeared under any of the above calorimetric conditions. Experiments are being conducted now to re-establish the laser effect or to explain why it stopped working. You may use this information in any way you wish, including an addendum.

With regard to reporting negative results, consider this: Cravens and Letts discovered the laser effect in September 2000 and reported the positive results publicly in August 2003. We spent 3 years testing the credibility of our result before reporting publicly. We anticipate behaving in a consistent manner now - we have negative results but we're not in a rush to report until we're sure that we have negative results and try to provide some reasons why the results are negative. I believe that reporting results formally by 2007 will be consistent with our previous work and should not be considered 'keeping negative results hidden'.,"

I am sure that neither Letts nor Cravens are trying to hide negative results. Like most CMNS researchers, they are honestly following scientific methodology of validation of claims. But, as explained by McKubre, outomes of experimental results often depend on unknown parameters. That was a good illustration. No new samples were ever

sent to me.

What a coincidence! While I am describing this past cooperation Dennis Letts has just announced (March 2012) the development of a single mathematical equation that is able to accurately reproduce results from 40 experiments he conducted with Cravens and Hagelstein in 2007-2008. Additional experiments will soon be performed to test theoretical predictions. Is this going to lead to a great step forward? I hope so.

18) My Two Other ICCF11 Presentations

Those who attend scientific conferences know that some contributions are presented as posters. This is unavoidable when time is limited. My non-experimental presentations appeared as posters; both were published in the Conference proceedings. The first, entitled "Recent Cold Fusion Claims: Are They Valid," can be read online at:

http://pages.csam.montclair.edu/~kowalski/cf/152summary.html

It was a manuscript--a review of the CMNS field--with 37 references. I wrote it for publication in a mainstream scientific journal. Unfortunately, that manuscript was rejected by editors who received it. The second poster, as shown in the next Chapter, described my personal experience with the process of rejection of a CF paper.

Go to the next chapter
Go to the Table of Contents

19) History Of Attempts to Publish

My unsuccessful attempt to publish a letter to the Editor of one journal--Physics Today--has already been described in Chapter 13. What follows is a description of other unsuccessful attempts. Knowing that the second DOE review of the CMNS field was approaching, I summarized what I had learned about CF. This took the form of a manuscript that I wanted to publish, for the benefit of people inerested in science and technology. The title of the article was "Recent Cold Fusion Claims: Are They Valid?" Seven journals to which my manuscript was submitted were:

Physics Today, USA
American Scientist, USA
Scientific American, USA
Nature, UK
New Scientist, UK
The Physics Teacher, USA
Science, USA

a) The Cover Letter

Each submission had essentially the same cover letter. In that letter I wrote: *"I am sure that you are aware of the DOE move to review the cold fusion field, as reported in The New York Times (3/25/04). Attached is a review article which, I hope, can be published in [your journal]. The title is 'Recent cold fusion claims: are they valid?' It is not a paper defending cold fusion claims; it is a paper describing them, no matter what one is inclined to think. Scientifically literate readers are likely to appreciate my short summary of recent claims made by cold fusion researchers.*

Some of these claims, such as turning Sr into Mo, or Cs into Pr, without stellar temperatures, are even more extraordinary than the claims made by Pons and Fleischmann. The strange thing is that authors of such reports seem

to be reputable scientists associated with prestigious universities and laboratories. Is it a matter of fraud? Is it a matter of self-deception, or incompetence? Is it a matter of progressive degeneration due to the isolation of the field from mainstream science? My article does not try to answer these questions; its purpose is to present a summary of what has been recently reported without taking sides. The subject is interesting no matter what the final verdict of the second DOE evaluation will be.

Like many other science teachers, I am in no position to verify validity of hard-to-accept claims in a specialized laboratory. That is why, as suggested in the concluding section, a new evaluation of cold fusion claims, by an appointed panel of experts, is highly desirable. In writing the review I was not aware of the pending DOE investigation. I deliberately avoided references to social aspects, which are interesting but highly controversial. I am a physics teacher at Montclair State University. Studying cold fusion was my 2003/2004 sabbatical project."

b) Reply From the Editor Of Physics Today

," Dear Dr. Kowalski: We received your article submission titled, "Recent Cold Fusion Claims: Are They Valid?," and appreciate your sending it to Physics Today. After reviewing it, however, we have concluded that it does not meet our editorial needs. Thank you for your interest in Physics Today. Sincerely, Stephen G. Benka Editor-in-Chief."

c) **My Comment**

That is it. Not a single word about the content of the article. How can the phrase ,"does not meet our editorial needs," be interpreted? Why was the article not sent to referees? They do publish many field summaries each year. Why was my summary not given the same chance to be reviewed by experts? Was I writing about sociology, poetry, business or something else unconnected to physics? Are recent cold fusion claims described in the article already widely known to most physicists? Was my description of these claims erroneous? Was the article rejected because of its style, its limited scope, or its disregard for ethical standards?

d) Reply From the Editor Of American Scientist

"Dear Dr. Kowalski: Yes, we've received your original manuscript and the follow-up. I'm afraid we're not always able to acknowledge receipt immediately. I try to give a prospective author an idea of whether we'll be able to consider a manuscript, and sometimes it takes a little time to determine that. We have certain basic criteria for submissions. When a submission does not meet those criteria, I prefer to say that it cannot be considered rather than simply acknowledge receipt.

In the case of this submission, I'm unsure. We publish feature-length articles and commentaries based on original published research. The authors of American Scientist articles are the people who have done the work and therefore are in a position to survey their own field. I don't actually have evidence (in the form of cited publications or a c.v.) that you have done original research on the topic you propose to write about.

If you would like to publish a short commentary, we do have a department with different criteria, called "Macroscope." This is where we publish short essays conveying a scientist's point of view on a matter of personal or professional interest to scientists and engineers. The maximum word count is 1,500. If you would like us to consider publishing your piece in a short form, please let me know, and I'll share it with my colleagues and let you know the response. Sincerely, Rosalind Reid Editor, American Scientist."

e) My Reply:

"Dear Dr. Reid: Thank you for your prompt reply. I understand your hesitation. Protecting readers of American Scientist from people who are not qualified to write about science should be one of your tasks. To help you decide here is a little summary about myself.

I am an experimental nuclear physicist (Ph.D., 1963) with a large number of publications (mostly as coauthor) in that field. The attached abbreviated list of publications, spanning four decades, makes it clear that my teaching

commitment has not prevented me from active participation in nuclear physics research. Like most scientists, I accepted the 1989 verdict about cold fusion. And you are correct, I have no publications about cold fusion. My new interest in this field was triggered in October 2002. I attended a nuclear conference in New Mexico and heard several scientists talking about cold fusion research. It was the beginning of my sabbatical year. The paper I submitted is the product of that work.

I hope your hesitation will not prevent you from sending my article to competent and unbiased reviewers. Please let me know what your decision will be. Meanwhile I would like to follow your suggestion about writing a short commentary on the anticipated review of cold fusion by the DOE; see the attached file. Thank you for your consideration. Sincerely yours, Ludwik Kowalski.
A list of my selected publications, and a file containing my ,"short Golden Egg piece," (see below), were attached.

f) Seek Not The Golden Egg, Seek The Goose (attached file)
According to a recent article in The New York Times (3/25/2004) the US Department of Energy (DOE) is going to review the field of cold fusion this year. This is a significant event; the controversial field of cold fusion (CF) has often been called pseudoscience. If it were up to me I would suggest that the panel of DOE scientists focuses on essential scientific questions and not on practical applications which are far away, at best. Promising too much, and too early, was one of the mistakes made fifteen years ago. In my opinion the six most important scientific questions are:

1) Are unexpected neutrons, protons, tritons and alpha particles emitted (at low rates) in some CF experiments?
2) Is generation of heat, in some CF experiments, linearly correlated with the accumulation of ^{4}He at the rate of 24 MeV per atom of ^{4}He?
3) Have highly unusual isotopic ratios been observed among the elements found in some CF systems?
4) Have radioactive isotopes been produced in some CF systems?
5) Has transmutation of elements occurred in some CF setups?
6) Are the ways of validating scientific findings in the areas of CF research consistent with accepted methodologies in other areas of science? I think that a positive answer to even one of these six questions should be sufficient to justify an official declaration that ,"cold fusion, in light of recent data, should be treated as a legitimate area of research.," The normal peer review mechanisms will then be used to separate valid claims from wishful thinking.

g) After Waiting Several Days I Sent This Addendum

"I already mentioned two reasons making such review urgent: the 15th anniversary of the Utah announcement and the pending DOE investigation. In my opinion, by publishing my paper, or a review written by somebody else, you will contribute to something desirable. Nobody is happy with the unhealthy feud between a group of well motivated researchers and official representatives of 'mainstream science.' Most people are passive but those who do take extreme positions often use highly perjorative adjectives, such as 'pathological', stubborn, misguided, and fraudulent.' Please do not miss an opportunity to contribute to ending this unnecessary feud. I would be happy to give you names and addresses of top people in five main areas of cold fusion.

So now you have several excuses for bending a rule of your editorial policy. They are: a) the anniversary, b) the pending DOE investigation, c) my paper is a review describing (very objectively, and without accusations of any kind, as you probably noticed) several very different areas of a broad field, d) my background as an active nuclear physicist, and e) my unpublished research in two areas of cold fusion. You are certainly aware how difficult it is to publish cold fusion research papers in important scientific journals. Will the situation change after the pending DOE investigation of cold fusion? I hope so. Please help to contribute to this cause.

If you decide to approach Fleischmann, be aware that he is an electrochemist; I do not consider him to be an expert in nuclear physics. This became clear in 1989 and contributed heavily to the cold fusion controversy. One can only imagine what would happen if Fleischmann and Pons, who are chemists, refused to participate_in the infamous press release, organized by the administrators of the University of Utah, and decided to work with Steven Jones, who is a physicist. A year or two later they would publish a peer reviewed paper and [...] But I refuse to speculate; my goal is to heal the wound by focusing on purely scientific topics and by ignoring stupid things people said or wrote before.

Please help me. I think that cold fusion, no matter what the final verdict will be, is a highly significant episode in the history of science. Let your journal be a part of that history."

I also gave Dr. Reid names and e-mail addresses of five people (who are certainly much more knowledgeable than myself) suggested that she contact one of them to write a longer review paper for the journal. Steven Jones, Martin Fleicshmann and George Miley were among the scientists I selected. I did not hear from Dr. Reid again. Will she accept my ,"Golden Goose" item? Probably not.

h) Reply From The Editor of Scientific American

,"Dr. Kowalski: Thank you for your offer to contribute to SCIENTIFIC AMERICAN. After much consideration, I regret to say that the piece you propose is not suited to our somewhat limited editorial needs. We appreciate your interest in SCIENTIFIC AMERICAN. Regards, Jacob Lasky Editorial Administrator.,"

i) Reply From The Editor of Nature

,"Thank you for your inquiry about submitting your paper entitled 'Cold fusion 15 years later' to Nature. I regret that the paper that you describe seems unlikely to prove suitable for publication in Nature, and we accordingly suggest that you pursue publication elsewhere. I am sorry that we cannot respond more positively on this occasion. Yours sincerely Dr Karen Southwell, Senior Editor.,"

j) My Comment

I was aware, from browsing their web site, that the rate of acceptance in Nature is about 1 out of 10. On that basis I should have expected a rejection. Frustrated that my timely review of the Cold Fusion field is being delayed I decided to send it to another UK journal, **New Scientist**. But they never responded.

k) Reply From The Editor Of The Physics Teacher

, "Dear Professor Kowalski: We have reviewed your manuscript ,"Cold Fusion 15 Years Later," in the light of the recent Physics Today article 'DOE Warms to Cold Fusion.' While a paper in TPT on this subject may be warranted, we do not believe there is any great urgency to publish one immediately. After all, according to the Physics Today piece, DOE Deputy Director Decker says that their 'review of cold fusion will begin in the next month or so [that was back in April]' and it 'won't take a long time--it's a matter of weeks or months.'

We believe that it would be premature to publish a cold fusion paper in TPT before the results of the DOE review are announced. Were we to do so, a follow-up piece would almost certainly be required later, regardless of how that review turns out, and we don't feel that two papers on the subject are warranted. We will consider your paper again (along with any revisions induced by the DOE report) after the report is made public.,"

l) My Reply

"Dear Dr. Mamola": Was my manuscript examined by referees? I would very much like to see what they had to say about its content. Thank you in advance.," This message has not been answered. Will I ever see the referee's comments? Probably not.

m) Reply From The Editor of Science

"I've consulted with our editorial staff in the physical sciences. Unfortunately, we don't think this topic is an appropriate one for review in Science at this time. Thanks for thinking of Science. Sincerely yours. Donald Kennedy."

n) My Comment

Hmm, it was rejected on the basis of the topic, not on the basis of the content. George Miley was right; the editors of

most journals put this topic on their blacklist. The scientific methodology of validation of claims, made by recognized experts, does not count anymore.

I can now say that I have had personal experience with peculiar aspects of CMNS area: irreproducibility of experimental results and censorship imposed by editors of journals.

20) Transmutation Of Radioactive Nuclei--Or An Artifact.

As mentioned in the Introduction, I came to the Albuquerque conference to learn about a claim made by a physicist who was not a CMNS researcher. He was discussing practicality of the idea of destroying radioactive materials by bombarding them with high-energy neutrons. That topic was at the center of my attention earlier, when I was on sabbatical leave in France. I had a chance to participate in the collection of experimental data on production of energetic neutrons by using energetic protons, from a large accelerator.

What a coincidence! One of the CF researchers I met at Albuquerque, a university professor, claimed that he was able to reduce radioactivity of uranium via a CMNS process. I definitely wanted to participate in the next phase of his experiment. But the scientist was not enthusiastic about this idea, claiming that it might create patent-related complications. Fortunately, I later learned that another CF researcher, Hal Fox from Salt Lake City, UT, made a similar claim, destroying radioactive thorium via a CMNS process. This time my suggestion that we should replicate the experiment together, in Hal's laboratory, was welcome.

Their high voltage electrolysis cell was similar to that shown in Chapter 9. The essential difference was that the cathode was made from zirconium, not tungsten, and that the substance dissolved in water was a thorium salt. To prepare myself for this task I read the paper by Hal Fox and Dr. Shangxian Jin very carefully. It had been published in Journal of New Energy. Hal was more an organizer and businessman than a scientist. But his younger co-worker was a highly qualified nuclear physicist.

It occurred to me, while reading their paper, that the destruction of thorium might have been an illusion, resulting from not taking under account one possible effect. I described this to Hal, before coming to Salt Lake. He agreed that the effect I suggested should be investigated. That is what we did during one week in 2003, in his Salt Lake City laboratory.

The experiment was performed twice, first more or less as described in their 1998 paper and then in the way I suggested. The first experiment consisted of the following four steps:

Step 1: A small amount of radioactive thorium salt was dissolved in water, in an open glass jar.

Step 2: A sophisticated detector placed outside the jar was used to measure gamma rays emitted by thorium. The result was close to 20,000 counts.

Step 3: An electric current was passed through the salt solution in the jar, a process claimed to be responsible for the destruction of radioactivity. After about 30 minutes the current was turned off. The immersed zirconium cathode delivering electricity to the solution was partially decomposed during this step; metallic fragments could be seen at the bottom of the jar.

Step 4: Our detector was placed in the same position as before and thorium radioactivity was again measured for two hours. This time the number of counts was close to 10,000. In other words, the final count was one half of the intial count. In that sense the replication of the 1998 experiment was very successful.

Why was the experiment performed in an open jar and not in a pressurized container, as in the original experiment? Because we believed that the setup could eventually be used by teachers to demonstrate a CMNS effect. Jars are widely avalable in school laboratories. And they are safer than sealed pressurized containers. Let me now describe our second experiment. The open jar and all instruments were the same as in the first one. The underlying idea of counting gamma rays before and after Step 3 was also the same. But the way of counting was modified, according to my suggestion.

The salt was first placed on top of the detector and gamma rays were counted for ten minutes. The number of counts was close to 100,000. This was not surprising, considering the very short distance between the source of radioactivity and the detector. Then the salt was dissolved in water and the electric current was passed through the solution for 30 minutes, as in the Step 3 of our first experiment.

Next we heated the jar and allowed all the water to evaporate. The thorium salt remained in the jar, forming a white precipitate, mixed with metallic debris from the partially destroyed zirconium rod. The deposit was collected and placed on top of the detector. Gamma radiation was again measured, for ten minutes. Suppose that the original claim--destruction of 50% of thorium by electric current--was correct. In that case the final count would be about 50,000, one half of the initial count. Our final count, however, was close to 90,000, a strong indication that the fraction of destroyed thorium was much lower than 50%.

Results from the two experiments allowed us to reach the following conclusions: (a) The final count was indeed reduced by a factor of two, as originally reported by Fox and Jin. (b) The reported reduction of count, however, was not due to destruction of atoms of radioactive thorium; it was due to the suspected artifact, redistribution of thorium in the jar, during Step 3. (c) The approximately 10% reduction of counts was attribued to thorium escaping with steam during the process, or deposited on the inner walls of the jar. Hal did not participate in this experiment personally. But he took the remaining precipitates and sent them to a chemical laboratory.

This episode put me in a rather delicate situation. Being a scientist, I wanted to publish the result, perhaps in the same journal in which the original claim appeared. But it was not my experiment and I decided to do nothing more. Hal had generously invited me (I stayed in his home, met his family, etc.) and the task of publishing the new result should have been on his shoulders. He said that he would wait for the result of chemical analysis. Did the results of that analysis reveal presence of transmutation products, expected by Hal? I do not know.

This was the first successful CMNS experiment in which I personally participated. The term success does not mean finding what was suspected. In the context of a scientic exploration to succeed means to obtain a clear yes-or-no answer--in this case about destruction of thorium atoms. I would be equally happy, or probably happier, if the last count were close to 50,000 rather than close to 100,000. That would be a strong indication that about 50% of thorium was indeed destroyed (rather than redistributed) during the process. Two other successful CF experiments, in which I participated, are described in the next two chapters.

21) The Galileo Project

In November 2006 Steven Krivit, editor of the online magazine New Energy Times, started recruiting researchers for what he called The Galileo Project. They were to replicate experimental results obtained in the US Navy laboratory in San Diego, known as SPAWAR. A team of scientists from that laboratory, headed by electrochemist Pamela Boss, he wrote: " produced something unique in the 17-year history of the scientific drama historically known as cold fusion: simple, portable, highly repeatable, unambiguous, and permanent physical evidence of nuclear events using detectors that have a long track record of reliability and acceptance among nuclear physicists."

The task was to follow the SPAWAR protocol and detect alpha particles by using CR-39 detectors. Naturally I was

one of the six people who immediately agreed to participate. Scott Little, with whom I had worked in Texas, also became one of the independent participants. Oriani refused to join because, in his opinion, the SPAWAR CR-39 pits were due to corrosion rather than to alpha particles. I was well prepared for this task. Working at Montclair State University, with a student helper, I was able to replicate SPAWAR results in about three weeks. The Winter Meeting of the American Chemical Society was approaching and I knew that Pamela Boss was scheduled to talk about the original SPAWAR results.

That prompted me to sign up for the conference. Fortunately, my "last minute" application was accepted. They gave me a time slot to present the results, at the same session. The meeting was in Denver and I was able to be there just on time. Photos on my slides were practically the same as on those shown by the SPAWAR team. That was the happy part of my presentation; I could see smiles on faces of SPAWAR researchers.

But the ending was not happy; my conclusion was similar to Oriani's--the pits were not due to alpha particles. But I am not a corrosion expert, like Oriani. I said that the pits might have been due to much larger nuclear projectiles, such as fission fragments. To reach this conclusion I measured sizes of typical SPAWAR-like pits and compared them with sizes of pits due to particles from my alpha radioactive source. Friendly personal relations with Pamela deteriorated rapidly after the conference.

But we debated the issue on pages of European Physics Journal. Fortunately, its open-minded editor does send CF-related submissions to referees. The experiment was successful, a clear "yes" answer was obtained to the replication-of-experimental- results question. The disagreement was about the interpretation of results, not about the results themselves. I respect SPAWAR scientists; their numerous publications are certainly up to high standards. But R. Park, and others like him, probably continue calling them pseudo-scientists, without any justification. That is very unfortunate.

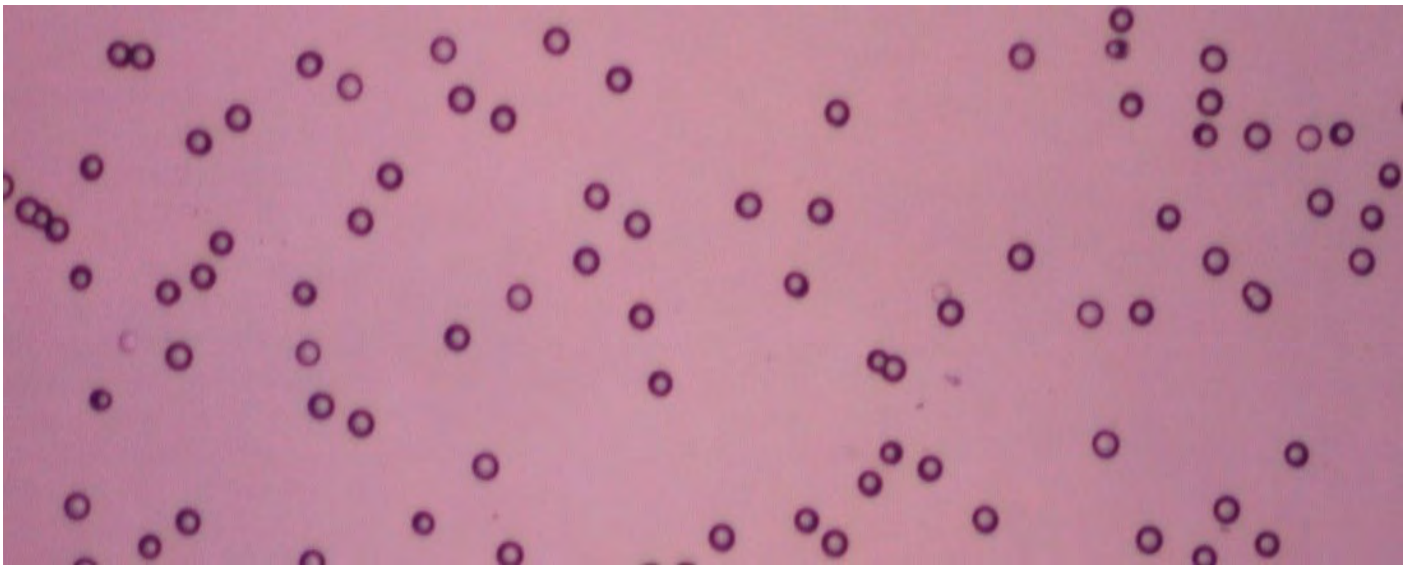
22) The Curie Project

My cooperation with Richard Oriani, described in Chapter 16, was not successful; the answer about reproducibility of results was neither "yes" nor "no." That was not a pleasant situation. But our cooperation was resumed after he changed the procedure (covering experimenta CR-39 chips with thin foils of Mylar). He submitted a paper with a new impressive results to a prestigious US journal, Physical Review. That manuscript was rejected but results were presented at our 2008 conference (ICCF14), in Washington, DC. His paper prompted me to make another attempt to replicate new data.

My 20 consecutive experiments, lasting three days each, were performed on the 27th floor of an apartment building, rather than in a private home with granite walls. The probability of being exposed to radon at this location was relatively low, especially in my study, where the window was kept slightly open. Additional precautions were made to minimize exposure of CR-39 to radon. Chips ready to be used were kept in distilled water, not in air. Etching of CR-39 chips and counting of pits, on the other hand, was done at the university. The photo below shows typical circular tracks of alpha particles in CR-39, as seen through a microscope.



The mean track density reported by Oriani was 122 per square centimeter; it was significantly higher than his measured background. My mean density, from 17 experiments, was only 16 per square centimeter; it was not significantly different from my measured background. Total elimination of background is not possible, due to radon, cosmic rays, and other contaminants.

Track densities on three of my experimental chips turned out to be very much higher than those reported by Oriani. My results, in other words, were not in agreemen with those reported by Richard. The exceptional results from these three experiments were attributerd to contamination. In a subsequently published paper I wrote that "attempts to identify contaminants were unsuccessful. Alpha radioactive substances such as uranium, thorium and radium are known to be present in our environment. One nano-gram of radium, for example, emits 37 alpha particles per second. Atmospheric testing of nuclear weapons in the 1960s contributed to contamination of our environment with long-lasting alpha-radioactive isotopes."

No one knew about my undeniable disagreement with Oriani's published results. Before sharing my data with others I summarized his results and asked, using the Internet, for people interested in replicating them, in the same way SPAWAR results were replicated in the Galileo Project. Three individuals expressed interest. One was a young engineer I had met in Denver, after the ACS conference (Jeff Driscoll). Two others (Mike Horton and Pete Lohstreter) were high school physics teachers.

Our cooperation, called the Curie Project, was very successful. Working independently, and unaware of each other's results, each experimentalist came to the same conclusion--measured track densities were not significantly different from those due to the measured background. The results were subsequently published in the Journal of Condensed Matter Nuclear Science, a peer-reviewed journal of the International CMNS Society. It can be downloaded as

<www.iscmns.org/CMNS/JCMNS-Vol5.pdf>.

Numerous details and illustrations are in this short article (pages 34 to 41). Would I volunteer to participate in another CF project? Probably not. But I will continue paying attention on future claims, as illustrated in the next chapter. My most recent publication in this area is the letter to the editor of Progress in Physics. The title is " Social Aspects of Cold Fusion: 23 Years Later." The link is:

<www.ptep-online.com/index_files/2012/PP-29-L2.PDF>

In the concluding section I wrote: *"The CF controversy is unprecedented in terms of its duration, intensity, and caliber of adversaries on both sides of the divide. Huizenga and Fleischmann were indisputable leaders in nuclear science and electrochemistry. CMNS researchers are mostly also Ph.D. level scientists. The same is true for those scientists who believe that the announced discovery of CF was a "scientific fiasco". We are still waiting for at least one*

reproducible-on-demand demonstration of a nuclear effect resulting from a chemical (atomic) process. In the case of CF the self-correcting process of scientific development emphasized by Huizenga has not worked. This fiasco seems to be due to the fact that scientists appointed to investigate CF claims did not follow [the welll established] rules of scientific methodology."

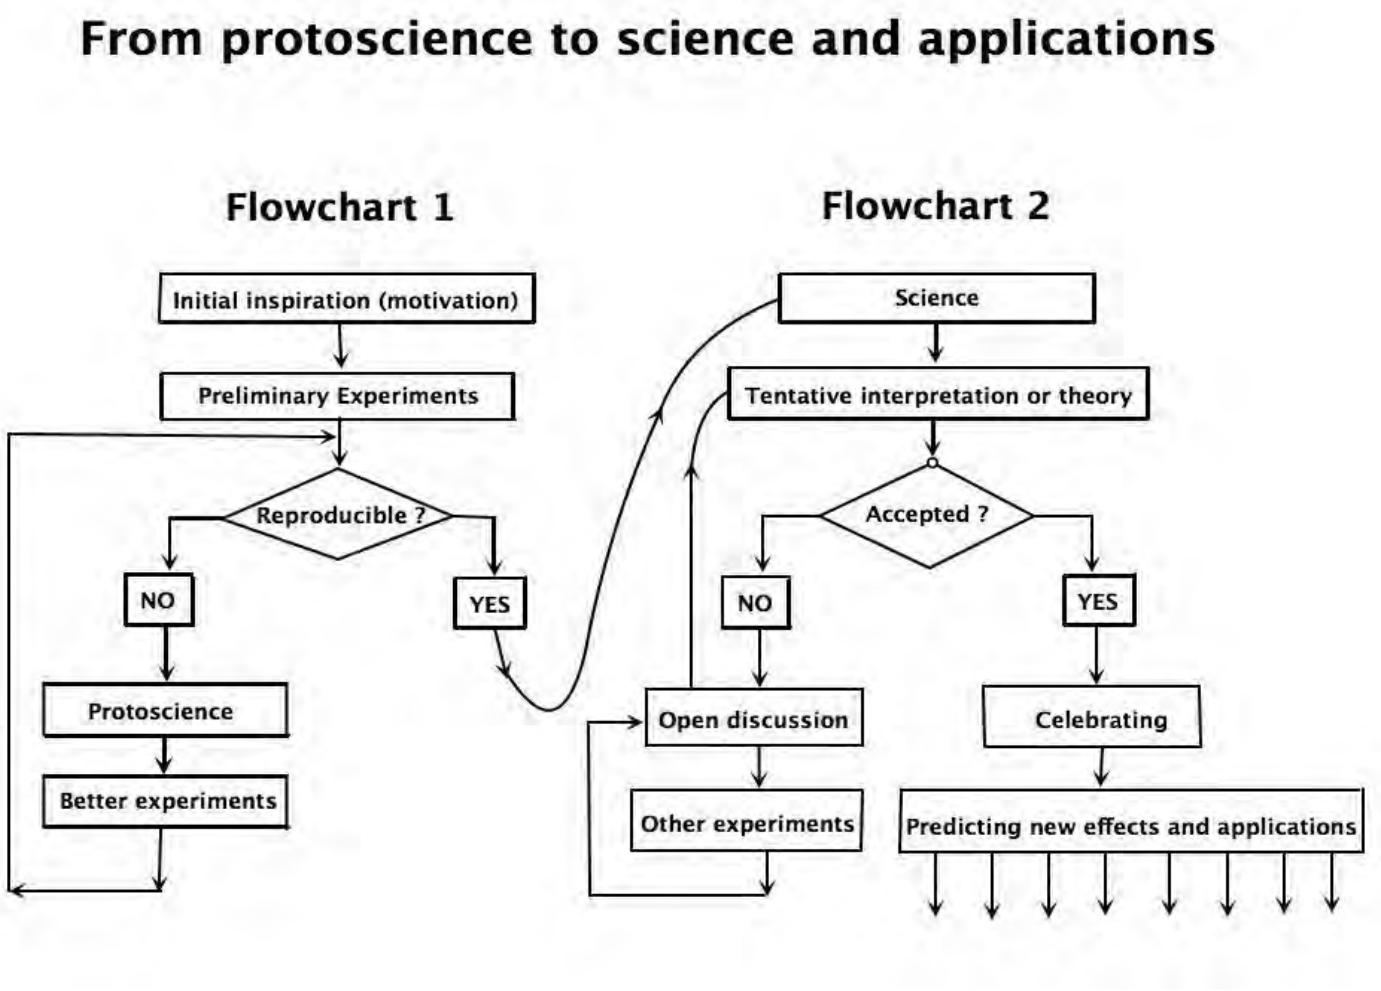
23) Flowcharts:The Last CF Conference I Attended

CMNS conferences take place each year. The next one will be in South Korea (summer 2012). But the last CF conference in which I participated took place in 2008, in Washington DC. The title of my presentation was "Nuclear Or Not Nuclear: How To Decide?



The above diagram was part of my presentation. It illustrates a typical experimental discovery process. What triggers the process (see the top of the left flowchart) is irrelevant. A subsequent experiment might or might not be reproducible. Non-reproducible results, in my opinion, belong to protoscience, not science. But they may become science, sooner or later. The next task is to interpret (understand) the result. The scientific community might or might not agree on a proposed explanation (theory).

This typically leads to other debates, and to calls for additional experimental data, as shown in the diagram. Practical applications might or might not emerge immediately, after a discovery is recognized as valid. But a valid discovery does become part of science, like each little stone is part of a magnificant cathedral. Practical applications usually

result from sets of many discoveries, including those made long ago.

CMNS claims, I said, still belong to protoscience. *"It is unfortunate that, except for The Galileo Project, researchers work in isolation from each other. This is understandable, each resercher does what matches his/her expertise and limited resources. This kind of work was going on for 19 years. [...] The task of turning protoscience into accepted science is still waiting for us. How to approach this difficult task and how to proceed more effectvely? In my opinion, well-focused cooperative investigations, as in The Galileo Project, are likely to be more productve, in the next two or three years, than uncoordinated efforts of many individuals."*

What is the main difference between hot fusion and cold fusion communities? In both cases the goal was to build a device whose energy output exceeds the energy input, without consuming chemical fuel. The hot fusion community has been trying to achieve the "break-even" point for five decades and it knows exactly why reaching it is so difficult. The cold fusion community, on the other hand, started by experimenting with break-even devices without understanding what was going on and why. What is the probability that something profoundly new will emerge from hot fusion? It is much lower than from cold fusion, in my opinion. In any case turning hydrogen bombs into candles is not going to be any easier than turning swords into plowshares.

24) Andrea Rossi's Unbelievable Claims

As mentioned at the end of Chapter 2, I have a website devoted to CF--a cross between a logbook and a diary describing participation in CMNS activities. Writing this book would be much more demanding if this free online resource were not available to me. Another resource was a private Internet list for CMNS researchers. On February 26, 2010, the following patent description was posted on our list: "The patent applicant is engineer Andrea Rossi, owner of a small company, employing 2-5 people. In the patent he claims that *'A practical embodiment of the inventive apparatus, installed on October 16, 2007, is at present perfectly operating 24 hours per day, and provides an amount of heat sufficient to heat the factory of the Company EON of via Carlo Ragazzi 18, at Bondeno (Province of Ferrara).' (Italy).* This suggests that power output is at least tens of kilowatts!"

This is a reasonable estimate. Excess heat generated at the rate of tens of thousands of watts, for several months, was indeed a sensational claim. That would be equivalent to burning several tons of coal. Most excess heat demonstrations generate excess heat at the rate of one watt, or less, for much shorter durations.

Several people commented on the above announcement. I responded. *"A suggestion was made, two days ago, that someone should visit the place where spectacular results are available on demand. The visitor would either confirm or refute what has been reported. I do not think that an outsider would be able to evaluate the setup. What is needed is a blueprint and a detailed protocol. Following the protocol a team of competent researchers would try to build the device from scratch and to measure excess heat with their own instruments. Only team members should be allowed to enter the room in which the device is being constructed.*

Yes, I am thinking about the possibility of fraud. Fraudulent people, such as identity thieves and those who solicit profitable partnerships by email, do exist. Someone replied: "I strongly support your suggestion to organize a group to replicate the Rossi patent and I offer myself to assist. I have a modest laboratory and am well equipped to undertake gas absorption experiments."

Unfortunately, things did not develop along the path I suggested. What happened was a demonstration, on January 14, 2011, at Bologna University in Italy. It was followed by a press conference, etc., as photographically illustrated at:

http://www.journal-of-nuclear-physics.com/

The Bologna demonstration could have been more effective than it was, without revealing the nature of the secret catalyst. Rossi could have provided the blueprint of the apparatus to a trusted authority, for example, an Italian government laboratory, asking them to manufacture his simple device. They could have brought it to the University of Bologna and allowed Rossi to place the secret fuel (nickel powder mixed with something else) into the cylinder. He would not have been allowed to do anything else to the apparatus. That would eliminate any suspicion of a hidden energy source somewhere within the apparatus.

This, however, would not have eliminated another possible suspicion--that a chemical fuel was mixed with nickel. But suppose the powder supplied by Rossi is weighed, both before and after the experiment. Suppose the change in weight is negligible, in comparison with what it would have been if a suspected chemical fuel were present. That would rule out a possibility of the chemical-fuel fraud.

_
Generation of a huge amount of excess heat was not the only claim made by Rossi. He also wrote that 30% of nickel was transformed into copper, during six months of operation of his 12 kW reactor, that the radiation level was negligible, etc. Such claims were in conflict with everything I knew about nuclear physics. After becoming aware of this I decided to publish a paper that even undergraduate physics students would be able to understand. Unable to find a publisher I posted the paper at my website. This was in April of 2011. The article, entitled "Rossi reactors--reality or fiction," was subsequently published, in Progress in Physics (January 2012). The link is:

http://www.ptep-online.com/index_files/2012/PP-28-07.PDF

Rossi does not want to be involved in discussing physics--he is an inventor, not a scientist, he keeps emphasizing. He believes that the validity of his discovery will be confirmed by a large number of satisfied customers. At one time (January 2012) he stated that he had found two customers for his 1000 kW power plants. But their identity has not been revealed. I agree with him that a large number happy users will be a convincing argument. But I would not advise anyone to invest in his "secret technology" at this time. The possibility that Rossi has discovered something totally unknown is real but the probability of it is very low, in my opinion. I wish him well. We do need alternative sources of pollution-free energy.

"Is Andrea Rossi the world's greatest inventor since Nikola Tesla and the savior of mankind, or is he one of the worst scoundrels of the year? It's very difficult to say at this time, but the question really is that basic. There are those who would like to tread some middle ground on the topic, but there is no middle ground; it's either one way or the other. The mystery remains, and we have no way of knowing for sure which is the truth. The good news is that, given a little bit of time and patience, the answer to this question will be clear. Meanwhile this is indeed such an incredibly fun and interesting story to watch unfold." I am quoting John Ratcliff, the author of an online article "Andera Rossi: Sinner or Saint?," published on January 21, 2012. <www.examiner.com>.

25) What Is Next?

The process of sharing what I know and think about CMNS will consist of three steps. The first step was to address mainstream scientists. This has been accomplished in a short Letter To The Editor of "Problems In Physics", published in January 2012 (see the link in Chapter 22). The second step was to address generally-educated people; this book is written for them. The third step will be to address philosophers of science, at a congerss in Montreal (June 2012). My paper, entitled "Cold Fusion 23 Years Later: Social And Philosophical Aspects Of That Controversy," has been accepted. What follows are excerpts from slides I am now preparing.

Excerpt 1:

(a) Mathematics, in my opinion, is much closer to theology than to science.

(b) Validation of claims in theology is based on acceptance of initial axioms (self-evident truth) and on logical consistency. The only way to justify the rejection of a claim (either in theology or in mathematics) is to find a logical error in the derivation.

(c) In science--both physical and social--claims are not based on logic only; in the final analysis they are based on experimental data. Mathematics is formalized logic; it is not science.

Excerpt 2:

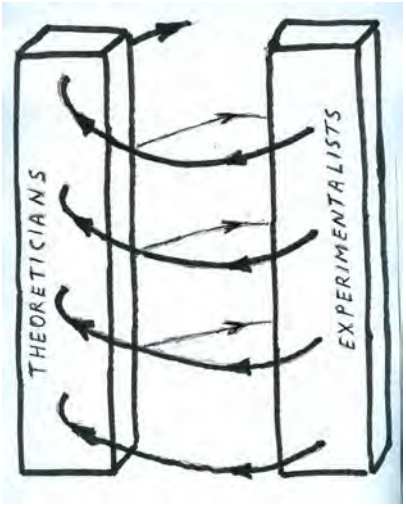
Reproducibility on demand is an important scientific requirement. **But suppose a reproducible result conflicts with an existing theory. What should be rejected, the experimental result or the theory?**

Excerpt 3:

Basic scientific assumptions, derived from philosophy, are: **(a)** reality is objective, **(b)** humans have the capacity to perceive reality accurately, and **(c)** rational explanations of phenomena in our material world are useful.

Excerpt 4:

"Theoreticians guide while experimentalists decide? Yes, but theories are based on verified results from experiments and observations. **The chicken and the egg dilemma? Not really.** Why not? Because the process of accumulation of scientific knowledge is not circular; it is spiral, as illustrated below:



Excerpt 5:

In 1942 Robert Merton described **CUDOS,** the prevailing Norms of Science. In this acronym,
C is for communalism (discoveries are not private property, they belong to all scientists),

U is for universalism (principles of validation of claims are universal, not subject-specific),
D is for disinterestedness (primary motivation for scientists is not money; it is love of truth), and
OS is for organized scrutiny (skepticism is very useful).

Excerpt 6:

A leading CMNS researcher Edmund Storms once asked this question: "**Which is the greater threat to science and mankind, accepting a claim that can have no possible benefit or rejecting a claim that can have great benefit?**

This question was addressed to editors of scientific papers who often deprive CMNS researchers of the peer review process.

Excerpt 7:

(a) Why are scientific investigations usually more effective than investigations in any other field? This is due to the so-called **"scientific method,"** a set of rules developed to deal with difficulties, especially with mistakes and controversies.

(b) Most scientific mistakes are recognized when new results are discussed with colleagues, or via **the peer review process**.

(c) Depriving PhD-level scientists of the peer review process is **a crime against science**.

This is the end of the book.

404) Cold Fusion Is Not Like Hot Fusion

Ludwik Kowalski

April 4, 2012

As most of visitors to this Cold Fusion web site know, I occasionally report voices from a private discussion list for CF researchers. Let me do this again. Instead of revealing names To begin with I will refer to authors as M1, M2, M3, etc., where M stands for "Message." Later I will ask authors for names or initial, to be used, if they prefer. My contributions will be identified by LK.

M1 (in another thread) :

... I would instead suggest the following procedure:

1. Imagine a mechanism.
2. Is that mechanism internally consistent?
3. Is that mechanism compatible with what is generally known in physics and chemistry?
4. Does some kind of special structure (Nuclear Active Environment--NAE) exist, where this mechanism can produce detectable amount of heat and helium? (As a first approximation ignore transmutation, energetic particles and other less prominent features.)

If the answer to any of the questions 2-4 is negative, return to step 1) and start again; otherwise proceed further.

LK:

That sequence makes sense. Fleischmann and Pons (F&P) had experimental data and the mechanism they imagined was the D-D fusion. They even reported emission of neutrons, probably thinking about the He3+n decays of compound nuclei. But presence of neutrons was not confirmed by later investigators. Premature interpretations of experimental data backfired. Referring to this episode, in the article I am preparing, I write:

"Fleischmann and Pons made a devastating mistake in 1989. They announced experimental facts and they speculated about interpretation. They had no evidence that the claimed excess heat was due to a nuclear reaction. The only thing they knew was that it could not be attributed to a known chemical reaction.

Suppose that the experimental facts had been described without any interpretation, and the phenomenon had been named 'anomalous electrolysis.' Such a report would not have led to a press conference; it would have been made in the form of an ordinary peer review publication. Only electrochemists would have been aware of the claim; they would have tried to either confirm or refute it.

The issue of 'how to explain excess heat' would have been addressed later, after the reported phenomenon were confirmed. But that is not what happened. Instead of focusing on experimental data most critics focused on the disagreements with the theory. Interpretational mistakes were quickly recognized and this contributed to the premature skepticism toward their experimental data."

M2:

I agree Ludwik, this would have been the better approach, except for one fact - the involvement of Steven Jones. Jones was actually studying hot fusion but both he and F-P imagined they both were seeing the same process. In fact, F-P were not seeing hot fusion but an entirely new process. But, they both wanted credit. This confusion between hot fusion and LENR, which continues even today, is the source of all the problems.

M3:

Ludwik, I would rephrase this statement a little to be consistent with my experience (and recollection). In 1989 there was probably nobody better qualified in the world by intellect and experience than Martin Fleischmann to know that what he and Stan had seen was not "cold hot fusion". He knew this more certainly than any man. The idea that deuterium involved itself in some form of fusion process to produce what we now call the Fleischmann Pons Heat Effect (FPHE) was certainly worthy of speculation and the original paper used the word fusion with a question mark (Fusion?) which was later stripped off. Neutrons were confirmed multiply by later investigators (Menlove, Wolf, Gozzi, Scaramuzzi, many others) but at levels between 8 and 10 orders of magnitude down on expected hot fusion rates. So it is not "cold hot fusion" - but nobody serious ever believed that it was. This is a straw man argument used maliciously to discredit F&P and the field.

The only "faults" I lay at Martin's door are:

1) His implication that repeating the effect would be "easy".
2) His exaggerated faith in the talent of the average electrochemist and belief that a well trained physicist could somehow pick up this skill.
3) His belief that his mode of calorimetry would/should be easily understandable by all.

I am not sure what you mean by "Premature interpretations of experimental data". Without theory all our discussion is premature, but we have that right and so did Martin - particularly since he had done a number of experiments. I agree with Ed that the prematurity had a lot to do with the U of U *vs*. BYU rivalry. I do not agree, however, that anything Martin and Stan did or did not do could possibly have changed the reaction of the more vocal and hostile parts of the physics community. If we were to wipe away everything in the last 23 years except the specialized knowledge of those few of us who have done actual experiments or calculation, and then hire the "best" PR firm to help us release this discovery to the public, the outcome would be essentially the same today. It is simply too important.

LK:

1) I have no doubt that Fleischmann was one of the best electochemists in the world. This is confirmed by several formal recognitions he received.

2) Mike wrote "the original paper used the word fusion with a question mark (Fusion?) which was later stripped off. That does not convince me that M@F were originally not thinking in terms of the compound nuclei resulting from fusion of individual D ions. On the other hand, Fleischmann's paper at ICCF10 (last paragraph on page 1) does refer to "many-body effects." Hot fusion, on the other hand, is known to be a two-body reaction. In 2003 he disassociates himself with the incorrect interpretation, used by Huizenga, and other opponents.

3) What other old evidence do we have (beside the later-removed question mark) that F&P were already thinking about the "many-body effects" in 1989? I have no reason to think that what he said in 2003, about their thinking in 1989, was a lie. I am asking about an old document in which the term "many-body effects," or something similar, was used.

4) In their 1989 position I would be loudly emphasizing that the CMNS heat has nothing in common with simple two-body collisions of individual ions, if that were my way of thinking.

M4:

Not necessary. This was obvious - to everyone - even to me after I spent a few minutes thinking about it and

considering the conservation laws. A hideous misconception/misdirection lingers to this day because "fusion" means something very specific to one (tiny) group of people (but the very group whose territory was/is threatened) and something quite general to others. This misconception has been used cynically by some - and carelessly by others. I only speak up because it is time to stop feeding the trolls.

LK:

1) Rejections of experimental data on the basis of a disagreements with models developed to explain something else makes no sense. But it became very common since 1989. Unfortunately, Fleischmann did not ridicule this in 1989, as far as I know.

2) It would probably be useful to have a documented description of the "cold-fision-is-not hot fusion" idea, between 1989 and 2003, when Fleischmann used the term "many body effects." Was this term, or something equivalent used before 2003, either by F&P or anybody else. Please share what you know. I would be happy to write a web page (at my CF web site) on this important topic. Feel free to contribute anonymously, if you prefer. But be specific (proving references, dates and quotations).

4) Rejections of experimental data on the basis of a disagreements with models developed to explain something else makes no sense. But it became very common since 1989. Unfortunately, Fleischmann did not ridicule this in 1989, as far as I know.

5) It would probably be useful to have a documented description of the "cold-fision-is-not hot fusion" idea, between 1989 and 2003, when Fleischmann used the term "many body effects." Was this term, or something equivalent used before 2003, either by F&P or anyone else. Please share what you know. I would be happy to write a web page (at my CF web site) on this important topic. Feel free to contribute anonymously, if you prefer. But be specific, providing references, dates and quotations. Even old e-mail messages are worth sharing. I am addressing all of you, not only M4. Future generations will appreciate our desire to record the CF events correctly.

M5
I have been reading all the papers describing the field over the years and have reached a basic conclusion. Hot fusion and LENR are two entirely different processes having different mechanisms and NAE. A basic problem present early in the field's history, and even now, is that the detected radiation is not properly assigned to these two different processes, which can occur at the same time under some conditions. Jones used the conditions expected to produce hot fusion by fractofusion and detected neutrons having an energy typical of hot fusion. F-P tried and failed to detect neutrons as did dozens of efforts that followed. Neutrons are not produced by LENR and when they are, tritium appears to be produced as well. I will make a paper available soon that explains these conclusions very clearly. Meanwhile, you need to consider the possibility that people have been seeing two entirely different kinds of nuclear reactions, one related to hot fusion and the other related to LENR. To be clear, LENR involves fusion, but that is caused by a different mechanism.

M6:

Well stated M5! Trying to fit into your adversary's pidgeon hole was counterproductive.

LK:

On Apr 5, 2012, at 11:02 AM, M5 wrote: I have been reading all the papers describing the field over the years and have reached a basic conclusion. Hot fusion and LENR are two entirely different processes having different mechanisms and NAE.

THAT IS UNDENIABLE, CONSIDERING WHAT HAS BEEN REPORTED

A basic problem present early in the field's history, and even now, is that the detected radiation is not properly assigned to these two different processes, which can occur at the same time under some conditions.

I AGREE; THE EARLY HISTORY IS NOT CLEAR TO MANY. THAT IS WHY IT SHOULD BE BETTER DOCUMENTED.

1) M4 WROTE: THAT THE CF=HF "MISCONCEPTION HAS BEEN USED CYNICALLY BY SOME --AND CARELESSLY BY OTHERS." WHO WERE CYNICS AND WHAT EVIDENCE DO WE HAVE THAT THEY DELIBERATELY SPREAD THE CONFUSION? A REASONABLE SUSPICION BASED ON THE CONFLICT OF INTERESTS IS NOT SUFFICIENT.

2) ANOTHER PART OF OUR HISTORY, WORTH DOCUMENTING--I AM THINKING ABOUT ED'S NEXT ARTICLE--HAS TO DO WITH THE MULTI-BODY MECHANISM. WHAT ADDITIONAL EVIDENCE DO WE HAVE THAT FLEISCHMANN'S PATH TOWARD THE 1989 EXPERIMENTS WAS VIA THEORETICAL QED CONSIDERATIONS, AS HE CLAIMED IN 2003? WHEN DID HE FIRST SAY THAT CF IS A MULTI-BODY PROCESS AND NOT THE TWO-BODY PROCESS, SIMILAR TO HF?

3) MY EXAMINATION OF THE TWO DOE INVESTIGATIONS OF THE CMNS FIELD, IN:

(L. Kowalski, " Cold Fusion: Reality or Fiction," Progress in Physics, April 2012, L17-L19.

SEE ONLINE: http://www.ptep-online.com/index_files/2012/PP-29-L2.PDF)

CAN ALSO BE ENRICHED BY THOSE WHO WERE PERSONALLY INVOLVED. MY EMPHASIS WAS ON DISAGREEMENTS WITH THE SCIENTIFIC METHODOLOGY OF DEALING WITH CLAIMS. BUT I SUSPECT CYNICISM AS WELL, ESPECIALLY DURING THE SECOND INVESTIGATION, WHEN MORE EVIDENCE WAS AVAILABLE.

Jones used the conditions expected to produce hot fusion by fractofusion and detected neutrons having an energy typical of hot fusion. F-P tried and failed to detect neutrons as did dozens of efforts that followed. Neutrons are not produced by LENR and when they are, tritium appears to be produced as well. I will make a paper available soon that explains these conclusions very clearly. Meanwhile, you need to consider the possibility that people have been seeing two entirely different kinds of nuclear reactions, one related to hot fusion and the other related to LENR. To be clear, LENR involves fusion, but that is caused by a different mechanism.

THAT IS NOW CLEAR TO MOST OF US. BUT IT WAS NOT CLEAR TO ME IN 1989. F&P EMPHASIZED VERY HIGH PRESSURE OF IONS INSIDE PALLADIUM. THAT IS WHY I WAS THINKING ABOUT HIGH PRESSURE PLASMA (INSTEAD CONDENSED MATTER). [I DID NOT REALISE THAT THE TERM "PRESSURE" WAS USED METAPHORICALLY. THEY HAD IN MIND THE "EQUIVALENT PRESSURE," NEEDED TO REDUCE THE AVERAGE DISTANCE BETWEEN THE IONS TO ABOUT $1.5*10^{-8}$ CM. WERE I THE ONLY ONE TO BE CONFUSED BY THE TERM PRESSURE? IN ANY CASE, OUR EVOLUTION TOWARD THE IDEA OF MORE THAN TWO DIFFERENT MECHANISMS (VIA PUBLISHED PAPERS) IS ALSO WORTH DOCUMENTING.

M8

This quote from Fleischmann and Pons 1989 paper still seems insightful. I have added the bold. "It is known that at potentials negative to + 50 mV on the reversible hydrogen scale, the lattice is in the beta-phase, **hydrogen is in the form of protons** (as shown by the migration in an electric field) and is highly mobile (D = 10-7 cm2 s-1 for the ?-phase at 300 K). The overall reaction path of D2 evolution consists of steps (i) and (ii) [2] so that the chemical potential of dissolved D+ is normally determined by the relative rates of these two steps. The establishment of negative overpotentials on the outgoing interface of palladium membrane electrodes for hydrogen discharge at the ingoing interface [3] [determined by the balance of all the steps (i) to (iv)] demonstrates that the chemical potential can be raised to high values. Our own experiments with palladium diffusion tubes indicate that values as high as 0.8 eV can be achieved readily [4] (values as high as 2 eV may be achievable). The astronomical magnitude of this value can be appreciated readily: attempts to attain this level via the compression of **D2 [step (iv)] would require pressures in excess of 10E26 atm. In spite of this high compression, D2 is not formed; i.e. the s-character of the electron density around the nuclei is very low and the electrons form part of the band structure of the overall system.** A feature which is of special interest and which prompted the present investigation, is the very high H/D separation factor for absorbed hydrogen and deuterium (see Figs. 4 and 6 of ref. 2). This can be explained only if the H+ and D+ in the lattice behave as classical oscillators **(possibly as delocalised species) i.e. they must be in very shallow potential wells.** In view of the very high compression and mobility of the dissolved species there must therefore be a significant number of close collisions and one can pose the question: would nuclear fusion of D+ such as" Fleischmann, M., S. Pons, and M. Hawkins, Electrochemically induced nuclear fusion of deuterium. J. Electroanal. Chem., 1989. 261: p. 301 and errata in Vol. 263.

LK:

Thank you, M8; the link to the entire paper is:

http://www.lenr-canr.org/acrobat/Fleischmanelectroche.pdf

Note that reactions V and VI describe traditional thermonuclear collisions resulting in D+D fusion. Were F&P aware that inclusion of these two reactions (on the opening page of their first publication) was an open invitation for a very confusing situation--thinking that CF is like HF? I do not think that they were aware of this. The main source of confusion was their paper, in my opinion.

Abd ul-Rahman Lomax:

At 10:02 AM 4/5/2012, Edmund Storms wrote: I have been reading all the papers describing the field over the years and have reached a basic conclusion. Hot fusion and LENR are two entirely different processes having different mechanisms and NAE.

This is highly likely, as far as it goes. I'll point out that there is no particular reason to believe that there is only one LENR, and some good reasons to suspect that there is more than one. Trying to stuff PdD and NiH and biological transmutation results into the same small box may be a fool's errand.

We don't know yet how any of these work, and we have only hints, proto-theories, ideas. Few serious confirmations. Helium was predicted by Preparata. So that's one for Preparata. Helium is confirmed as the primary ash, there isn't any serious competitor. That was major progress, as Huizenga noted in 1993 or so. What do we have since then? Not a whole lot!

A basic problem present early in the field's history, and even now, is that the detected radiation is not properly assigned to these two different processes, which can occur at the same time under some conditions. I think this might not be clear. If we have cold fusion, releasing, say, 23.8 MeV/He-4 in some way, and even if the main reaction produces no detectable radiation, it might "leak" a bit. As a speculative example, suppose BECs in which Be-8 are created by fusion are the normal mechanism, and suppose that these ordinarily release their energy, relatively slowly, through a series of phonon emissions (I think that's more or less Hagelstein's idea, or similar to it, but I haven't studied it). What if something disturbs that BEC while it's doing its business? We might get some hot alphas, which can then cause secondary reactions, including hot fusion. Suppose the BEC bumps into a nucleus before decaying? We might

see some transmutations, Z+2. (The BEC is presumably neutral, so there is no Coulomb barrier.)

My point here is not the specific idea of a possible theory, but only that if fusion is happening, there could be some consequences resulting in hot fusion. Cold fusion can cause hot fusion, to some degree.

Jones used the conditions expected to produce hot fusion by fractofusion and detected neutrons having an energy typical of hot fusion. F-P tried and failed to detect neutrons as did dozens of efforts that followed. Neutrons are not produced by LENR and when they are, tritium appears to be produced as well.

I think this is correct, if we add the word "normally" before "not produced." If neutrons are produced, they are produced at levels below even that of tritium, which is produced at levels way, way below helium. Helium has been well-correlated with excess heat. Neutrons and tritium, largely not.

F-P did report low levels of neutrons, a famous error. Because of that error, they mentioned the hot fusion reactions in their initial paper. That confused the hell out of everyone. They did not help matters by posing their work as an answer to the question of whether or not classical fusion reactions could occur in the dense environment of PdD. So their comments, "It is evident that reactions (v) and (vi) are only a small part of the overall reaction scheme and that other nuclear processes must be involved," and "that reactions (v) and (vi) are only a small part of the overall reaction scheme and that the bulk of the energy release is due to an hitherto unknown nuclear process or processes (presumably again due to deuterons)," were largely ignored.

That was the error of Pons and Fleischmann. The error of the general physics community was in rejecting standing experimental evidence based on only theoretical arguments. It does appear that Pons and Fleischmann did their work as an attempt to confirm standing theory, based on approximations, that fusion could not occur even in an environment like PdD, so what was being rejected was experimental evidence from work designed to test the very theory that was used to reject it.

That was, indeed, a "scientific fiasco," transcending the mere errors of a few individuals.

I will make a paper available soon that explains these conclusions very clearly. Meanwhile, you need to consider the possibility that people have been seeing two entirely different kinds of nuclear reactions, one related to hot fusion and the other related to LENR. To be clear, LENR involves fusion, but that is caused by a different mechanism.

This is, by far, the most likely state of affairs. There is still some remote possibility that classical hot fusion is taking place in PdD, and that an entirely unanticipated mechanism is producing a different set of results. This requires the famous "triple miracle," though. I don't think so. While it's possible we have two miracles here, more likely there is just one. I.e., something that was not anticipated. It's extremely difficult to investigate the FPHE, in terms of trying to understand what's going on. It's hidden from our view, at least some of it. With plasma physics, it's all naked. I fully understand why physicists might not want to get their hands dirty with this!

An electrochemical cell is a true mess, the cathode attracts all kinds of gorp. The FPHE was erratic and would appear and disappear mysteriously, in the very same cell, under apparently the same conditions. However, physicists, from this, assumed that the effect must be near the noise. That was a failure to pay attention. It was not near the noise, it was far above it. Once you saw this fabulous beast, you became a believer. It wasn't a vague ghost spotted at night under poor conditions. But few exercised themselves to be able to see it. As soon as a few replication failures were reported, most gave up.

And we don't like to think that we failed at something. I'm learning to recognize that admission of failure is the key to progress, in fact.... Those who never fail aren't trying hard enough....

LK:

Thank you for the link, Abd ul-Rahman Lomax

http://en.wikiversity.org/wiki/Cold_fusion/Excess_heat_correlated_with_helium/Sources

I did not know that Huizenga commented on CF in the second edition of his book. Let me preserve what you reported and commented about.

“Huizenga, John R., [in his book] “Cold fusion, scientific fiasco of the century,” 2003, 2nd edition, [wrote]:

The invited paper by Miles, Bush, et al, made the most spectacular claim at the [1991] conference. It was reported that, The amount of helium (^{4}He) detected correlated approximately with the amount of excess heat and was within an order of magnitude of the theoretical estimate of helium production based upon fusion of deuterium to for ^{4}He.

This claim has been published elsewhere [cited, J. Electroanal. Chem] and I have commented on it previously (see p.136 and 212). If it were true that ^{4}He was produced from room-temperature fusion in amounts nearly commensurate with excess heat, one of the great puzzles of cold fusion would be solved! However, as is the case with so many cold fusion claims, this one is unsubstantiated and conflicts with other well-established experimental findings. [p. 243-244]

Old comment by Abd ul-Rahman Lomax: Huizenga's "well-established experimental findings" conflict, not with a finding of helium, but with the assumption that a heat/helium correlation must result from deuterium-deuterium fusion. Another, previously unknown, process that produces helium from deuterium would not conflict with those findings. Huizenga notes the "failure" of Miles to detect ^{3}He: --Abd 23:20, 26 September 2010 (UTC)

"hence, it is highly likely that the 4He is a contaminant from the atmosphere. In addition, if ^{4}He is produced in the amount claimed, it must be accompanied by large intensities (in fact lethal doses) of the associated 23.8 MeV gamma ray. Only when the 23.8 MeV gamma rays are observed on-line, can one be sure that the ^{4}He is produced by fusion and is not an experimental artifact. Finally, the 23.8 MeV gamma ray transfers essentially all the d+d -> ^{4}He + gamma reaction energy outside the cell and destroys the relationship between the helium production and the excess heat based on the assumption that all the reaction energy stays inside the cell. More recently, Miles, Bush et al reported that they can produce neither excess power nor ^{4}He from their electrolysis experiments.

... The editor of the Journal of Electroanalytical Chemistry thought the new claim was so exciting and so important that he accepted the author's manuscript without peer review. It is inconceivable that such an editorial decision could be made at this late date in the cold fusion saga. Due to the many ways that one can get spurious results on 4He in the gas phase, one would have expected the authors to have at least obtained confirmatory evidence that they had observed the 23.8 MeV gamma ray from the reaction D+D -> ^{4}He + gamma ray. This they did not do! Instead, the authors chose to repeat the mistake of most cold fusion proponents. After obtaining fragmentary evidence, the authors went to the press before performing the necessary checks and obtaining confirmatory experimental evidence. The validity of the Bush et al. claim requires three miracles: namely the fusion-rate, branching-ratio and concealed nuclear products miracles!

Present Comment by LK: This is a very good 1993 argument that the CMNS fusion, associated with production of helium, cannot possibly be the same reaction as the corresponding thermonuclear collision of two ions. If it were then the 23.8 MeV energy would not appear as heat released in the electrolytic cell. Huizenga used the argument to conclude that CF does not exist, rather than “cold fusion is not like hot fusion.” Why was this argument not used by F&P, in their first paper? When was it used for the first time and by whom?

M10

This is a good observation and question, Ludwik. Although many people may have realized that LENR was not the same as hot fusion, the question of the difference is a matter of degree. Many the theories focused on how much energy is required to cause hot fusion and on getting the deuterons closer together. No one acknowledged the need for a NAE, an idea that was rejected with great enthusiasm initially and to a lesser extent even now. People looked for neutrons and tritium, as would be expected to result from hot fusion. Failure to detected neutrons was explained by

failure to initiate LENR in the device being studied, not by realizing that no neutrons were produced by LENR. Even now, when a few neutrons are found, they are used to "explain" LENR. My opinion is that the realization that LENR is not related to hot fusion came gradually and is still not complete in some minds.

M11:

Julian Schwinger was a far better physicist than Huizenga. Julian was good. This, what I would call superficial debate (since, after all, only the experimental results are or were relevant at that time) was quite common at least for a few days, weeks or months after March 23. At that time I did not know what "must" or "must not" be true about nuclear processes. But I was completely comforted (to the point that I did not worry about it any more) by Schwinger's statement that concluded "the circumstances of cold fusion are not those of hot fusion". Huizenga's "must" [as quoted by LK] is a huge red flag. This is a political statement, not scientific. Huizenga claims omniscience?? He knows every possible way that 4He can be produced? It is the conservation of angular momentum that requires the energetic gamma ray from to isolated D's (which, by the way is not 23.8 MeV so even in detail he was wrong). What if 3, 4 or n bodies are involved? Huizenga's statement is worse than silly.....it is PR.

Abd ul-Rahman Lomax:

The confusion [cold fusion is like hot fusion] was easy, and might have happened anyway. That F&P paper was written quickly, and I doubt that the authors anticipated what ensued.

And no matter what mistakes they made, we don't depend on the character or flaws or mistakes of individuals in determining what is established in science.

Basically, they were brilliant, testing this wild idea, doing basic research. Then they enountered social forces beyond what they imagined. The University required them to announce, they clearly were not ready. We can look back and say that they did it wrong, they should have done this or that, but hindsight is always clearer than foresight.

What they found, if not for their diligent search, undertaken with their own energies, largely without support (for the first five years), might have escaped notice for a long time.

This was extremely difficult work -- that was one of the errors, making it look or sound easy. "Fusion in a jar." Right. It took the world's foremost electrochemist five years to pull this up to a rate of about 15% of cells showing excess heat, it took other electrochemists months of effort to start to see results, and a few scientists, with utterly inadequate information, tried for a few weeks, saw nothing, and started to claim that Pons and Fleischmann were frauds or idiots. And so it went.

It's really a shame that scientific politics inhibited research in this field for so long. It still has not recovered.

This "scientific fiasco of the twentieth century" (Huizenga's book title) carries some deep lessons about the hubris of scientists, where inadequately established conclusions become an orthodoxy, challenged only at personal risk. I met a skeptic who was afraid to let anyone know that he would even discuss cold fusion, he considered that he would suffer professionally.

I have a friend who is a mathematician, and when he found out that I was involved in CF research, he assumed I was being duped by con artists, and he proceeded to act to exclude me from an organization I'd helped to found -- since I was obviously dangerously crazy. The guy is actually brilliant. But absolutely certain that he's right, and unwilling to check out contrary evidence.

All he could see was Rossi (and worse, in his imagination).

M13:

Schwinger proposed H+D fusion would make He3. Unfortunately, this was not found. Instead, He4 was found with a

little tritium. This kept focus on the products from hot fusion. As for Huizenga, I agree with Mike, he was tying to eliminate CF for various reasons, as his book made clear. We once again have witnessed the ability of several leaders to create a myth in lesser minds for the purpose of promoting their self-interest. We see this happen all the time in politics, especially in the Republican debates. These leaders are not stupid. They knew that if CF were real, hot fusion and every other energy source would be at risk. They were able to stop the discovery process for awhile, which I'm sure they hoped would have been much longer. Now they have another problem not so easy to solve.

Abd ul-Rahman Lomax

... Look, my opinion is that cold fusion has been clumsily presented, even up to the present day. Look at the reviews of the field on that Wikiversitiy page you cited, and how they treat heat/helium. It's almost as if it is a footnote. And, in fact, much of the heat/helium evidence presented in the report by Hagelstein et al in 2004 to the DoE was in an appendix. It took me many readings of that appendix to understand what they were getting at. And I had to scour through other work to make heads or tails of it. I recognized very quickly that not all the necessary information was explicitly stated. The negative reviewer and the summarizing bureaucrat made an obvious -- and wrong -- assumption.

That was a result of ineffective communication. I'm suspecting that this comes from a habit of writing for scientific publication where the tone is very abstract and avoids bald assertion. Rather, the reader is supposed to figure it out. This requires very active, sympathetic readers. It's not a way to reach those who might be on the fence, not to mention hostile. Hagelstein et al are scientists, not writers of polemic. Nor would I want them to be anything other than what they are.

If there is another DoE review, the documents should be rigorously reviewed and read from a skeptical point of view, to discover what skeptical objections are possible, to anticipate them and answer them. Doing this without turning a document into a tome is not simple, it takes rare skill, and may take the work of more than one person. ...

Abd ul-Rahman Lomax:

Well, I suspect that Huizenga was, by that time, not thinking very clearly. He was making an obvious assumption, and appears not to have realized it.

I actually find the whole passage remarkable, because Huizenga does realize the import of Miles' work, to his credit. He didn't flap on about leakage, etc. He knew that correlation would cut through that noise.

A whole series of assumptions were made, each one being more or less reasonable or at least understandable. For example, multibody fusion is mentioned. At the time, it was not known that multibody fusion (hot fusion!) is greatly enhanced in PdD targets. I don't recall when Takahashi published that work, it might not have been available to Huizenga. The normal skeptical response to the idea of multibody fusion is that it would be rare upon rare, which follows from thinking in terms of collisions in a plasma.

People drew conclusions from what they were familiar with. Not surprising.

LK:

My recollection is that Pd targets, loaded with deuterium, were often bombarded with monoenergetic deuterons (in 1960s) to produce monoenergetic neutrons at varius angles via hot fusion. I was not aware of the “greatly enhanced” observations. That would indeed mean that cold fusion was discovered long before 1989. It is tempting to speculate about an accidental discovery of excess heat in a ready-to-use target. This would be like production of unexplained heat in radium, discovered by Pierre Curie.

M16:

Great enhancement only occurs when the bombarding D+ have low energy, where the neutron production rate is already very small. As a result, the term "great enhancement" has to be applied to a very small initial production rate.

No LENR is involved.

==========

Abd ul-Rahman Lomax:

At 11:32 AM 4/7/2012, Ludwik Kowalski wrote:
My recollection is that Pd targets, loaded with deuterium, were often bombarded with monoenergetic deuterons (in 1960s) to produce monoenergetic neutrons at varius angles via hot fusion. I was not aware of the “greatly enhanced” observations. That would indeed mean that cold fusion was discovered long before 1989.

I am not aware of such "greatly enhanced" results, and Ludwik may have misinterpreted what I wrote. I did not claim any observation reported before 1989, and, in fact, I was speculating that the multibody results were not available until after Huizenga wrote his statement.

I had a recollection that Takahashi's work on multibody fusion rates was fairly early, but what I could find at this point was this:

http://newenergytimes.com/v2/archives/fic/N/N199811.PDF page 5, a review of Takahahsi's 1998 publication in Fusion Technology.

In http://iccf9.global.tsinghua.edu.cn/LENR%20home%20page/acrobat/TakahashiAstudiesond.pdf, the earliest reference is to
A. Takahashi, et al: Fusion Technology, Vol.27 (1995) pp.71-85.

Since 1991, we have studied possible occurrence of highly enhanced multi-body deuteron fusion in metal-deuteride samples under low energy deuteron beam irradiation, based on our speculation that the order of atoms and electrons under transient motion around lattice focal points should greatly enhance the three-body fusion process, compared with random nuclear reactions.1-3
Our experimental results suggest that there exists strong screening effect on the Coulomb repulsive force of d-d interaction by transient “electronic quasi-particles”5, 6 and this greatly enhances 2D and 3D fusion reactions, and even 4D fusion reactions.

However, "multibody fusion" is mentioned in the title of a 1992 Paper by Takahashi, "Excess heat and nuclear products by D2O/Pd electrolysis and multibody fusion." From the Dieter Britz abstract of this paper:

The authors present their theory to explain the dearth of neutrons. At high
loadings, 3-body and 4-body fusions might take place, some producing no
neutrons or tritons, but alpha particles instead.}

Any review of the history of cold fusion theory should look at a paper I cited a few days ago:
http://lenr-canr.org/acrobat/ChechinVAcriticalre.pdf

Critical Review of Theoretical Models for Anomalous Effects (Cold Fusion) in Deuterated Metals
V.A. Chechin1, V.A.Tsarev1, M. Rabinowitz2, and Y.E. Kim3. Int. J. Theo. Phys., 1994. 33: p. 617.

4.5 Multibody Fusion
Four independent conjectures (Becker, 1989; Rabinowitz, 1990a; Kim, 1990c; and Takahashi, 1991) have been made suggesting the possibility of multibody fusion. Rabinowitz pointed out that although the probability for a three-body collision in free space is extremely smaller than a two-body collision -- in a solid, "Channeling increases the probability of a nearly one-dimensional collision, with essentially the absence of angular momentum in the final state. This may permit low energy resonances which greatly increase the fusion cross-section -- particularly for energy and

momentum conserving three-body collisions."

This "critical review" states, in the abstract,

we critically examine more than 25 theoretical models for CF, including unusual nuclear and exotic chemical hypotheses. We conclude that they do not explain the data.

and the last words of the paper's conclusion are:

It is an understatement to say that the theoretical situation is turbid. We conclude that the mechanism for anomalous effects in deuterated metals is still unknown. At present there is no single consistent theory that predicts or even explains CF and its specific features from first principles.

This situation appears to remain true. What theories we have that are plausible (the Chenin paper considers some of the theories they present as implausible), may explain this or that aspect of cold fusion, but no theory is complete, as published so far. However, given this, the Chechin paper is remarkably sanguine on multibody fusion:

There are two main consequences of this hypothesis. 1) In multibody fusion reactions, the released energy is carried by some particles that cannot escape the solid. So this energy heats up the lattice without the emission of visible nuclear products. 2). In reaction (46), energetic protons are released. In reactions (42,43,44, 46, and 48), energetic alphas (4He) are released which in turn can produce energetic n's and p's via the process 4He + d Ø 4He + p + n. This might explain the high energy components that have been seen (Chambers et al, 1990; Cecil et al, 1990; Takahashi et al,1990, 1992). Takahashi (1991) has suggested a number of multibody fusion scenarios in a solid to answer all the CF enigmas.

(Hindsight comment: it appears that energetic products at significant levels, with energies above 20 KeV, can be ruled out in the primary mechanism behind the FPHE, if Hagelstein's limit is valid. This, together with a *specific* predicted rate of fusion, remains the greatest difficulty remaining with multibody fusion theory, as far as I can tell.)

Critique: If one proceeds from habitual thinking drawn from conventional nuclear and plasma physics, the idea of multibody fusion appears wild to say the least. However, one has to take into account that the situation with CF is drastically different due to the presence in the solid of both periodically ordered positions for embedded d's and preferred directions for the motion of nuclei. This makes multibody collisions in principle more likely than in free space. However, no firm calculations have yet been presented which are testable. Quite independent of CF, interesting and unusual results have been obtained in channeling experiments of energetic particles in solids (Sorenson and Uggerhoj, 1987).

So "channeling effects" were known before 1989. Takahashi's experimental work as reported later shows, if his analysis is correct, an enhancement of 3D multibody fusion of 10^26 over naive expectation, if I've understood it correctly.

The reference: Sorenson, A.H. , and Uggerhoj, E. (1987). Nature 324, 311.

This does not mean that the deuteron bombardment that Takahashi used is relevant, in itself, to the mechanism behind cold fusion. Rather, the take-home point here is that condensed matter is experimentally known to be a different environment -- enormously different -- from a plasma, and that some reactions become possible or enhanced in condensed matter that are impossible, or ridiculously rare, in a plasma.

Huizenga would have been putting together the second edition of his book in 1993, and he reports 1993 publication by Miles. There was a flood of published work on cold fusion in 1989-1991; but Huizenga was writing a book on the topic that goes into great detail, when he wants to. In fact, certain details he repeats over and over. My own conclusion is that Huizenga wasn't really familiar with the work, he wasn't in "learning mode." He was just regurgitating his prior opinions. I notice that the only mention of Miles in this book was regarding the "most spectacular claim" presented at the Second Annual Conference. I.e., heat/helium.

Yet by the time Huizenga was writing his book -- even the first edition -- one might think he'd have known that Miles, whose preliminary negative results were shown in the 1899 ERAB report, later reported positive results, and even later, of course, reported the helium correlation that definitely got Huizenga's attention.

It is a common human practice to selectively observe evidence that confirms what we believe. We all need to recognize this, and guard against it. Huizenga interpreted the information coming to him, it's quite obvious, through his filters.

So, for example, Huizenga reports (2nd edition, page 243) in the same section on the Second Annual Conference,

[At the Conference] the substance of these claims was neither new nor different from that repeatedly proclaimed by believers over the past two years. ...The McKubre group of SRI reported excess heat of a few percent when integrated over the entire run. This was achieved in a closed isothermal flow calorimeter with high cathodic charging of deuterium (D/Pd > 0.9). The authors concluded that they cannot account for their excess heat by any chemical or mechanical process, and the inference is that the excess heat is due to a nuclear reaction. Although the McKubre experiment is considered by many advocates to be the premier evidence for excess heat, no nuclear reaction products were reported!

Right. There are no nuclear reaction products from the FPHE, at significant levels, except helium. At that point, McKubre et al had not, I think, investigated helium, but Huizenga, if he'd been thinking synthetically, would have known that helium was a possibility. But he wasn't. He was looking for reasons to confirm his own beliefs. *He was a believer.* (One of the characteristics of pseudoskepticism is to attribute comment and evidence from others, that might appear to contradict the pseudoskeptic's own beliefs, to "believers," and "proponents.") What Huizenga fails to do here is to credit the experimental competence of McKubre et al, who were, after all, consultants hired by the Electric Power Research Institute to investigate cold fusion. He doesn't really look at what they were reporting, he simply extracts from it sufficient "fact" to allow him to quickly dismiss it. Only a "few percent"? Why, piffle! That could easily be experimental error, some undiscovered artifact.

Not when you look at how the work was conducted. The FPHE suffers from a procedural problem. The input energy is necessary to build and maintain high deuterium loading in palladium. Most of it has nothing to do with the reaction itself. What is significant about, say, SRI P13/P14, is the difference between (1) the deuterium cell vs the hydrogen cell, in series with it, and (2) three different runs, with the same current excursion, yet the third run shows drastically different results, very significant excess heat, with *the same cathode* -- as it would appear. Obviously, something is different. And that difference represents the story of cold fusion, a story that Huizenga didn't tell. Instead, he gives us this:

As of March 29, 1993, the Droege experiments with high deuterium loading (D/Pd>0.9) continue to report null results. Tom Droege has reported that "the cleaner I get, the better I control the experiment, the more accurate I make the apparatus; the fewer bumps and anomalies I see."

Of course! Droege, very obviously, was not seeing the FPHE. The same as with the first two runs of P14 at SRI. Huizenga, note, by this time clearly gets that loading ratio might be important. If he was paying attention, he'd have known that FPHE work on a short time scale was very unlikeliy to see excess heat, so he'd have known that almost all the "negative replications" reported in his ERAB report were doomed to failure. So why wasn't Droege seeing results? It's quite apparent that loading is not a sufficient condition to see the effect, because P14 at SRI was also highly loaded, in all three excursions, but only showed the effect in one of them.

Remarkably -- and we should remember this -- Huizenga actually points out the problem. "No nuclear product." He knows that helium is a nuclear product, and his only problem there is that he expects the helium to be accompanied by a gamma. Did Droege ever look for helium? With no excess heat, we can be pretty sure that, if he had, he wouldn't have seen helium. On the other hand, McKubre did, later, look for helium, and found it, correlated with the heat, confirming Miles.

Huizenga, following Droege, here created a common pseudoskeptical trope: that when experimental technique was refined, excess heat results disappeared. Yet Droege had not ever reported XP, apparently. He simply found that noise that might have been interpreted as "maybe" excess heat disappeared. It was a unsubstantiated assumption that the negative replications were using more careful calorimetry than that of, say, McKubre et al.

But they may have been! It's actually irrelevant. More careful calorimetry is useless if you don't actually set up the effect!

No, this would have been a true negative report: a would-be replicator shows results the *same* as in the original report (or varying in the same range), and then improves the calorimetry and shows that the apparent results were from error -- or other artifact. Basically, to do replication, one should attempt to reproduce the *errors* of the original experiment. Basically, do it the same way, or don't claim that it's a replication, especially not a negative one. Don't "improve" your experiment first!

Back to Ludwik:
It is tempting to speculate about an accidental discovery of excess heat in a ready-to-use target. This would be like production of unexplained heat in radium, discovered by Pierre Curie.

It happened. Mizuno. He reports it in Nuclear Transmutation: The Reality of Cold Fusion (trans. Jed Rothwell, 1998), page 34. It's unfortunate that Mizuno did not report his observations at the time. My guess is that others saw cold fusion effects, as well.

August, 1978: Mysterious evaporation of heavy water electrolyte from an electrochemical cell using a three-cm palladium disk as a cathode, saturated with deuterium, used as a neutron target. "The 200 cc should have lasted a month [but evaporated in a day]... only two possibilities: the electric current might have increased, rapidly electrolyzing all of the liquid, or a large amount of heat might have caused the fluid to boil away. But at the time we could not imagine either of those scenarios, so we finally wrote off the incident as a mystery with no solution. We did not understand it until many years later."

May 1981: Loading titanium with deuterium, "... we activated an X-ray detector adjacent to the cell. It suddenly began to register continuous bursts of X-rays. In a panic, we checked our clothese and belongings for radioactive contamination. We moved the detector around to find the source of the X-rays. We finally concluded that the cell must be the source. But at the time we never imagined electrolysis could produce X-rays, so after careful consideration we decided it must be some kind of electrical interference. It turned out the cell really was generating X-rays, but I did not realize that until later."

(He goes on to note that the idea of fusion in electrolysis cells did occur to him as a possibility, later, "this kind of hypothesis would occur to any researcher studying metal and hydrogen systems." But..... "I never thought to pursue the matter and research the phenomenon further.")

FOLLOW-UP.

I decided to look to see if Droege ever found any excess heat. He seems to disappear from the cold fusion scene by about 1991. But he's mentioned by Richard Garwin in a review of Mallove's book on CF. There is this remarkable passage:

`Tom Droege, a superb engineer who has built state-of-the-art instrumentation for the particle physicists at Fermilab,

now ... perfects an extraordinary calorimeter," Mallove reports. Indeed, and in the process Droege has identified and overcome many problems that must have afflicted less cautious workers. At present, with electrolytic power input of some 1000 milliwatts his sensitivity is about 1 milliwatt, with no dear indication of net excess heat. Those who claim to know how to treat their cathodes to obtain excess heat would do well to adopt Droege's apparatus.

He's really doing quite the same as Huizenga, assuming that negative work is more accurate than positive. As to cold fusion results that are close to the noise, sure. Some CF reports may be flawed and a result of errors in calorimetry. However, Garwin goes on:

if anyone can show me a history and demonstration of strong, reproducible, emission of neutrons, tritium, or heat in a cold (or dry) fusion cell, I will not only urge support but repeat the experiment.

Liar, liar, pants on fire. Of course, he adds a qualifying word, "strong." From the point of view of science, though, "strong" means that a signal is clearly above noise. This was written in 1999. Garwin surely knows by this time that FPHE cold fusion doesn't produce significant neutrons or tritium, just helium. Surely Garwin would have recognized the significance of helium, as did Huizenga, and by this time, Miles' helium results had been confirmed.

As to any sensible intepretation of Garwin's promise, heat that is produced in a specific ratio to helium detected is "reproducible." You could run this blind: detect helium and continue running the cell until helium generated reaches a certain value. How much excess heat has been generated? That is the reproducible demonstration of heat. Some cells don't work, and..... so what? No heat, no helium, that actually confirms the calorimetry and helium measurement techniques, if the cells are otherwise identical.

What was "reproducible" was the heat/helium ratio. Heat, by itself, remained not reproducible under most conditions. Indeed, I'm interested in the work with dual laser stimulation because it appears that those results are reliable. That would be, I speculate, because the cell is being run below normal CF loading levels, and the reaction only takes place under the influence of the stimulation. It's controlled.

(We can also make a weaker argument for reproducibility with certain designs; for example, Miles' cells seem to have roughly a two-thirds rate of showing excess power. Reproducibility can be statistical.)

And I'll add: the effects and results of dual laser stimulation have not been confirmed. My impression of reliability is only based on what Letts is reporting.

405) AmoTerra Process:

Destruction of Low Level Radioactive Waste?

Ludwik Kowalski; 5/6/2012

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Nine years ago in Unit #186 click I wrote: "According to (2), a Canadian company is about ready to start destroying radioactive waste on an industrial scale. [Mrs. Anderson] said that the apparatus built for the company is able to destroy 50% of radium, whose half-life is known to be 1620 years, in only 3 days. It also changes thorium into lead. ... They plan to move to highly radioactive waste later. I said that I would like to come and observe the pyrolytic device in operation. They said that they would invite me, probably in several weeks. I hope this will happen; I would be happy to write a unit on the first industrial application of what is, according to Monti, a cold fusion transmutation process. Will they allow me to make some measurements? This remains to be seen." On 4/2/2012 I received the email message from Mrs. Anderson; she wrote:

"Dear Ludwik: A long time has passed since you last heard from us and much has happened. With a heavy heart, I am informing you that Ernst, my husband of nearly twenty years, passed over on November 28, 2011. It was totally unexpected and an enormous shock. However, I am proceeding on with our project." Responding to my short reply she informed me that the name of the company is now called AmoTerra, and that Roberto Monti is no longer part of it.

We started corresponding and I had a chance to familiarize myself with their ATM process. Here is a brief discription of it, based on what I read in materials sent to me by Eleonora. They begin with several grams of thorium, in the form of an oxide (ash from burning commercially available lantern mantles). They mix this original material with nearly 2 kg of proprietary combustibles and burn the mixture in a stainless furnace, for about 2 minutes, at the temperature of about 1000 C.

They claim that approximately 50% of thorium (plus or minus 20%, depending on conditions) is transmuted into non-radioactive isotopes, or into isotopes which decay much more rapidly than thorium (within days). The equipment used is commercially available, except the secret combustible mixed with the initial radioactive material. They used three approaches to validate the thorium destruction claim: gamma ray spectroscopy, mass spectroscopy, and nuclear activation analysis.

Suppose I accidentally discovered that placing powdered thorium into milk, for ten minutes, destroys a large fraction of that radiactive metal. What would I do to convince myselve, and others, that my claim is valid? I would also begin with gamma ray spectroscopy. The amount of thorium can be determined from its speciphic activity, A, that is from knowing how many atoms decay in each second in each gram of ^{232}Th. That well known number, calculated from the half-life (14 billin years), is 3940. It does not depend on the kind of structure in which the element is found: solid metal, thorium oxide, thoriom salt, thorium solution, etc.

Suppose one gram of thorium is placed at a distance of 20 cm from a gamma ray detector and that the number of counts recorded per second is M=1000. That allows us to calculate the coefficient of proportionality, k, between the

activity A and the measured counting rate, M. Knowing that

A=k*M

I would be able to say that k=3940/1000 = 3.94. The value of k depends on the size of the detector, and on its distance from the source. These two parameters--the detector and its distance from the source--must thus be kept constant when the amount of thorium is determined by measuring the counting rate, M.

Suppose the original counting rate, from a sample of thorium oxide, is M1=4000 per second. That means that the original activity is A1=3.94*4000 = 15760 per second. The corresponding mass of thorium is 15760/3940 = 4 grams. Suppose the final counting rate (after the sample was processed) is M2=2000 per second. The corresponding mass of thorium (calculated in the same way) is 2 grams. Could I conclude that the processing destroyed 50% of the original thorium? Yes I could, but not before convincing myself (and others) that no thorium was lost via escaping into the atmosphers, or remained in the apparatus. Loosing thorium in that way would have nothing to do with my claim--the destruction of thorium atoms.

Showing that nothing was lost would call for additional control experiments. This part of the procedure would probably be very demanding. Several independent confirmations of the "no hidden losses" would be necessary, considering the extraordinary nature of the claim--transmutation of thorium into another element, or elements.

The same approach would be used in the case of the activation analysis. The only difference would be that M1 and M2 would refer of counting rates due to radioactivity induced by neutrons, rather than to radioactivity of thorium.

In the case of the mass spectromerty, on the other hand, the M1 and M2 could refer, for example, to measured heights of the ^{232}Th peak in the mass spectra, before and after processing. The most difficult part of the procedure--showing that nothing was lost--does not depend on which approach is used.

Added on 5/8/2012

Using my numerical illustration (4 grams of Th-232 initially and 2 grams finally) let me imagine the worse possible scenario. Suppose that these 2 grams of thorium are lost rather than transmuted. Even in this case the lost activity is only:

2*3940=7880 decays per second

Suppose that all this is uniformly distributed over the area of 100 square meters (10^6 cm^2). This is the floor of a small classroom or of a large living room. The activity per unit surface would be:

7880 / 1,000,000=0.008 decays/cm^2 per second (or 28 decays/cm^2 per hour.)

Monitoring this kind of contamination would not be easy. To demonstrate the "nothing is lost" I would use radium instead of thorium. ^{226}Ra decays about 8.6 million times fastes than ^{232}Th. Suppose two grams of radium (rather than thorium) is uniformly distributed over the area of 100 square meters. In that case the activity of each square centimeter would be 6.8 million decays per second. That would be much easier to measure than 7880 decays per second.

Needless to say, experimenting with grams of ^{226}Ra, ^{60}Co, or ^{241}Am, even if these materials were availabe, and if using them were legal, would be fulish. A tiny fraction of one gram would be sufficient to conduct a "nothing-was-lost" test. Furthermore, such tests can also be condicted with non-radioactive isotopes, such as ^{36}S, whose natural abundace is only 0.02% . This is only a speculation; I do not know how practical this would be. The ^{37}S, produced from this stable isotope via neutron bombardment, is beta and gamma radioactive.

As one can see, I am assuming that a potentially-possible loss via escaping would depend on how the AmoTerra

equipment is designed and not on what element is being transmutted. This is not at all obvious.

Review Article

Biological Transmutations: Historical Perspective

Jean-Paul Biberian *

Aix-Marseille University, 13288 Marseille, France

Abstract

In this review paper, it is shown that in biological systems, chemical elements can be transmuted into other elements. These facts have been established since the early 19th century, but they have been ignored by established science ever since. The purpose of this work is to show how during the past two centuries, a number of experimentalists have questioned the mass conservation law established by Antoine Lavoisier [1] for chemical reactions. They have proved experimentally in plants, bacteria and other living organisms, some elements are transmuted into other elements.
 ISSN 2227-3123

Keywords: Biological transmutations, Cold fusion, History, LENR

1. Introduction

The discovery of Cold Fusion in 1989 by Stan Pons and Martin Fleischmann [2] has triggered new attention in the field of biological transmutations. Even though experiments have shown that transmutations of elements occur in living cells, this field has been totally ignored by the scientific community. The situation is not different now, but recently new experiments, in particular, by Vysotskii and Kornilova [3] have brought new results using modern analytical techniques.

It is interesting to recall the situation of chemistry before Lavoisier, which was the time of alchemy, when the modern scientific method had not yet been developed. Also the nature of the elements had not been clearly identified.

Most of the works come directly from Herzelee's experiments. They triggered the experiments made by Baranger, Kervran, Goldfein, Holleman and then Vysotskii. Many experimental results described in this paper are not of a good quality because they have been performed in the 19th century or in the early 20th century, and the full data are not easily available. Some are coming from a secondary source, and therefore are less reliable. However, if we consider the totality of these data, including the most modern ones, there is compelling evidence that biological transmutations are a real scientific fact.

Very few theoreticians have tried to understand the possible mechanisms involved in these kinds of reactions, and it is more likely to take a long time before a reliable theory can be developed. One of the reasons is the lack of useful data where all elements before and after are well known to the scientists.

In this review, I also recall some of the works that I have performed myself [4] with germinating seeds and bacteria.

 ISSN 2227-3123

2. Before Lavoisier

2.1. Jan Baptist von Helmont (1579–1644)

The work by von Helmont [5] in the 17th century is probably the first experiment that tried to study the workings of plants. He wanted to prove that the alchemical theory of the four elements was incorrect. He grew a willow tree in a clay vessel with 90 kg of dried soil. He covered the vessel with an iron cover having small holes. In his report, he explained that he did not take into account either falling leaves or dust. For 5 years, he watered the plant with filtered rainwater or if necessary with distilled water. He observed that the tree had gained 76 kg, whereas after drying the soil had only lost 57 g. He concluded: "Water alone had, therefore, been sufficient to produce 76 kg of wood, bark and roots". Von Helmont proved that the elements of water and earth were not elementary, since water had changed into wood, bark and roots. This experiment proved that the elements of water could change into elements of soil.

3. Antoine Lavoisier (1743–1794)

In 1789, the famous French scientist Antoine Lavoisier [1] performed very accurate experiments showing conservation of mass during chemical reactions. He wrote:

> *" We can state as an indisputable axiom that under all conditions, artificial or natural, nothing is created; an equal quantity of matter exists before and after the experiment and nothing occurs outside the changes and modifications in the combinations of the elements".*

Unfortunately, for him and science, he was beheaded because of his function as "fermier général", i.e. an unpopular tax collector of the old regime. It is also interesting to note his inventions of an accurate ice calorimeter to measure the heat of respiration of a guinea pig, proving that breathing is actually a combustion process.

Landolt [6] has confirmed the mass conservation during chemical reactions with better accuracy in 1908 with an accuracy of one part in 10^6, and later in 1913 by Manly [7] with one part in 10^8.

4. During the 19th Century

4.1. Johann Christian Carl Schrader (1762–1826)

From 1795 to1797, the Berlin Academy of Science announced a competition with the following aim:

> *" Of which types of the earthly materials, which are encountered by means of chemical analysis, of native grain species? Do they either come into the grains as they are found or come into being by means of the life force and brought into growth by the workings of the plant?"*

In 1799, the German scientist Schrader [8] won the competition for his experiments on the formation of minerals in grains. He used the seeds of wheat, barley and rye, amongst others, to germinate in an artificial medium of flowers of sulphur (amorphous sulfur in fine powder) (that was shown to be completely ash free) and watered with distilled water. The dust contamination was prevented during the experiments. From the analyses of the developed seedlings, he compared with the seeds which are planted, he concluded that the mineral matter had indeed been created.

4.2. Henri Braconnot (1780–1855)

In 1807, the highly reputable French scientist Henri Braconnot [9] reproduced Schrader's experiments. He allowed plants from seed to grow on different artificial media (flowers of sulphur, red lead oxide, granulated lead, pure river sand and even an organic product; decomposed wood that was extracted using hot water). He concluded that considerable formation of the mineral components, especially potassium in experiments with mustard seed and radish, had taken place.

4.3. Louis Nicolas Vauquelin (1763–1814)

In 1799, the French chemist Louis Vauquelin [10] became intrigued by the quantity of lime which hens excrete every day. He isolated a hen and feed it a pound of oats, which were analyzed for lime (CaO). Vauquelin analyzed the eggs and faeces and found that five times more calcium was excreted than was consumed. He observed, not only the increase of calcium but also a subsequent decrease of silicon. He is certainly the first scientist to have demonstrated the biological transmutation of silicon into calcium.

In his conclusion he remarked that a loss of only 1.274 g of silica cannot account for an increase of 14.118 g of limestone. He concluded that lime had been formed, but could not figure out how it happened. Further more, he encouraged other scientists to replicate his experiment.

4.4. Albrecht Thaer (1752–1828)

In the 18th century organic reactions are attributed to a "life force". Thaer [11] showed that under some circumstances, calcium transforms into silicon. According to him, silicon could come from potassium. Under certain circumstances calcium in the plant became changed into silicon, whilst this substance may itself be formed from potassium

4.5. William Prout (1785–1850)

In 1822, the English physiologist, Prout [12] studied chicken eggs in incubation. He found that hatched chicks had more lime (calcium) in their bodies than originally present in the egg, and it was not contributed from the shell.

4.6. Wilhelm Augustus Lampadius (1772–1842)

In 1832, Lampadius [13] thought that plants themselves create silicon in plants.

4.7. Vogel

In 1844, a German researcher named Vogel planted watercress seeds (Lepidum satirum) in a bell jar in crushed glass in a controlled air environment. They were fed nothing but distilled water, yet when grown they contained more sulphur than had been in the seeds originally. J.J. Berzelius reported the experiment in his book [14]. Vogel's answer was that sulphur was not a simple element or that sulphur was introduced from sources unknown.

4.8. Choubard

In 1831, Choubard [15] germinated watercress seeds in clean glass vessels and showed that the sprouts contained minerals, which did not previously exist in the seeds.

4.9. John Bennet Lawes (1814–1900) and Joseph Henry Gilbert (1817–1901)

In 1856–1873, two British researchers, Lawes and Gilbert observed an inexplicable variation in the amount of magnesium in the ashes of plants. They could "extract" more elements from the soil than the soil actually contained in the first place, in particular the formation of magnesium in grass.

4.10. Albrecht Von Herzeele(1821–?)

In 1876 Herzeele [16], a German pharmacist published a series of books in which he showed research proving that plants continuously create material elements. From 1875 to 1883, in Berlin, he conducted 500 analyses with different types of seeds. He worked with: clover, crimson, vetch, rapeseed, barley, watercress, bean, white beans, kidney beans, turnips, rye, peas lupine, coltsfoot and angelica. A typical experiment showed the variation of calcium, potassium and phosphorus in Vicia sativa during germination with or without addition of mineral salts in distilled water.Also he showed that the addition of various calcium salts to the medium increased the formation of potassium. The addition of K_2CO_3, increased the formation of calcium.

He concluded that "Plants are capable of affecting the transmutation of elements". His publications outraged so much the scientific community of the time that they were removed from libraries. His writings were lost for more than 50 years until about ca.1930 when a collection was found by accident in Berlin by Dr. Hauschka, who subsequently published Von Herzeele's findings (the philosopher W.H. Preuss had dedicated an article to him; Preuss defended the idea that inorganic nature was a product of the organic; Herzeele was in agreement, apparently inspired by Goethe).

5. During the 20th Century

5.1. Freudler

Freudler was a Professor at the famous French University, La Sorbonne. In 1928, he published a book based on his 10 years of research on the production of iodine by algae. He noticed a connection between tin and granite in which the algae produced and iodine in the plants.

5.2. Earle Augustus Spessard

In 1940, Spessard [17] performed an experiment in which an organic process was studied in a hermetically sealed container. The bottles were weighed after some years. At the end, living protozoa were still seen through the glass walls. Presumably plant assimilation and animal respiration followed each other more or less in balance. There was a weight *increase* of a few tenths of a milligram (with a balance accuracy of 0.02 mg). Sources of errors, so far as they were known, were carefully eliminated. The predicted continuation of this work did not appear. The increase in weight that was found was far too big to be considered as a "materialization" of the received light rays.

5.3. Rudolph Steiner (1861–1925)

Rudolph Steiner [18] in 1924 gave a series of lectures giving indications for the development of a new approach to agriculture that later became known as biodynamics. In the 5th series of his lectures, he referred to composting, he stated "even according to the purely external standards of analytical chemistry, this ought to betray the fact that there is a kinship between the way in which oxygen and nitrogen are connected in the air and that in which lime and hydrogen are connected in organic processes. Under the influence of hydrogen, lime and potash are constantly being changed into nitrogenous matter, and finally into actual nitrogen. And the nitrogen, which has come into being in this way, has a

tremendous value for plant growth. Silicic acid, as we know, contains silicon and this in turn undergoes transmutation in the living organism. It is changed into a substance which is of exceptional importance but which is not reckoned by present-day science to be among the elements."

5.4. Henri Spindler

In 1946–1947, the French Scientist and Director of the Laboratoire Maritime de Dinard, Spindler [19] discovered Herzeele's work on the decrease of phosphorus and increase of calcium. In 1959, he measured an increase of iodine by 30% in algae, Laminaria flexicaulis and 80–100% in Laminaria sacharina.

5.5. Rudolf Hauschka (1891–1969)

An Austrian chemist, Hauschka [20] during the years 1934–1940, in sealed glass containers, weighed cress seeds, and found an increase in weight of 0.54% during the full moon, and a decrease of 0.58% during the new moon. He published several books in which he re-evaluated Herzelee's work, which he included as appendix in his books, *Substanzlehre* (though it has not been included in the English translation, *The Nature of Substances*).

5.6. Perrault

French scientist Perrault [21], from the Paris University, found that the hormone aldosterone provoked a transmutation of Na to K, which could be fatal to a patient.

5.7. Julien

Julien [22] was a French Scientist, from the Besançon University. In 1959, he proved that if tench are put in water containing 14% NaCl, their production of KCl increased by 36% within 4 h.

5.8. George 0shawa (1893–1966)

Oshawa [23] was a Japanese scientist, and an inventor of macrobiotics. He collaborated with Louis Kervran. His opinion was that transmutation occurs during mastication.

5.9. Pierre Baranger (1900–1970)

Pierre Baranger was a French Scientist, a professor of organic chemistry at the famous Ecole Polytechnique, and head of the Laboratory of Chemical Biology. He became intrigued with Herzeele's experiments, but he thought that the number of trials had been too limited and the precautions against error were insufficient. Baranger decided to repeat the experiments with all possible precautions and a very large number of cases, which would allow a statistical study. His research project from 1950 to 1970 involved thousands of analyses. Baranger verified the content of phosphorus, potassium, calcium and iron of vetch seeds before and after germination in twice-distilled water to which pure calcium chloride was not added. Hundreds of samples of 7–10 g each were selected, weighed to 1/100th milligram, and graded, then germinated in a controlled environment.

Baranger found an increase of 4.2% in calcium, and 8.3% of iron, and subsequently a decrease in phosphorus of 1.9%, and of potassium of 1.1%. Interestingly, an addition of $MnCl_2$ increases the amount of iron produced.

None of the specialists who examined Baranger's work were able to find any experimental errors. Baranger concluded:

"These results, obtained by taking all possible precautions, confirm the general conclusions proposed by Von Herzeele and lead one to think that under certain conditions the plants are capable of forming elements, which did not exist before in the external environment".

In May 1959, he submitted an article for publication in the French Academy of Sciences, but was not accepted. Later in 1972, his family tried another submission without success. He had difficulties in publishing his findings, and died without being able to do so. Later, in 1977, his family asked Jean Marie Gatheron, a close friend of Baranger to publish Baranger's work [24]. In 1976, his family submitted the final report of Baranger to the Academic Commission of the French Academy of Agriculture. It was decided that the work would be presented to the full assembly in a secret meeting. The proposal of publication in a public meeting was rejected without any reason.

Baranger failed to provide relevant theory to explain his findings.

5.10. Leendert Willem Jacob Holleman (1906–1994)

From 1975 to 1989 Holleman [25], a Deutch scientist, performed experiments with alga Chlorella. He observed a decrease, then subsequent increase, of potassium. However, in spite of several attempts, he could not reproduce his own first positive experiments.

5.11. Correntin Louis Kervran (1901–1983)

Kervran is certainly the most well-known scientist having worked in the field of biological transmutations. He had a broad knowledge of plants, geology and nuclear science. His findings have been published in French in ten books [26], some of them have been translated into English [27]. He was also nominated for the Nobel Prize.

Observations

From 1935 Kervran [28] collected facts and performed experiments, which showed that transmutations of chemical elements do indeed occur in living organisms. It started when he investigated fatal accidents from carbon monoxide poisoning when none was detectable in the air. Next he analysed why Sahara oilfield workers excreted a daily average of 320 mg more calcium than they ingested without decalcification occurring.

Kervran pointed out that the ground in Brittany contained no calcium; however, every day a hen would lay a perfectly normal egg, with a perfectly normal shell containing calcium. The hens eagerly pecked mica from the soil, and mica contains potassium. It appears that the hens may transmute some of the potassium into calcium.

Experiments with seeds

From 1960 to 1980, Kervran reported the astounding results of his research showing that living plants were able to accomplish limited transmutation of elements. Then Kervran was the Conferences Director of the University of Paris, and his first paper was published in La Revue Générale Des Sciences, July 1960.

Kervran found that in nuclido-biological reactions, oxygen is always in the form of O, never O_2; reactions with nitrogen occur only with N_2, insofar as is known. The following reactions have been proposed:

$Na^{23} + H^{1} \rightarrow Mg^{24}$ $Na^{23} + O^{16} \rightarrow K^{39}$ $Na^{23} - O^{16} \rightarrow Li^{7}$

$Na^{23} \rightarrow Li^{7} + O^{16}$ $K^{39} + H^{1} \rightarrow Ca^{40}$ $Mg^{24} + Li^{7} \rightarrow P^{31}$

$Mg^{24} + O^{16} \rightarrow Ca^{40}$ $F^{19} + O^{16} \rightarrow Cl^{35}$ $C^{12} + Li^{7} \rightarrow F^{19}$

$Cl^{35} \rightarrow C^{12} + Na^{23}$ $Fe^{56} - H^{1} \rightarrow Mn^{55}$ $2\ O^{16} - H^{1} \rightarrow P^{31}$

$O^{16} + O^{16} \rightarrow S^{32}$ $2\ N^{14} \rightarrow C^{12} + O^{16}$ $N^{14} + Mg^{12} \rightarrow K^{19}$

$Si^{28} + C^{12} \rightarrow Ca^{40}$ $Si^{28} + C^{12} \rightarrow Ca^{40}$ $P^{31} + H^{1} \rightarrow S^{32}$

In 1980, Kevran [29] performed an experiment with oat seeds analysed using mass spectroscopy. They looked at phosphorus and calcium variations. They observed the following:

	Phosphorus (mg)	Calcium (mg)
Seeds	485	76
Plants	310	115.5
Difference (mg)	–175	+39.5

It is clear that the calcium increased with germination, whereas phosphorus decreased. There are certainly other elements that played a role, but they were not analysed in this experiment.

The French Society of Agriculture

In 1971, the laboratory of the French Society of Agriculture sprouted rye seeds under controlled conditions.

	Seeds	Sprouts	Difference (mg)	Difference (%)
Mg (mg)	13.34	3.20	–10.14	–335%
K (mg)	7.36	16.67	+9.31	+133%

These results are in good agreement with Kervran's previous findings.

Kervran was very active in promoting his work through books, conferences and mass medias. However, the Academy of Agriculture strongly opposed his efforts. In October 7, 1970, Stéphane Henin on one side and Léon Guéguen and Allez on the other side sent reports to the Academy by criticizing Kervran's results [30].

5.12. J.E. Zündel

Zündel [31] was a Swiss scientist, head of a paper company, and a chemical engineer at the Polytechnic School of Zurich (ETH Zurich) in Switzerland. Following Kervran's observations from 1970, he studied germinating seeds and observed a 54–616% increase of calcium. In another experiment, he grew 150 oats seeds (flämingkrone) in a controlled environment for 6 weeks. 1243 sprouts were analysed using atomic absorption spectroscopy for the presence of magnesium and calcium. The potassium decreased by 0.033%, the calcium increased by 0.032%, and magnesium decreased by 0.007%. The variation of magnesium was not significant, but the decrease in potassium balanced the increase of calcium. In 1972 with oat seeds, he observed an increase of calcium of 118%, a decrease of magnesium of 23%, and potassium 29%.

In 1971, he gave a lecture at the French Academy of Agriculture (Bull No. 4, 1972). In his lecture, he announced the following variations between seeds and sprouts:

	SiO_2	Ca	Mg	K
Seeds	111 mg	28 mg	27 mg	108 mg
Sprouts	123 mg	116 mg	27 mg	70 mg
	+10%	+314%	0%	–35%

In spite of the excellent quality of his works, the audience criticized him, including S. Henin, the head of the Department of Agronomy.

Later in 1979, Zündel, using a mass spectrometer at the the Microanalysis Laboratory of the French National Scientific Research Center, and neutron activation analysis at the Swiss Institute for Nuclear Research in Villigen (Aargau), confirmed the increase of calcium by 61%. There was also an increase of 29% in phosphorus and 36% in sulphur) [32].

However, the French Atomic Energy Commission has analysed Zündel's experiments in 1975 by neutron activation analysis of oat seeds. They found no change in calcium, sodium and manganese, but only a small decrease of potassium, also no isotopic variation in Ca^{48} and K^{41}.

5.13. Hisatoki Komaki

Following Kervran's work in 1970–1980, Komaki [33] from the Biological and Agricultural Research Institute studied the development of bacteria, mould and yeast. Among those: *Aspergillus niger*, *Penicillum chrysogenum*, *Rhizopus nigricans*, *Mucor rouxii*, *Saccharomyces cerevisiae*, *Torulopsis utilis*, *Saccharomyces ellipsoideus* and *Hansenula anomala*. Komaki reported that eight strains of microorganisms grown in potassium deficient culture media increased the total of potassium by transmutation of calcium to potassium. He also showed that phosphorus can be formed by the fusion of nitrogen and oxygen: $N + O \rightarrow P$. He even marketed a brewer's yeast product that, when applied to composts, increases their potassium content.

6. Present Times

6.1. Panos *T. Pappas*

In 1998, Pappas [34] published an article suggesting that biological transmutation occurs as a form of cold fusion in the cellular membrane sodium–potassium pump. According to Pappas, the ions are not pumped back and forth through the membrane, but instead transmute back and forth between Na and K.

6.2. Jean-Paul Biberian

Experiments were performed with seeds: wheat and oats as well as bacteria: Marine bacteria (Marinobacter sp strain CAB) and Lactobacilius [4]. In most of the experiments, variations in the concentration of minerals have been observed. In particular, it is interesting to note that when the seeds grew, heavy metals decrease in large amounts. Even though these results are only preliminary, they confirm the observations made by others, in particular Kervran.

6.3. Vladimir Vysotskii

Vysotskii is a scientist from Ukraine. He started working on biological transmutations in the 1990s. He is well known for using modern analytical techniques. In particular, he used Mossbauer spectroscopy, very sensitive to Fe^{57}, to measure its production. In natural iron, Fe^{57} represents only 2.2% of the total. The main isotope of iron is Fe^{56}, which represents 91.7%. Measuring Fe^{57} is also very easy by mass spectroscopy, since there is no possible interference with another element. The proposed transmutation is

$$Mn^{55} + D^2 \rightarrow Fe^{57}.$$

The experiments conducted by Vysotskii and Kornilova [3] were performed with bacteria capable of developing in heavy water. They chose *Bacillus subtilis*, *Escherichia coli* and *Deinococcus radiodurans*, as well as a yeast culture *Saccharomyces cerevisiae*. When manganese was introduced with $MnSO_4$, a clear spectrum was measured, indicating that manganese had been transmuted into iron. The authors analysed the material by time-of-flight mass spectroscopy showing that the mass 57 peak was as large as that of mass 56. This is another confirmation of the production of Fe^{57}. Vysotskii and Kornilova have also analysed another reaction

$$Na^{23} + P^{31} \rightarrow Fe^{54}.$$

In natural iron, Fe^{54} represents only 5.8%. The bacteria developed in a medium without iron, and after development they measured Fe^{54} as large as Fe^{56}.

In similar experiments they observed the following reaction

$$Cs^{133} + H^1 \rightarrow Ba^{134}.$$

In experiments destined to reducing radioactivity, they conducted experiments with synthetic microbiological cultures, which were up to 20 times more effective than the standard microbiological cultures. It was shown that Ba^{140}, which is radioactive with a half-life of 12 days, transforms into Sm^{152}, which is stable with the possible following reaction:

$$Ba^{140} + C^{12} \rightarrow Sm^{152}.$$

Interestingly, Cs^{137}, which is radioactive with a half-lifetime of 30 years, transmutes into Ba^{138}, which has a much shorter lifetime of 310 days.

$$Cs^{137} + H^1 \rightarrow Ba^{138}.$$

This work is certainly the best proof of biological transmutations.

6.4. Edwin Engel, Rudolf Gruber

In 2006, Engel and Gruber [35] from Germany wished to confirm Kervran and Baranger's works. They showed that during germination, manganese transmutes into iron. They used mung beans sprouted in $MnCl_2$. They showed an increase of iron. They assumed the following reaction

$$Mn^{55} + H^1 \rightarrow Fe^{56}.$$

7. Negative Experiments

Even though many positive experiments have been performed by indicating the reality of the phenomenon of biological transmutations, several experiments contradict these findings.

7.1. Nicolas Théodore de Saussure (1767–1845)

In 1804, de Saussure published his work: "Recherches chimiques sur la végétation", Nyon, Paris (Chemical Researches on Végétation). As a follower of Lavoisier, Saussure stood strongly with the standpoint of the conservation of matter and referred all transmutations and creation to the realm of fables. He puts special emphasis on the necessity of this field to be absolutely certain, with experiments, that the so-called created matter was not already present in the environment. So he demonstrated, for example, that the presence of silicates in plants, which were attributed to the life-force by Lampadius, was in reality determined by the amount of silicon present in the soil.

7.2. Jean-Louis Lassaigne (1800–1859)

Lassaigne initially worked in the laboratory of Louis-Nicolas Vauquelin. He was a professeur at Ecole Vétérinaire d'Alfort. His works were published in 1821 with the germination of grains supported the findings of de Saussure. His later works on the development of chicks contradicted the results of Vauquelin.

7.3. P.E. Jablonski

In 1836, Jablonski found no increase in the amount of ashes in the plants above the one in the seed. Therefore, criticizing Schrader and Braconnot.

7.4. Arend Joachim Friedrich Wiegmann (1770–1853) and A.L. Polstorff

Wiegmann and Polstorff made the following experiment: They followed the techniques of their predecessors, but with a soil that consisted of the most inert material known to them at that time. They let 28 seeds of garden cress (Lepidium sativum) germinate in distilled water in a platinum crucible that was filled with fine platinum wires. The crucible was placed under a glass bell jar through which circulated a mixture of 1% carbon dioxide. The seeds germinated and grew into small plants until, after 26 days, they began to die. After drying the crucible and its contents, ashing and weighing obtained 0.0025 g of ash. The weight of the ash obtained from 28 seeds was likewise 0.0025 g. Therefore, there was neither weight change nor new elements formed. However, this conclusion does not contradict previous experiments, since only the weights were compared. No attempt was made to check for the transmutation of one element into another.

7.5. M. Emile Rinck

In 1947, Rink checked Hauschka's work and found only 0.02% weight change.

7.6. Léon Guéguin

In 1970, Guéguin from the INRA (The French Institut of Agronomical Research) has shown that there was no transmutation in Kervran's type experiments.

7.7. D.B. Long

Long was a British scientist, from the Michaelis Nutricional Research laboratory, Harpenden, UK. In 1971, he published a report [36] indicating that he did not observe differences in K, Mg, Ca, Mn, Fe, Zn and Cu when looking at rye and oat seeds germinated. The table shown below shows his experimental results.

Elements	Seeds		Plants		Change (%)
	Average value	Standard deviation	Average value	Standard deviation	
Potassium (mg)	1.582	0.009	1.506	0.016	–4.8
Magnesium (mg)	1.270	0.006	1.273	0.006	+0.2
Calcium (μg)	2.122	0.016	2.157	0.019	+1.6
Manganese (μg)	28.8	0.1	24.9	0.2	–13.5
Iron (μg)	49.7	0.2	48.6	0.5	–2.2
Zinc (μg)	20.9	0.2	21.7	0.05	+3.8
Copper (μg)	6.22	0.2	6.57	0.1	+5.6

7.8. L. Soubiès and R. Gadet

Following Baranger's work, and his attempts to get his findings accepted by the scientific community, Soubiès and Gadet performed similar experiments with the Baranger's protocol and a more rigorous one. They presented their results in 1972 in the bulletin of the French Chamber of Agriculture. They demonstrated that using their better protocol no transmutation is detected, whereas with the original one there is less sodium produced. They proposed that the anomalies were due to diffusion of minerals from the glass used in the experiments.

7.9. Horber

In 1976, Horber, a Swiss scientist from Zurich, looked at calcium variations by neutron activation analysis. He found a 2% variation, but with a precision of ±5%.

7.10. J.A. Jungerman and Murphy

In February 1977, Professor Jungerman and Murphy from the University of California, Davis reported the results of an experiment: the growth of oat seeds under carefully controlled conditions. Analysis was made by atomic absorption and X-ray fluorescence for Ca and K. They found no evidence of transmutation.

7.11. Carolyn E. Damon

In 1978, Damon from the U.S. Customs Technical Service Division conducted tests for biological transmutation with *Aspergillus terreus* and *Rhizopus nigricans*, he obtained negative results.

7.12. Bernd Franke

In 1978, Franke defended his thesis for States Exam at the Botanical Institute of the University of Heidelberg in Germany, the title of which was: "Critical examination of tests on the transformation of biological elements". He analysed calcium, magnesium and potassium during the growth of oats seeds (*Avena sativa*) and yeast (*Sacharomycus cervisiae*). He did not find any significant changes in the composition of the seeds and yeast during their analyses.

7.13. Enrico Di Vito, Carla Candian, Luigi Garlaschelli and Antonio Triassi

In 2002, these scientists from Italy failed to replicate Kervran's work. They looked at the growth of oat seeds (cultivar *Nave*). They analysed their products using ICP emission, but found no variation in Ca, Mg and K in sprouting oat seeds.

8. Theory

8.1. Kervran

Kervran thought that the nuclear reactions that occur in biology were connected to the structure of the nucleus. He developed a unique model of the nucleus with a design that explains the potential transmutations.

8.2. Costa de Beauregard(1911–2007)

Costa de Beauregard [37] was the Research Director at the Centre National de la Recherche Scientifique, Paris, and Professor of Theoretical Physics at the Institut de Physique Théorique Henri Poincaré. He studied Kervran's works in 1962 and began to correspond and met with him. He suggested that such transmutations neither take place through strong interactions nor through electromagnetic forces, but through the weak interaction. This takes place through the neutral current of the intermediate vector boson, the so-called Zo, particle. Kervran's reaction for a biological transmutation from potassium to calcium in germinating oats is thus explained as being initiated by neutrino capture (from cosmic rays) and the weak interaction follows mediated by the *Z*, neutral current.

$$\vartheta + {}^{1}_{1}\mathrm{H}^{+} + {}^{29}_{14}\mathrm{K}^{+} \xrightarrow[+\text{enzyme}]{+Z^{0}} {}^{40}_{20}\mathrm{Ca}^{++} + \vartheta^{-}.$$

In 2006, I called Costa de Beauregard at his home in Paris, and asked him if he continued his research. He replied that he did not.

8.3. Goldfein

In 1978, an officially funded effort from the U.S. Army Mobility Equipment Research and Development Command, Fort Belvoir, Virginia positively confirmed that mechanisms for elemental transmutations could occur in biological systems. The work was performed under the direction of Emil J. York, Chief of the Material Technology Laboratory. Solomon Goldfein was the principal investigator for the effort. Robert C. McMillan, Chief of the Radiation Research Group of the laboratory, provided guidance on matters of physics and nuclear physics. The abstract of the final report [38] reads as follows:

"The purpose of the study was to determine whether recent disclosures of elemental transmutations occurring in biological entities have revealed new possible sources of energy. The works of Kervran, Komaki and others were surveyed, and it was concluded that, granted the existence of such transmutations (Na to Mg, K to Ca and Mn to Fe), a net surplus of energy was also produced. The proposed mechanism was described in which Mg adenosine triphosphate, located in the mitochondrion of the cell, played a double role as an energy producer. In addition to the widely accepted biochemical role of Mg-ATP in which it produces energy as it disintegrates part by part, Mg-ATP can also be considered to be a cyclotron on a molecular scale. The Mg-ATP when placed in layers one atop the other has all the attributes of a cyclotron in accordance with the requirements set forth by E.O. Lawrence, inventor of the cyclotron." "It was concluded that elemental transmutations were indeed occurring in life organisms [sic] and were probably accompanied by a net energy gain."

Goldfein postulated a conformational structure of a stack of Mg-ATP molecules forming a helical chain. The Mg-ATP chelate produces oscillating electrical currents, which act as a micromini-cyclotron that accelerates hydrogen ions to relativistic speeds with sufficient potential to transmute an element to the next higher number. It was concluded that the elemental transmutations occurring in living organisms are accompanied by losses in mass representing conversion to thermal energy and that such energy probably is a net gain when compared to the amount required to effect the transmutation.

8.4. Conclusion

Lavoisier has established a mass conservation law which is valid in chemistry. Now we know that it is not true when nuclear reactions are involved. The review of more than two centuries of research demonstrates that this is not true in biology. It appears that all living organisms can under some circumstances produce nuclear reactions. However, there is an important need of finding an adequate theory to explain these results. It is highly probable that such a theory should also be capable of explaining Cold Fusion, or more generally, nuclear reactions in condensed matter. Another point is the irreproducibility of some experiments. Probably, in order to produce significant transmutation of an element, it is necessary that another element be missing. It seems that nature has a tendency to find ways to transmute an element into another to provide the necessary ingredients for the healthy growth of the four kingdoms of bacteria, fungi, plants and animals, including human beings.

Historically, the sequence of discoveries in biological transmutation is the following: Vauquelin was the initiator in 1799. Later Herzelee in 1876–1883 did a lot of research, but his work was removed. Later Hauschka rediscovered Von Herzelee's work. Baranger and Kervran discovered this work. As a consequence of their contribution to the field Zündel continued the work as well as Goldfein. Finally Vysotskii knowing the work of Kervran brought an important contribution.

This review shows that biological transmutations deserve a lot of attention from the scientific community. The consequences of this are important for science, medicine, agriculture and diet. The cost of research in this field is so low compare with other fields that it is unacceptable not to do it.

Studies of the process called cold fusion or Low Energy Nuclear Reactions (LENR) over the past 22 years show that nuclear reactions of various kinds can be initiated in inorganic solid materials under conditions similar to those present during the claimed biological transmutations. These reactions all have the basic characteristic of producing energy as would be required of a spontaneous reaction. In contrast, many of the proposed nuclear reactions in biological systems cannot result in energy production because mass is not lost in the process. Instead, the mass gain would require the concentration of significant energy from the environment. This violates the basic laws of thermodynamics and makes the suggested reactions impossible. In addition, the elements involved in the proposed nuclear reaction must have a way to find each other in the same biological structure and experience a reduction in their Coulomb barrier before interaction can occur. These several limitations severely limit possible explanations. However, these limitations do not make the nuclear reactions impossible, just more of a challenge to explain. The basic question to be answered is do such reactions actually occur in Nature? The evidence strongly indicates that some of the observed reactions actually occur, requiring an explanation to be found.

Acknowledgements

I wish to thank various people who have helped me in the realization of the biological transmutation experiments: The Holleman Stichting, David Cuthbertson, Valérie Michotey, Jean-Jacques Allegraud and Pascal Gos.

Abstract

Unexplained emission of charged nuclear projectiles due to electrolysis has been reported by Richard Oriani. Experimental results were said to be highly reproducible. Working independently, we were not able to observe emission of charged nuclear particles (in a chemical process similar to Oriani's) and therefore are unable to provide supporting evidence that the effect is reproducible.

Keywords: Cold Fusion, CMNS, LENR, Nuclear Reactions

1. Introduction

Radioactivity, such as emission of alpha particles, has long been thought to be independent of chemical processes, such as electrolysis. The same is true for nuclear reactions including fusion and fission. The reason for this is that the kinetic energies of molecules in a typical chemical process are too small to overcome the Coulomb repulsion between positively charged nuclear particles [1]. This expectation was challenged by Pons and Fleischman [2], Oriani [3, 4], and other scientists, as described by Storms [5]. We were attracted by Oriani's work because his findings were impressive

*E-mail: kowalskil@mail.montclair.edu

(a nuclear process taking place during electrolysis) and his methodology was simple. Our goal was to either confirm or refute the claimed reproducibility of the effect.

The electrolyte in Oriani's cell, Li_2SO_4, is usually dissolved in light water at the concentration of 0.022 g per cubic centimeter. The cathode electrode is usually nickel while the anode electrode is usually platinum. To detect charged nuclear particles, Oriani uses CR-39 chips. This method of detection is widely used in personal neutron dosimeters as well as in other fields of research [6] such as measuring the amount of radon in the air and studying thermonuclear reactions. In Oriani's 2003 experiment, described in [3], the detector was suspended in the electrolyte between the anode and the cathode. The mean track density on the experimental chips was 470 tr/cm^2 while the mean track density on control chips was 168 tr/cm^2. The corresponding standard deviations were 384 and 99 tr/cm^2, respectively.

Referring to such results, Oriani et al. concluded in 2003 that: "a nuclear reaction of as-yet unknown nature can accompany the electrolysis." Experimental results, according to Oriani's more recent 2008 paper [4], are now highly reproducible. The purpose of the present study was to verify this assertion.

2. Oriani's Cell and New Experimental Results

The cell used in Oriani's new study [4] is shown in Fig. 1. It was similar to the cell used in [3]. The essential difference was the addition of a thin Mylar film (6 μm) placed between the CR-39 detector and the nickel cathode. That film was chosen to protect the CR-39 detector from the electrolyte without interfering with detection of expected nuclear particles.

Twenty-one experiments were performed and 42 CR-39 surfaces were examined, as described in his 2008 paper [6]. The track density on one of these surfaces was reported as "too large to count." Track densities on the remaining 41 experimental surfaces ranged from 9 to 498 tr/cm^2, as illustrated in Fig. 2. The histogram was drawn without making a distinction between surfaces facing the cathode and surfaces facing away from the cathode. Note that the distribution of densities is not bell-shaped. Track densities on control CR-39 chips were usually much lower (mean 21 tr/cm^2 and standard deviation 9.7 tr/cm^2) than on most experimental chips (mean 122 tr/cm^2 and standard deviation 124 tr/cm^2). Mean track densities on surfaces facing the cathode, according to data published in [4], were essentially the same as mean track densities on surfaces facing away from the cathode.

On the basis of these observations Oriani concluded that "the present technique has consistently produced evidence that a nuclear reaction of some sort has been generated in the course of electrolysis." Investigations described in this paper were undertaken to determine if Oriani's results could be reproduced in another laboratory.

3. Our Cells and Experimental Results

Our experiments, done in four separate laboratories, were performed using cells that were similar to Oriani's cell. Figure 3 displays a generic diagram of our cells. We used the same electrolyte (Li_2SO_4 in distilled H_2O, at the initial concentration of 0.022 g/cm^3) as Oriani; our electrodes were also made from Ni and Pt. Oriani's nickel cathode wire and our nickel cathode wires were from the same spool. All of us used the 6 μm Mylar which is capable of transmitting alpha particles with energies higher than 2 MeV. Distances between the cathodes and the anodes were approximately 3 cm, which is approximately the same as Oriani's. The essential cell parameters of Oriani's and our experiments were the same.

Differences between Oriani's experiment and our experiment are the following: Platinum wires for the anodes did not come from the same manufacturer. Oriani's cathode was spot-welded to a vertical titanium rod, placed inside a glass tube. Vertical parts of our electrodes, on the other hand, were placed into long heat shrink tubes (not shown in Fig. 3). Lower parts of our shrink tubes were thermally compressed, to prevent capillary creep of the electrolyte. Also note that Oriani's cell exposes the bottom surface (the side away from the electrolyte) of the CR-39 detector to air while our

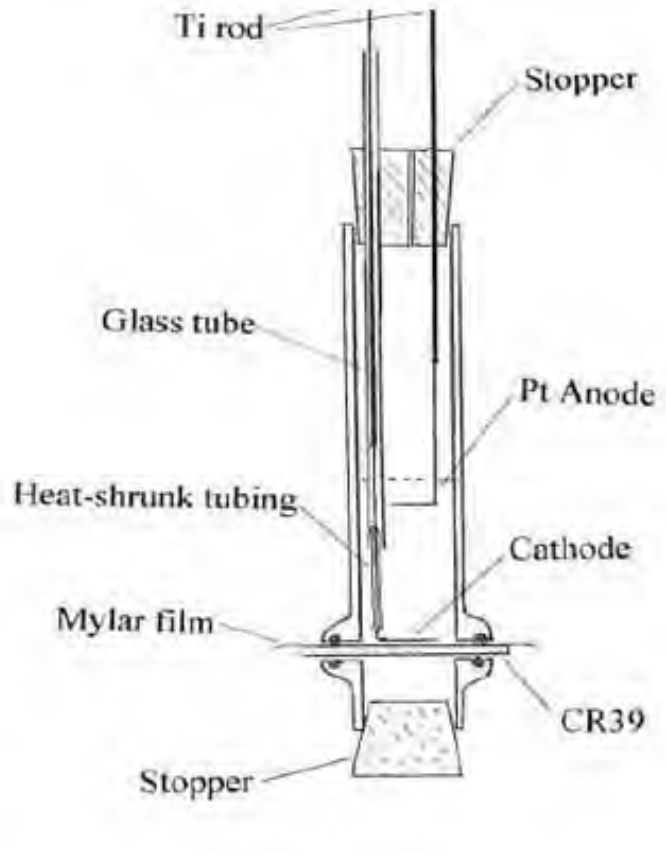

Figure 1. A diagram of an Oriani cell from his 2008 paper [4]. Small circles are cross sections of O-rings placed between the two sections of the cell. A clamp (*not shown*) is used to press the sections toward the CR-39 detector.

cells do not. In our cells, the bottom surface of the CR-39 is in contact with a 25" layer of polyethylene. That layer was clamped to the cell. The leakage of the electrolyte was prevented by squeezing the CR-39, Mylar and O-ring between the polyethylene and the cell.

Both we and Oriani used Fukuvi CR-39 material purchased from Landauer. The delivered sheets of that material are protected from scratches and alpha particles in air by a thin layer of polypropylene plastic. That layer usually peels off when the sheet is cut into small chips. Our unprotected chips were kept in salty distilled water (NaCl concentration of about 10 mg/cm^3). Furthermore, all control chips were kept in unused electrolyte during electrolysis. Salty water prevents potential accumulation of electric charges on CR-39 surfaces kept in air. This precaution was taken to reduce the possibility that electric charges on CR-39 surface in air might attract or repel radioactive ions. No chips were exposed to air for more than one hour. One author (P.L.) compared track densities on two CR-39 chips, one kept in

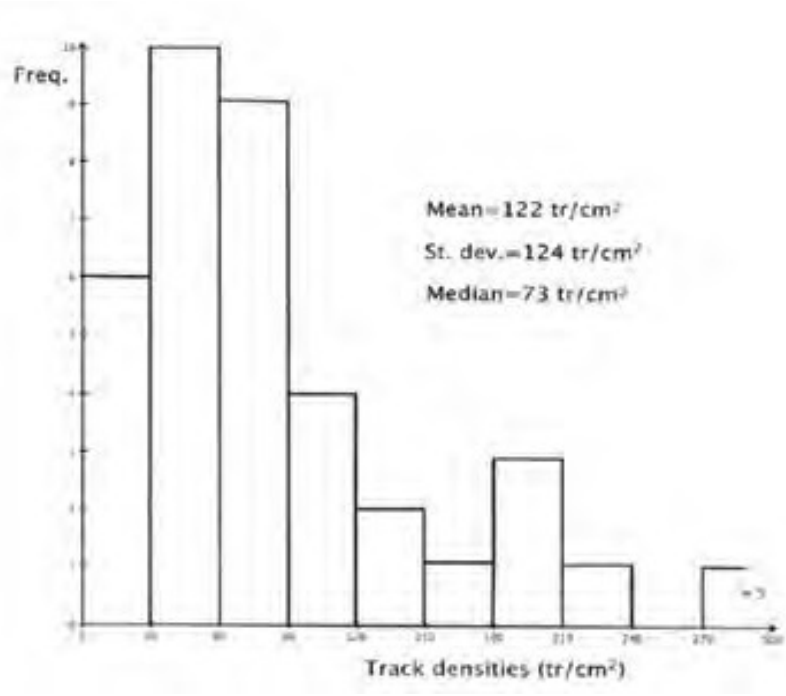

Figure 2. Oriani's distribution of track densities from his 2008 paper [4]. The +5 and 500, near the lower right corner, refer to five surfaces where track densities were between 300 and 500.

distilled salty water and in air, for 15 days. The track density turned out to be 30 tr/cm^2 on the chip kept in salty water and 505 tr/cm^2 on the chip kept in air. This can be explained by the big difference between ranges of alpha particles in air (centimeters) and in water (microns). Oriani did not use salty water; he wrapped the chips in aluminum foil and kept them in air. All of our "control" chips were kept in unused electrolyte during the time that the "experimental" chips were exposed to electrolysis.

Like in [4], we typically exposed the experimental chips to electrolysis for three days. During this time the electric current was changing slowly from 60 to about 90 mA, due to the loss of water. The corresponding voltage across the electrodes was typically 7– 8 V and was kept constant during the experiment. The cell was dismounted after each experiment and the CR-39 chip was removed. It was then etched for 12 h in the stirred water solution of NaOH (concentration 6.5 M, temperature 72˚C). The pits on CR-39 surfaces, identified as tracks of nuclear particles, were subsequently counted under the microscope. The uncertainty of up to plus or minus 5% (in reported track densities) was common due to difficulties in distinguishing tracks from certain surface defects. Each experimenter was given a CR-39 chip with one corner that was exposed to alpha particles from an ^{241}Am source. This helped the experimenter learn the difference between pits and defects. Pits due to particles from that source are shown in Fig. 4. They had the same size as pits found on control and experimental chips.

The mean and standard deviation on eight of P.L.'s experimental surfaces were 87 and 46 tr/cm^2. The mean and standard deviation on his five control surfaces were 59 and 38 tr/cm^2. This information, as illustrated in the Appendix, can be used to justify the statement that the reported difference between mean track densities on experimental and

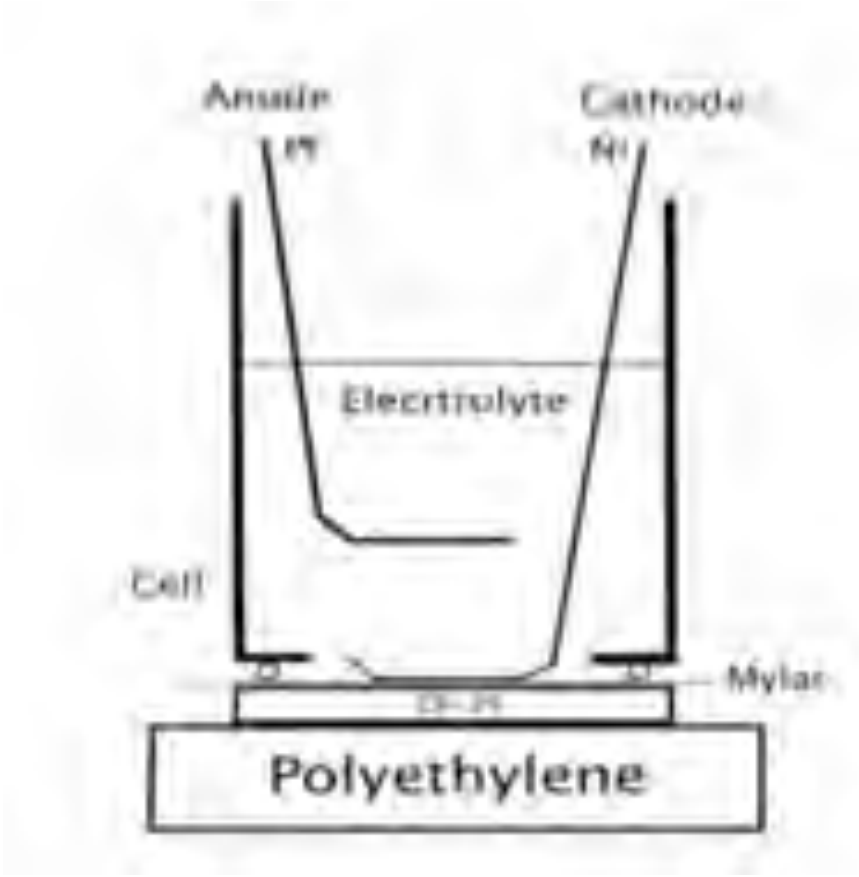

Figure 3. A generic diagram for our electrolytic cells. Small circles are cross sections of the compressed O-ring.

control surfaces, 87–59 = 28 tr/cm^2 was not statistically significant, considering small numbers of examined surfaces.

The mean and standard deviation on six of M.H.'s experimental surfaces were185 and 73 tr/cm^2. The mean and standard deviation on his eight control surfaces were 192 and 72 tr/cm^2. This information was also used to justify the statement that the reported difference between mean track densities on experimental and control surfaces, 185–192 = –7 tr/cm^2 was not statistically significant.

The mean and standard deviation on eight of J.D.'s experimental surfaces were 98 and 17 tr/cm^2. The mean and standard deviation on his six control surfaces were 125 and 29 tr/cm^2, respectively. This information was used to justify the statement that the reported difference between mean track densities on experimental and control surfaces, 98–125 = –27 tr/cm^2 was not statistically significant.

The mean and standard deviation on nineteen of L.K.'s experimental surfaces (excluding three exceptional surfaces from experiments 13, 14 and 15 — see below) were 16 and 8 tr/cm^2. The mean and standard deviation on his 16 control surfaces were 14 and 5 tr/cm^2, respectively. This information was used to justify the statement that the reported

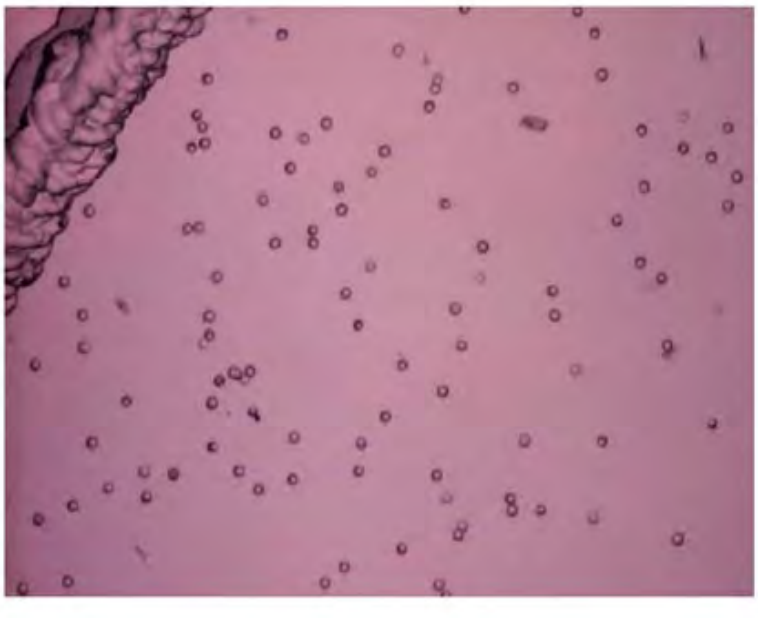

Figure 4. A CR-39 surface seen under the magnification of 40, after 12 h of etching. Small circles are pits due to alpha particles from an Americium source. The upper left corner shows a mechanically damaged area.

difference between mean track densities on experimental and control surfaces, 16–14 = 2 tr/cm^2 was not statistically significant. In other words, experimental results from our four sets of experiments are consistent with each other. But they are not consistent with the results reported by Oriani.

Let us address the issue of extremely high track densities on three surfaces from experiments 13, 14 and 15. The estimated track density on the up-facing surface of the CR-39 chip from Experiment No. 13 were around 15,000 tr/cm^2. This is two orders of magnitude higher than typical densities reported by Oriani [6]. The other side of the chip had nothing but the usual background. The area covered by copious tracks, nearly two square centimeters, matched the circle delimited by the O-ring. Distribution of tracks in that area was more or less uniform, except near the boundaries, where the track density decreased progressively.

Copious tracks from Experiment Nos. 14 and 15 were very different from Experiment No. 13. On these two surfaces, tracks were concentrated in small areas, near a hole drilled in each CR-39 chip. The holes were drilled to facilitate etching; each CR-39 chip was suspended in the etching solution by means of a thin copper wire threaded through the hole. These copper wires were from a telephone cable of unknown origin. The area covered by copious tracks from Experiment No. 14 was about 10 mm^2; the estimated track density was 200,000 tr/cm^2. The area covered by copious tracks from Experiment No. 15 was approximately 3 mm^2; the estimated track density was close to 12,000 tr/cm^2. Track densities outside of the small affected areas were about the same as on control chips.

It is remarkable that in each of the three cases of high track density, the mean density on the other side of the chip was essentially the same as on the control chips. That is very different from what was reported in [4]. The most likely cause of copious tracks was migrating radioactive contamination. Attempts made to identify it were unsuccessful. Alpha

radioactive substances such as uranium, thorium and radium are known to be present in our environment. One nanogram of radium, for example, emits 37 alpha particles per second. Testing of nuclear weapons in the 1960s contributed to contamination of our environment with long-lasting radioactive isotopes, tritium and uranium for example. Note that track densities on our three exceptional surfaces were much higher than those reported in [4].

Project participants worked independently of each other in four different states. Collective results, shown in Table 1, became available to participants only after their own results were submitted to L.K. He collected results after counting tracks on his own CR-39 surfaces. Note that Experiment No. 12 was performed without using the Mylar film. Low track densities resulting from this experiment seem to indicate that all experiments could have been performed without Mylar. Oriani used Mylar to protect the CR-39 from potential chemical effects. Most tracks on control chips were probably due to natural background, most likely due to radon, radium, etc. Concentrations of such substances are known to be location dependent. That fact was probably responsible for differences between mean track densities on the control chips of individual researchers.

4. Conclusion: Facts and Interpretations

The purpose of our four independent investigations was to find evidence for reproducible emission of nuclear particles described in Oriani's 2008 paper [4]. No such evidence was found. We examined 40 CR-39 surfaces and found only three cases of excessive tracks. No excessive tracks were found on the remaining 37 surfaces.

We do not know why we were not able to observe emission of charged nuclear particles (in a chemical process similar to Oriani's). There could have been a setup or procedural difference between the experiments. Further experimentation is needed to confirm the existence of nuclear particle emission in light water electrolysis, understand the causes of such

emission and determine the conditions required for reproducibility.

Appendix: An Example of Statistical Analysis

The mean and standard deviation on eight of P.L.'s experimental surfaces were 87 and 46 tr/cm^2. The mean and standard deviation on his five control surfaces were 59 and 38 tr/cm^2. Is the difference between mean track densities on experimental and control surfaces, 87–59 = 28 tr/cm^2 statistically significant? To answer this question one must estimate uncertainties associated with actually measured track densities (87 and 59). The uncertainty about 87 is 46/2.8 = 16, where 46 is the reported standard deviation while 2.8 is the square root of 8 (the sample size consisted of eight surfaces). Likewise, the uncertainty about 59 was 38/2.23 = 17 tr/cm^2, where 2.23 is the square root of 5 (the sample size consisted of five surfaces).

The difference of 28 tr/cm^2 is too small to be significant, considering large uncertainties associated with the reported mean densities (59 and 38 tr/cm^2).

The same approach was used to show that differences between mean values on experimental and control chips of –7, –27, and 2 tr/cm^2, as reported by M.H., J.D., and L.K. respectively, were also statistically insignificant.

Acknowledgement

Dr. Richard Oriani helped us to design experimental set-ups; Dr. Helen Roberts helped us to perform statistical analysis of experimental data. Constructive criticism from two anonymous referees was also highly appreciated.

Rossi's Reactors – Reality or Fiction?

Ludwik Kowalski
Montclair State University, New Jersey, USA
E-mail: kowalskil@mail.montclair.edu

A tabletop prototype of a new kind of nuclear device was demonstrated at the University of Bologna, several months ago. It generated thermal energy at the rate of 12 kW. A set of one hundred of such interconnected devices, able to generate energy at a much higher rate (up to 1000 kW) is said to be now commercially available. The inventor claims that the energy was produced via nuclear fusion of hydrogen and nickel. This note addresses conceptual difficulties associated with such interpretation. Experimental facts reported by the inventor seem to conflict with accepted knowledge. This, however, should not be a justification for the rejection of experimental data. Refutations and confirmations should be based on independently performed experiments.

1 Introduction

An interesting website, describing an ongoing research project, has been created by an Italian engineer Andrea Rossi [1]. He is the inventor of a tabletop device in which powdered nickel, mixed with common hydrogen, reported to generate thermal energy at the rate of 12 kW, for six months. A large percentage of nickel was said to be converted into copper, during that time. The device was recently demonstrated at the University of Bologna. The most obvious questions, raised by the reported features of the reactor are:

1. What lowers the coulomb barrier, between the atomic nuclei of hydrogen and nickel?
2. Is the reported accumulation of copper consistent with the well known half-lives of radioactive copper byproducts?
3. Is the measurable isotopic composition of nickel, in spent fuel, consistent with the amount of released energy?
4. The radiation level, outside the operating 12 kW reactor, was said to be comparable to that due to cosmic rays. Spent fuel, removed from the reactor, one hour after the shutdown, was found to be not radioactive [1]. How can these purported facts be explained?

Results from earlier experiments (2008 and 2009) are described in [2]. In one case the device was used to heat a "small factory" (probably two or three rooms) for one year.

2 Reported 2011 results

One demonstration of the device – January 14, 2011, at the University of Bologna – is described in [3–5]. Subsequent experiments – February 10, and March 29, 2011 – are described in [6–8]. In both cases the apparatus consisted of a cylinder containing nickel. Pure hydrogen was forced to flow through the hot nickel powder. The amount of powder was 100 grams [8, 9], or slightly more than one cubic inch, depending on the level of compression. Reactions between nickel and hydrogen turned out to be extremely exothermic, generating thermal energy at the rate of about 12.4 kW. This was 31 times higher than the rate at which electric energy was supplied, to operate the equipment [4].

In the February experiment the amount of thermal energy was determined from the flow rate of cooling water, and the difference between its input and output temperature. In the January experiment the water flow rate was slower; the entering water was a liquid, the escaping water was a vapor. The amount of thermal energy released was determined from the amount of liquid water (initially at 15 ^{o}C) transformed into 101 ^{o}C vapor. Rossi claims that most heat is produced from nuclear reactions:

$$p + Ni \rightarrow Cu,$$

where p is nothing but ionized hydrogen. This is very surprising because the temperature of hydrogen was below the melting point of nickel. Addressing this issue in [10] Rossi reported that about 30% of nickel was turned into copper, after six months of uninterrupted operation. A schematc diagram of the reactor, and additional details are in [11, 12].

Comment 1

Many physicists have studied fusion of protons with nickel nuclei. But their protons had much higher energies, such as 14.3 MeV [13]. Rossi's protons, by contrast, had very low energies, close to 0.04 eV. The probability of nuclear fusion, expressed in terms of measurable cross sections, is known to decrease rapidly when the energy is lowered. How can 0.04 eV protons fuse with nickel, whose atomic number is 28? Rossi is convinced that this is due a catalyst added to the powdered nickel. The nature of the catalyst has not been disclosed. This prevents attempts to replicate the experiments, or to discuss the topic theoretically. Secrecy might make sense in some business situations, but it is not consistent with scientific methodology.

Comment 2

How can 30% of nickel in Rossi's reactor be transmuted into

copper? This seems to be impossible, even if the coulomb barrier is somehow reduced to zero by his catalyst. To justify this let us focus on the ^{58}Ni and ^{60}Ni isotopes–they constitute 94.1% of the nickel initially loaded into the device. The reactions, by which copper is produced, from these isotopes, would be:

$$p + {}^{58}Ni \rightarrow {}^{59}Cu \quad \text{(half-life is 3.2 s)} \qquad \text{(A)}$$

and

$$p + {}^{60}Ni \rightarrow {}^{61}Cu \quad \text{(half-life is 3.3 h)} \qquad \text{(B)}$$

The reported amount of accumulated copper – 30% of the initial nickel being turned into copper, after six months of operation–would indeed be possible, via reactions (A) and (B), if the produced copper isotopes were stable, or had half-lives much longer than six months. But this is not the case, as shown above. The produced copper isotopes, ^{59}Cu and ^{61}Cu, rapidly decay into ^{59}Ni and ^{61}Ni. Each reaction, in other words, would lead to accumulation of these isotopes of nickel, not to accumulation of copper, as reported by Rossi. The accumulation of copper would practically stop after several half-lives. Note that ^{63}Cu and ^{65}Cu, if produced from fusion of protons with ^{62}Ni and ^{64}Ni, would be stable. But natural abundance of these isotopes of nickel, 3.63% and 0.92%, respectively, is too low to be consistent with the claimed accumulation of 30% of copper.

Comment 3

How much of the original ^{58}Ni should be destroyed, after six months of continuous operation, in order to generate thermal energy at the rate of 12 kW? Let us again assume that Coulomb barriers are somehow reduced to zero by Rossi's secret catalyst. The ^{58}Ni is 68% of the total. On that basis one can assume that 68% of 12 kW is due to the radioactive decay of ^{59}Cu, and its radioactive daughter, ^{59}Ni. Thus $P'_1 = 0.68 \times 12 = 8.16$ kW. This is the thermal power. The nuclear power P_1 must be larger, because neutrinos and some gamma rays do escape from the vessel. As a rough estimate, assume that the nuclear power is

$$P_1 = 16 \text{ kW} = 16{,}000 \text{ J/s} = 10^{17} \text{ MeV/s}.$$

The excited ^{59}Cu, from the reaction (A), releases 3.8 MeV of energy, as one can verify using a table of known atomic masses. In the same way one can verify that the energy released from its radioactive daughter, ^{59}Ni, is 4.8 MeV. In other words, each transformation of ^{58}Ni into ^{60}Ni releases 3.8 + 4.8 = 8.6 MeV of nuclear energy.

The number of reactions (A) should thus be equal to $10^{17}/8.6 = 1.16 \times 10^{16}$ per second. Multiplying this result by the number of seconds in six months (1.55×10^7) one finds that the total number of destroyed ^{58}Ni nuclei is 1.80×10^{23}, or 17.4 grams. A similar estimate can be made for other initially present nickel isotopes. The overall conclusion is that the isotopic composition of nickel, after six months of operation, at the 12 kW level, would change drastically, if the reaction A were responsible for the heat produced in the reactor invented by Rossi.

The amount of ^{59}Ni, for example, would increase from 0% (natural abundance) to 17.4%. The amount of ^{58}Ni, on the other hand, would be reduced from 68% (natural abundance) to 50.6%. The isotopic composition of nickel in spent fuel was measured, according to [1], but results remain "privileged information".

Comment 4

The level of radioactivity, next to the reactor generating heat at the rate of 12 kW, was reported as not much higher than the natural background [5]. Is this consistent with reaction (A) being responsible for most of the heat? The answer is negative. How can this be justified? In the steady state the rate at which radioactive atoms, in this case ^{59}Cu, are decaying is the same as the rate at which they are produced. That rate, as shown in Comment 3, is 1.16×10^{16} atoms per second. In other words, the expected activity is

$$1.16 \times 10^{16}/3.7 \times 10^{10} = 313{,}000 \text{ Curies}.$$

The emitted radiation would include gamma rays of 1.3 MeV, able to escape. The level of radiation, next to the reactor, would depend on the wall thickness. It would certainly exceed the background by many orders of magnitude. Absence of excessive gamma radiation might be an indication that the reactions producing heat were different from the p+Ni fusion.

3 Addendum

Note that the reported fuel power density of 120 W/g would be at least ten times higher than in a fuel element of a nuclear reactor based on ^{235}U. What can be more desirable than higher safety and lower cost? Did Rossi really invent a new kind of nuclear reactor? Logical speculations, such as those above, are not sufficient to answer this question. Only independently performed experiments can do this.

Rossi's claims, if confirmed, would present a challenge to theoretical physicists. Physics, unlike mathematics, is based on confirmed experimental facts, not on axioms. Newly discovered facts often lead to improvements of accepted theories. Let's hope that Rossi's incredible results can be independently confirmed in the near future.

LETTERS TO PROGRESS IN PHYSICS

Social Aspects of Cold Fusion: 23 Years Later

Ludwik Kowalski

The field of Cold Fusion, now called Condensed Matter Nuclear Science (CMNS), remains controversial. The original 1989 claim made by M. Fleischmann and S. Pons was that a chemical process in an electrolytic cell could initiate a nuclear reaction–fusion of two deuterium nuclei. More recent CMNS claims, made by experimental scientists, are: emission of charged nuclear projectiles during electrolysis; accumulation of ^{4}He; production of radioactive isotopes; and transmutation of elements. In the US, CMNS claims have been evaluated in two Department of Energy (DOE) investigations, in 1989 and 2004, as summarized in this article. These investigations did not lead to any resolution of the controversy. Scientists and adminstrators are not ideal; competition among them, as among other groups of people, tends to have both positive and negative influences.

1 Introduction

The so-called "scientific methodology", a set of norms developed to deal with difficulties, especially with mistakes and controversies, is well known. Most scientific mistakes are recognized when new results are discussed with colleagues, or via the peer review process. Occasional errors in published papers are subsequently discovered during replications conducted by other researchers. Scientific results, if valid, wrote Huizenga [1], must be reproducible on demand. "When errors are discovered, acknowledged and corrected, the scientific process moves quickly back on track, usually without either notice or comment in the public press." The scientific process, in other words, is self-corrective. The purpose of this presentation is to analyze an ongoing controversy about the so-called "cold fusion" (CF). The author of this article, and three other researchers, tried to verify one recent CF claim – emission of alpha particles during electrolysis. The results were negative, as described in [2]. Critical analysis of some CF claims, as illustrated in [3], can enrich nuclear physics courses, even at the undergraduate level.

Why is the CMNS controversy started in 1989 unresolved? Because CF claims are still not reproducible on demand, and because they conflict with accepted theories. A theory, in this context, is not just a hypothesis, or only a logical/mathematical argument. It is a logical structure that is known to agree with a wide range of already verified experimental data. Researchers know the rule–theories guide but experiments decide. But they are very reluctant to abandon accepted theories. To be reluctant means to insist on additional verifications of new experimental results. Referring to such situations, Huizenga wrote: "There are occasionally surprises in science and one must be prepared for them." Theories are not carved in stone; scientists do not hesitate to modify or reject theories when necessary. Rejecting a highly reproducible experimental result "on theoretical grounds" would not be consistent with scientific methodology. Unlike mathematics, science is based, in the final analysis, on experimental data, not on logical proofs.

2 The Original Claim

It is well known that two hydrogen nuclei can fuse, releasing energy. But this happens only at extremely high temperatures. At ordinary temperatures the probability of the reaction is practically zero, due to the well known coulomb repulsion of positive nuclei. This has been confirmed by reliable experimental data. But two scientists – Steven Jones, a physicist, and Martin Fleischmann, a chemist – independently speculated that this might not always be true. The term CF was introduced by them to identify the claimed fusion of hydrogen nuclei (ionized atoms dissolved in solid metals). The DOE supported Jones' work long before Fleischmann and his colleague Pons (F&P) applied for similar support. That is why the DOE asked Jones to evaluate the new research proposal. He was later accused (by the administration of Utah University) of stealing the idea of CF from F&P. Trying to establish priority, Utah University organized a press conference (March 23, 1989) at which the discovery of generation of nuclear heat in an electrolytic cell was announced to the world. The released heat was declared to be due to fusion of deuterium nuclei – ionized atoms dissolved in palladium. At that time Jones and his co-workers had already authored numerous peer-reviewed articles [4]. But their claim was not excess heat; it was emission of neutrons.

3 The First DOE Investigation

Most scientists immediately rejected claims conflicting with well-known facts and theories. But many attempts to replicate F&P's poorly-described experiments were made. Some attempts were successful (unaccounted heat was generated at rates close to one watt), while others were not [5]. That was the beginning of the controversy. Fleischmann and Pons wanted to study the CF phenomenon for another year or so but

were forced to announce the discovery by the university administrators [6]. They had no evidence that the measured heat was due to a nuclear reaction. The only thing they knew was that it could not be attributed to a known chemical reaction.

Suppose their experimental results had been described without any interpretation, and the phenomenon had been named "anomalous electrolysis". Such a report would not have led to a sensational press conference; it would have been made in the form of an ordinary peer review publication. Only electrochemists would have been aware of the claim; they would have tried to either confirm or refute it. The issue of "how to explain excess heat" would have been addressed later, if the reported phenomenon were confirmed. But that is not what happened. Instead of focusing on experimental data (in the area in which F&P were recognized authorities) most critics focused on the disagreements with the coulomb barrier theory. Interpretational mistakes were quickly recognized and this contributed to the premature skepticism toward their experimental data.

But the significance of CF, if real, was immediately recognized. Some believed that ongoing research on high-temperature fusion, costing billions of dollars, should be stopped to promote research on CF. Others concluded, also prematurely, that such a move would be opposed by "vested interests" of mainstream scientists. Responding to such considerations, the US government quickly ordered a formal investigation. A panel of scientists, named ERAB (Energy Research Advisory Board), and headed by John Huizenga, was formed to investigate CF in 1989. The final report, submitted to the DOE several months later, interfered with the normal development of the field. It should be noted that ERAB scientists investigating the CF claims were not personally involved in replications of experiments. Their report [7], based on visits to several laboratories rather than participation in experiments, can be summarized by the following statements:
Conclusions:

1. There is no evidence that a nuclear process is responsible for excess heat.
2. Lack of experimental reproducibility remains a serious concern.
3. Theoretically predicted fusion products were not found in expected quantities.
4. There is no evidence that CF can be used to produce useful energy.
5. The CF interpretation is not consistent with what is known about hydrogen in metals.
6. The CF interpretation is not consistent with what is known about nuclear phenomena.

Recommendations:

7. We recommend against any extraordinary funding.
8. We recommend modest support for more experiments.
9. We recommend focusing on excess heat and possible errors.
10. We recommend focusing on correlations between fusion products and excess heat.
11. We recommend focusing on the theoretically predicted tritium in electrolytic cells.
12. We recommend focusing on theoretically predicted neutrons.

Note that only one conclusion (item 2) refers to CF experiments. Conclusion 4 is about anticipated practical uses of CF while the remaining four conclusions (1, 3, 5, and 6) are about various aspects of the suggested interpretation of experimental results. Instead of focusing on reality of excess heat critics focused on the fact that the hypothesis was not consistent with what was known about hot nuclear fusion. The same observation can be made about recommendations. Only one of them (item 9) refers to possible errors in experiments. Items 7 and 8 refer to future funding while items 10, 11, and 12 refer to what was expected on the basis of the suggested hot-fusion interpretation. It is clear that the ERAB observations were based mostly on "theoretical grounds,"and not on identified errors in experimental data. Recommendations about future financial support for CF were very important. But they were ignored by the DOE. Support for CF research practically stopped in 1989. Another result of the first DOE investigation was that editors of some scientific journals stopped accepting articles dealing with CF research. Why was the scientific methodology of validation of claims – theories guide but experiments decide – not followed by the DOE-appointed scientists? Why did "rejections on theoretical grounds" prevail?

4 The Second DOE Investigation

The second DOE investigation of CF was announced in March 2004, nearly 15 years after the first one. Links to three online documents related to that investigation – Conference Agenda, Meeting Agenda, and DOE CF Report – can be found in [8]. The six most important scientific questions, based on new experimental claims, were:

a) Is it true that unexpected protons, tritons, and alpha particles are emitted [9, 10] in some CF experiments?
b) Is it true that generation of heat, in some CF experiments, is linearly correlated with the accumulation of ^{4}He and that the rate of generation of excess heat is close to the expected 24 MeV per atom of ^{4}He [9, 11]?
c) Is it true that highly unusual isotopic ratios [9, 12] have been observed among the reaction products?
d) Is it true that radioactive isotopes [9, 13] have been found among reaction products?
e) Is it true that transmutation of elements [10, 14] has occurred?

f) Are the ways of validating of claims made by CF researchers (see conference reports presened at [16, 17, 18]) consistent with accepted methodologies in other areas of science?

A positive answer to even one of these questions would be sufficient to justify an official declaration that cold fusion, in light of recent data, should be treated as a legitimate area of research. But only the (b) question was addressed by the selected referees [8]. They were asked to review the available evidence of correlation between the reported excess heat and production of fusion products. One third of them stated that the evidence for such correlation was conclusive. That was not sufficient; the attitude of the scientific establishment toward cold fusion research did not change.

5 Conclusion

The CF controversy is unprecedented in terms of its duration, intensity, and caliber of adversaries on both sides of the divide. Huizenga and Fleischmann were indisputable leaders in nuclear science and electrochemistry. CMNS researchers are mostly also Ph.D. level scientists. The same is true for those scientists who believe that the announced discovery of CF was a "scientific fiasco". We are still waiting for at least one reproducible-on-demand demonstration of a nuclear effect resulting from a chemical (atomic) process. In the case of CF the self-correcting process of scientific development emphasized by Huizenga has not worked. This fiasco seems to be due to the fact that scientists appointed to investigate CF claims did not follow the rules of scientific methodology.

Cold Fusion, hot and cold

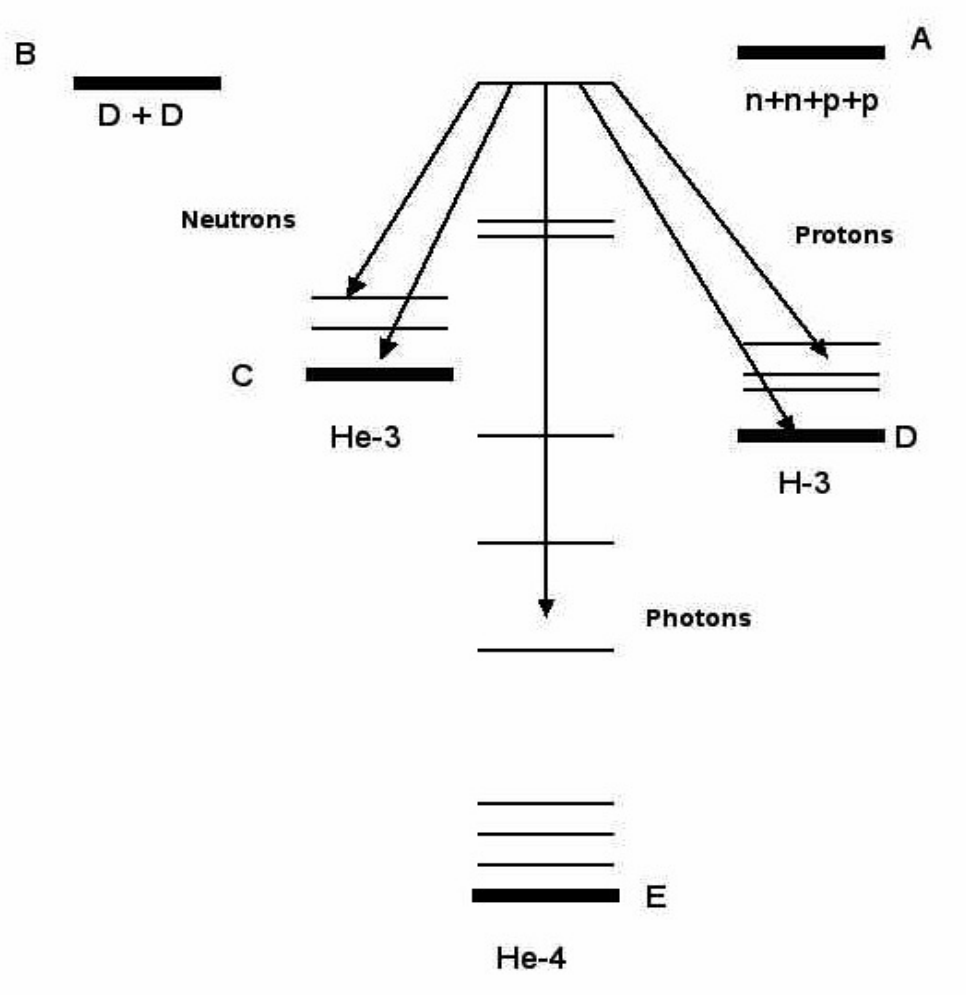
This unit is the summary of what I read from a paper of CMNR researchers, A. Meulenberg and K.P. Sinha (both from Malaysia). Their paper, entitled " Extensions to Physics: Low-EnergyNuclear Reactions," has been presented at the most recent "International Conference on Cold Fusion" (ICCF17) in Korea (September, 2012). That paper prompted me to post the following two messages, on the private Internet forum for CMNR researchers.

Message 1(9/18/2012):

1) Suppose two 2H (whose combined atomic mass is 2*2.01410=4.0282 u) fuse to form one 4He (atomic mass of 4.00226 u). The excitation energy of the "compound" 4He becomes 24 MeV, as calculated with the E=m*c^2 formula. This is trivial. Why are the quotation marks? Because the name compound nucleus is used only for much heavier structures (A>30). Which name would be more appropriate? In any case, the name has nothing to do with the question about the distribution of energy.
2) One possibility is that most of the released 24 MeV becomes the kinetic energy of one neutron, while the kinetic energy of the remaining 3He structure is negligible, or vice versa. Another possibility is that most of the released 24 MeV becomes the kinetic energy of one proton, while the kinetic energy of the remaining 3H structure is negligible, or vice versa. And what about a possibility that the pp and nn (structures inside the excited 4He) share equal amounts of energy among them? These temporary structures can be called biproton (2He) and bineutron. Such speculations are triggered by reading one of the papers written by Akito Takahashi.
3) And here is another question; it has to do with hot fusion. The probability of the 3He+n decomposition and the probability of the 3H+p decomposition (of the excited 4He) are practically identical. This is a well-known experimental fact. How can it be explained?

Message 2 (9/20/2012)

Below is a diagram that I have in mind while thinking about the D+D fusion, either hot or cold. The thick line A refers to combined mass of two neutrons and two protons. Likewise, the thick line B represents the combined mass of two deuterons. It is easy to verify, by using a table of atomic masses, that B is smaller than A. That is why the line B is below the line A.



The line C represents the combined mass of one neutron and one unexcited He-3 (ground state). It is easy to verify that C is smaller than B. That is why the C line is lower than B. Likewise, the line D refers to the combined mass of one neutron and one tritium, also in the unexcited (ground) state. It is easy to verify ...; that is why the line D is below the line C. And, as you probably guess, the line E represents the mass of He-4, in the ground state. As I demonstrated yesterday, the rest mass E is by nearly 24 MeV smaller than the rest mass B.

The thin horizontal lines refer to excited states of corresponding nuclei, He-4, He-3 and H-3, respectively. Fusion of two slow deuterons produces He-4 in the excited state; the level of that state is the same as the level of B, or slightly higher (when the kinetic energy of fusing deuterons is not negligible).

The arrows show what is energetically allowed. One possibility is emission of one neutron and one He-3 nucleus, either in the ground or excited state. Another possibility is emission of one proton and the H-3, either in the ground state or in the excited state. The third energetically allowed decomposition of the excited He-4, is emission of one or several (Andrew calls it a cascade) photons. Evaporation of two neutrons and two protons from the He-4 compound nucleus, on the other hand, is energetically impossible, unless the kinetic energy of fusing deuterons is larger than the difference between the A and B levels.

The nuclear "ash" associated with emission of a single neutron is He-3, the nuclear "ash" associated with emission of a single proton is H3, and the nuclear "ash" associated with the emission of photons is He-4.

It is interesting that the maximum "energetically-possible" energy released via the photon de-excitation is much higher than the maximum "energetically possible" energy released via the n or p channels.

The p and n channels, as we know, are dominant in hot fusion but not in cold fusion. Why is ir so? This is one of the puzzles to be solved. Another puzzle has to do with the reported accumulation of the He-4 ash, in cold fusion. Why is it not accompanied be emission of the matching number of high energy photons?

Feel free to use this post in any way you wish. But be aware that vertical distances between the horizontal lines, in my illustration, are not drawn according to energies calculated from known masses of atomic nuclei. The same applies to excitaion energy levels; their numbers and locations, for three nuclei, are not realistic.

411) Messages from the CMNS list (December 2012)

Ludwik Kowalski; 12/17/2012

Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Some of you might be interested in the following messages from the private discussion list for CMNS researchers. They were posted in the first week of December 2012.

1) Posted by X1:

... **X2 Ludwik Kowalski** suggests that some of our distinguished CMNS scientists are in a way accomplices of Rossi's scam..... [I am certainly not one of them; my critical comments on Rossi's claims can be seen at:]

http://pages.csam.montclair.edu/~kowalski/cf/408rossi.pdf

2) Posted by X3:
I have not yet received a response from X2. Regarding my wager, I am confident that commercial hot fusion energy will not happen in my lifetime despite hearing this promise of abundant energy for as long as I can remember.

3) X6 :
I also do not expect to live long enough to see commercial applications. But should I expect to see the first reproducible-on-demand demonstration of an undeniably nuclear effect resulting from a chemical process, such as electrolysis? This would be a giant step toward practical applications.

4) Posted by X5 (And ul-Rahman Lomax)
It exists. Unfortunately, it's a fairly expensive experiment. It's the X6's experiment. Use the state of the art to run a substantial series of F&P type cells to see excess heat. Run the cells in such a way as to allow the secure collection of helium and measure it. Compare excess heat and the amount of helium produced. The helium will be proportional to the heat, and if you end up capturing all the helium, which may take some special techniques, the ratio will be as expected for deuterium conversion to helium. The individual cells will vary in heat, but the ratio will be constant.

That is a reproducible experiment, it's been reproduced many times. There are approaches which have shown excess heat in most cells, such as the Energetics Technologies replications at SRI and ENEA.

It's much less expensive to do this without the helium collection, but then all you have is heat, which is not an undeniably nuclear effect.

The problem, Ludwik, is that the F&P Heat Effect produces essentially no "nuclear products" other than helium, which is not unmistakably "nuclear" by itself, unless you take the levels above ambient, and still the skeptics will carp, because they did. However, heat correlated with helium at the fusion ratio is strong

enough evidence for anyone who is reasonable.

It's possible that this could be done with tritium, but I don't see that the *reliable production* of tritium has been studied. The rumor is that tritium is not correlated with heat, but I've never seen published values that would show this, and it's a suspicious claim.

5) Posted by X6:

Yes indeed. Production of ^{4}He from ^{2}H, even without generation of excess heat, is an undeniable nuclear event, like other reported transmutations. But the correlation with excess heat, at the rate of about 24 MeV per atom of He (even if it were 24 +/- 10 MeV), would be very significant.

How much would it cost to reconstruct a setup, and to perform ten experiments? Who would be able to perform such experiments, if money becomes available?

6) Posted by X7

Evidently X2 has not done his research! None of the persons criticized in his blog are ISCMNS leaders! And his conclusions regarding the ISCMNS position do not seem to be based on any relevant facts.

I went on record, during the ISCMNS Annual General Meeting at ICCF16 (February 2011) warning the community of the brewing storm. Allow me to quote some key points from my presentation:-

"Recently a demonstration was made of a prototype energy “Catalyzer”
If it works as described, it may be a blessing to humanity and vindicate 21 years of patient work by this community. If it fails spectacularly, it will create bad publicity for everyone working in the field.

Some advice to inventors
Get your invention independently validated.
Demonstrations which hide technical details create unease.
Non disclosure agreements can protect secrets.

Advice to Users
If you acquire any technology, whether secret or not, do not accept any clauses which require you to keep quiet if it doesn't work.
We need whistle blowers.

Advice to Evaluators
It's probably not appropriate to make a public statement in support of a demo miracle device, if you have not examined it yourself.
If you do make a statement, at least make sure that you can correct any eventual errors.
Take care if you get on film, as film will be edited."

This is of course a personal perspective, but it was discussed by the ISCMNS members present at the meeting.

If X2 has any evidence of fraud, I suggest he contacts the appropriate authorities.

7) Posted by X5:

First of all, it's been done. As I recall, Miles performed about six experiments, taking a total of 33 samples for analysis. ....This is the kind of work that can be done in many ways. The exact protocol is not important,

but I do caution against going outside the basic PdH approach. Other approaches *might* involve different mechanisms.

If one can obtain or make an active cathode -- ENEA seems to be able to supply functional cathode material, and seems to have a grip on what sets up the necessary initial conditions -- measuring heat is not the most difficult part of this; one should, of course, use good calorimetry, for the accuracy of the ratio will not exceed the accuracy of the calorimetry.

The difficulty, though, is in capturing and measuring all the helium. McKubre followed an approach, in some of his work, that involved rigorously excluding helium from the cell materials and cells. Helium can diffuse through some materials. Seals must be helium tight, and tested to be so. And if the cell needs to be disassembled for any reason -- connections fail, etc., -- then the whole process must be repeated.

Storms, in "Status of cold fusion (2010)", working from the results of various studies, comes up with 25 +/- 5 MeV/He-4. That's rather obviously a bit seat-of-the-pants. I'd say, however, that the results show better than 24 +/- 10 MeV (and I'm not saying that Storms' result is incorrect).

At this point, the work is solid enough that the default hypothesis as to the ash from the FPHE is that it is helium, with the fuel being deuterium. Transmutations and other products are found at levels far too low to explain the heat, by many orders of magnitude. This does *not* establish mechanism, but it obviously puts some severe constraints on mechanism. If the mechanism involves neutron formation, why the products would so tightly focus on helium would have to be explained -- or other products would need to be identified, which has not happened. One possible mystery product, of course, could be deuterium, since it would not be detectable in heavy water experiments, nor, for that matter, in light water experiments, so plentiful is deuterium in light water.

Miles first reported helium somewhere around 1991, and his first extensive correlation report was published in time to be covered in the second revision of Huizenga's book, "Cold fusion, scientific fiasco of the century." Huizenga was highly impressed, in fact, saying that, if confirmed, a major mystery of cold fusion would have been solved, i.e., the ash. He held on to his skepticism by saying that, of course, it was unlikely to be confirmed, because no gamma rays were reported.

Huizenga was showing, clearly, how the skeptics thought about cold fusion and why they thought "it" was impossible. "It" was d-d fusion, through "overcoming the Coulomb barrier," in the classic way or something like it. And "it," when it produces helium -- i.e., rarely -- always produces a gamma ray. I consider it likely that they were correct, what they thought of as cold fusion is indeed impossible. They were gloriously and spectacularly incorrect, though, in making the assumption that if there was cold fusion, it would be a new way of making hot fusion.

(And all the theories that involve ideas whereby somehow deuterons in condensed matter attain sufficient energy to directly penetrate the barrier are missing the point. That is not happening. Piezoelectric fusion -- used in certain commercial neutron generators -- isn't cold fusion, it's hot fusion, and that's why it serves to generate neutrons. But the apparatus is at room temperature ....)

Because a notable author objected to the idea of this "replicable experiment," I'll answer his post separately, as to why what he expects has not appeared. But what I described is indeed replicable, and reliably so, I'll assert -- there is going to be a need for some detailed discussion about this -- and *it has been replicated*, quite enough that under normal conditions, the result would be a generally accepted fact.

Sitting here twenty years after a cascade, though, conditions still are not normal.

8) Also posted by X5, shortly after the above message:

X6 asked “How much would it cost to reconstruct a setup, and to perform ten experiments? Who would be able to perform such experiments, if money become available?”

What it would cost is something that could be estimated by those who have done the work in the first place. Notably, as to those who are active, and off the top of my head, this would be Miles -- first and foremost --, McKubre, who did the most accurate work to date, and Violante, who may have done the work at least expense, plus, of course, any of their co-workers and those reported in Storms, 2010.

I doubt that it would cost more than $10,000 per cell, though, as a rough guess, particularly if a worker already had good calorimetry in place or easily adaptable. If a lot of cells are run, the cost per cell may go down. Most of this cost, indeed, is labor.

As to who, my plan is to write a survey of cold fusion criticism, with a goal toward identifying significant and important unresolved issues. The replication of heat/helium is not significant as far as it is not impeding progress significantly, but because there are lingering doubts about it, it may be politically important. If heat/helium is established, if 24 MeV is confirmed, independently, and with greater accuracy, it confirms cold fusion, very amply, as a side-effect, and it narrows the possibilities for theories as to mechanism.

Matters are still at the point where Larsen can suggest that 24 MeV is only approximate and he can attempt to shoehorn his neutron transmutation ideas into it. Note that in spite of what Krivit has implied, Larsen has *confirmed* at least some of McKubre's work, as to his personal opinion.
This work must be divorced from theory. The goal of any confirmation should be, not to confirm or reject any theory as to mechanism, but simply to measure the ratio of helium to heat. The experiments might as well look for other things that can be done without compromising the heat/helium goal.

An important approach may be to define a protocol to be followed, and the broader the consensus on the protocol, the more likely that multiple workers will attempt it. Because few have access to mass spectrometers that are helium-qualified (He-4 must be resolvable from D2), the protocol will need to include a sampling protocol, which will require cooperation between experimenters and labs ready to do the measurements. If a single and simple protocol for submitting samples is followed, actual helium measurement should be relatively cheap per sample.

If every researcher does their own fabrication, that's expensive. If a common protocol is agreed upon, with identical cell design, there is *no harm in cooperation in fabrication.* What would be important would be that the cell materials would all be accessible for thorough testing. I.e., someone could analyze them to make sure that someone didn't sneak helium into the palladium, in particular. Ideally, there would be an independent supplier of materials and cells, with traceability. All that a researcher, then, in a report, need state, is that they used XYZ company's model NNN cell assembly.

XYZ company, then, is highly motivated to facilitate consensus among its potential customers as to desirable cell design. The Galileo project would have seen much wider participation if there had been such a common fabrication supplier. Indeed, I began working as a supplier of kit materials because, I saw, it should be possible to supply a Galileo-type cell, ready to hook up to a power supply and run, for about $100 per cell *and make a (modest) profit doing it.*

(But that design only looks for radiation evidence, from small palladium-plated cathodes in heavy water, and is utterly inadequate, as such, for heat/helium work.)

9) Posted by X6:

Thank you for interesting posts, X5. You are probably assuming that a high resolution mass spectrometer (able to distinguish the D-2 peak from the He-4 peak) would be available at no cost. Such instruments are not disposable.

10) Another post by X5

Other reported transmutations would be nuclear, but they occur at levels far, far below those of helium in F&P type experiments. Helium itself is problematic because helium is present in ambient air at levels that are generally higher than those expected from the heat. However, that has been addressed in several ways:

1. If enough heat is accumulated, and helium is accumulated, the helium levels can be expected to -- and do -- rise above ambient, without slowing, indicating a source of helium other than leakage from ambient.

2. Controls do not show helium.

3. If an experiment shows reasonably robust heat, and the cell environment is small, helium as an elevation above ambient can be observed. That this is what Violante did escaped Steven Krivit, who criticized Violante without understanding what he'd done.

The big problem with heat/helium work is that helium has very low mobility in palladium, yet it appears that the reaction does implant helium at some (small) depth in the palladium, so as much as roughly half of the helium can be trapped in the palladium. McKubre attempted to flush the helium by repeated deuterium loading/unloading, which appears to have worked, but this is an unconfirmed technique, and it would be useful if more definitive methods could be used. For example, earlier work looking for nuclear products in Arata/Zhang DS cathodes (hollow palladium with palladium black in the interior) not only looked in the interior gas phase, but also sectioned the cathodes and heated the pieces; helium becomes mobile at high temperatures. I've also thought that dissolving the cathodes electrolytically might work and might be simpler, if a researcher doesn't have direct access to helium measurement and must send off samples to a lab.

(With those Arata/Zhang cathodes, helium was not found above ambient, and the signs are that the cathode interior volume was breached, the helium leaking out. What was found, though, was He-3, at very significant levels, apparently as a decay product from tritium. The He-3 was found trapped in the palladium, at variable distance from the interior, indicating that it was the product of tritium that had decayed to He-3, becoming immobile, as the tritium diffused through the palladium. But this is unconfirmed work; like much cold fusion work, it's crying out to be replicated.)

11) Also by X5:

There are those on this list with substantial experience with this, perhaps they will help us understand the issue.

However, Miles did not have such a spectrometer. It is not necessary, obviously, for the researcher running the cells to have a mass spectrometer.

SRI has the necessary device, so does Dr. Storms, in his home lab. They are quite expensive, but not impossibly expensive, and, in any case, it is probably a better idea to create a sampling protocol such that a lab or labs can provide analytical services, efficiently.

If one were to run 10 cells, that could only be 10 samples to analyze, plus a few controls. It's kind of crazy to buy a mass spec to make ten measurements, eh?

It does appear, from what I've heard, that modern mass spectrometers are both cheaper and more accurate than the services that were available to Miles.

Yes, for deeper investigational work, in-line, continuous measurement of cell gas could make the investment in a dedicated mass spec worthwhile. But, note: serious exploration of the parameter space leads to a concept of running many cells simultaneously. That can be done through a sampling protocol.

Maybe an advanced cold fusion lab would indeed have a mass spectrometer that could be used for in-line, real-time analysis, and then used for analysis of samples that are stored up for later study.

It looks like a helium mass spectrometer might be rentable for on the order of $2K - $3K per month. These are used as leak detectors. Used mass spectrometers seem to be going for $10K - $40K.

A Varian 979 Helium Mass Spectrometer Leak Detector is on offer on eBay, for quite some time, at $15,000.

I think it likely that someone with access to an adequate helium mass spectrometer would be willing to provide services at a reasonable cost. It's not impossible that such services could be donated. The cost of equipment does not seem to be so high that, if a analysis services are not available, a provider could be set up for that purpose. The real cost of heat/helium measurements, as to the labor of preparing the equipment, running the experiments, and collection of samples, is quite likely much higher than the cost of helium analysis.

P.S.
I cited some figures for helium leak detectors. I don't know how capable these are of separating out the D2 peak. I do know that low-mass mass spectrometers are readily available that can easily resolve the peaks. As I mentioned, Storms has one. D2 can also be eliminated from the gas stream, but that introduces a possible source of error.

It's pretty much a non-issue, really, because it is not necessary for the researchers to own a mass spectrometer. The key will be a sampling and testing protocol, especially one that allows storage of samples for extended periods if necessary. That could be difficult enough! But it is doable. And blinding the tests so that the helium testers don't know anything about the sample origins can cover a host of contingencies, assuming that control samples are included, some as ambient air, perhaps, some as coming from dead cells, etc.

12) Posted by X7:

Here is a typical university in-house rental fee for a mass spectrometer:

Students who have a demonstrated need for the unique capabilities of this instrument can be trained to run their own samples. The training is billed at a rate of $100 per hour, with the usual training session taking 4 hours. Up to four students can attend the same training session to divide the cost.

Non-routine samples submitted to us to be run on the Q-TOF are billed at $100 per hour.
Student use of the instrument is billed at $50 per hour.

13) Posted by X8:

X5, a leak detector is useless for separating He from D2. These instruments focus on mass 4 but they are

not designed to separate D2 from He. After all, no D2 is expected to be present in the apparatus being tested for leaks by applying He.

The only error is just how much He is present. Several methods can be used to reduce this error by calibration.

14) Posted by X9:

X8, Can your spectrometer distinguish D2 from He-4? Most cannot do this.

15) Posted by X8:

The spectrometer is made by MKS and has a range of mass 1 to 6. He and D2 are cleanly separated.

16) Posted by X10:

Folks, a brand new MKS MicroVision II for measuring deuterium versus helium cost about $12,000 according to the company rep. It operates at a pressure of 1E-5 torr(?). It has a ten week lead time to order.

17) Posted by X6:

The costs reported in this thread are clearly negligible, in comparison with how much the DOE has been spending yearly to support hot fusion research. Failure to perform replication of ^{4}He experiments, during the second DOE investigation, was certainly not due to prohibitively high costs. [That investigation was described in my article at]:

http://pages.csam.montclair.edu/~kowalski/cf/409social.pdf

In philosophically-oriented article (to be published in 2013?) I wrote that "the DOE experts were not asked to perform correlation experiments; they were asked to read the report submitted by five CF scientists (21), and to vote on whether or not the evidence for the claim was conclusive. Such a way of dealing with a controversy was not consistent with the scientific method of validation or refutation of physical science claims."

412) Summary of a Recent Discussion

Ludwik Kowalski:
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, USA

Edmund Storms (1, 2) has been studying cold fusion (CF) phenomena since 1989. He now refers to them as LENR (Low Energy Nuclear Reactions). Today, on 2/22/2011, he posted the following brief summary of his ideas, at our private Internet list for CMNS researchers:

References

1) http://home.netcom.com/~storms2/index.html

2) E. Storms "Science of Low Energy Nuclear Reaction: A Comprehensive Compilation of Evidence and Explanations about Cold Fusion" at: http://www.amazon.com/Science-Energy-Nuclear-Reaction-Comprehensive/dp/9812706208

==========

"The phenomenon called LENR has several basic features that have to guide a model and were, ironically, the cause of its rejection. These features are:
1. The mass-energy is released in small quanta rather than as energetic particles, as is the normal case by nuclear reactions and hot fusion in particular.
2. The phenomenon is very rare on a geological time scale and difficult to replicate in the laboratory.
3. The nuclear products are not the expected ones based on experience with the hot fusion process.
4. The process only occurs in condensed matter, especially in certain solids.
5. The process does not require applied energy to be initiated although extra energy will increase its rate.

These features do not need additional demonstration or experimental detail to be accepted as real by a knowledgeable observer. The challenge is to create a logically consistent model that does not conflict with what is known about "conventional" nuclear reactions and is consistent with what is observed. The need for such an explanation, even thought it is incomplete, flows from the fact that this phenomenon is too complex to investigate successfully using trial and error. In fact, all experiments in science are guided at some level by an explanation, which is sometimes informal and based on current observed behavior but more often is based on established laws of Nature. The best model is the one that is consistent with the largest number of observations and makes accurate predictions about previously unseen behavior. These models are not designed to or are required to justify belief that the phenomenon called LENR is real. They are required to guide effective research that might eventually provide the required justification for acceptance.

To do this, a few assumptions are required. These assumptions must be consistent with the laws or rules known to apply to the chemical systems in which the LENR effect occurs. Agreeing on which assumptions are consistent with the required rules (laws) and which are not, has been the basic cause of conflict and argument about the proposed models.

Before listing the assumptions, we need to acknowledge that several nuclear processes and reactions can occur in a material at the same time. For the discussion to be clear, we need to focus on only one reaction at a time. Initially the discussion will focus on the most active reaction that results in the major amount of detected heat energy.
Several models propose processes other than fusion. These models involve either creation of neutrons or their release

from a stabilized form in the material. The resulting neutrons then interact with nuclei to form the observed nuclear products. This discussion is not focused on this claim other than to note that the observed behavior is not consistent with this process and many parts of the model conflict with basic laws of nature. Therefore, this path will not be explored here. The present discussion focuses only on fusion of hydrons as the process called LENR.

Three basic processes have to occur at the same location and at the same time. No significant delay may separate these three events. These events are:

A. Two or more hydrons must occupy the same location at the same time in the material.
B. Two or more hydrons must overcome the Coulomb barrier separating them.
C. The resulting reduction in mass-energy must be converted to heat-energy.

The basic assumptions used here are:

1. The behavior involves only one basic mechanism that occurs at the same basic location in the active material being examined.

2. The nuclear process can involve any isotope of hydrogen.

3. The entire process must be consistent with all known laws of physics and chemistry, although gaps in knowledge are accepted.

The above assumptions and observed behavior alone allow a useful model to be proposed. To start the process, the location of the nuclear process in the material must be identified. I call this location, the Nuclear Active Environment (NAE). Consequently, a new assumption is introduced that says:

4. The NAE is a new physical structure having no connection through quantum mechanical processes or the laws of thermodynamics with the atoms that form the lattice structure.
This assumption eliminates a number of proposed models from consideration, which is discussed later.

I have explained previously why I propose that the nuclear reaction occurs in cracks of a critical size, so I will not repeat this argument here. Once the crack forms, the three basic processes (A, B, C above) must take place in this structure. The model now must describe how this series of events happens.

First, the hydons that are present in the surrounding lattice as H+ or D+ must enter the crack and create a structure that is able to reduce the coulomb barrier. The only way this process has been seen to occur is either by applying enough kinetic energy to force the two nuclei together (hot fusion) or by insertion of a muon between two D. Both methods produce the typical and expected energetic particles. Use of ion bombardment has revealed that the electrons normally present in a material are able to reduce the magnitude of the Coulomb barrier for the conventional hot fusion process. Consequently, the logical implication is that electrons are also involved in the LENR process, but in a different way.

Regardless of their involvement, the Coulomb barrier reduction process must take place in a manner to allow the mass-energy to be released gradually in small quanta before the fusion process is complete. Otherwise, if mass-energy remains in the final structure, it must result in gamma emission to be consistent with known behavior. At this point in the model, we are faced with a dilemma. What process can be proposed that satisfies the observed behavior but does not conflict with known and accepted concepts in physics? All of the proposed models are faced with this dilemma while attempting to solve the problem different ways. The only question is which of the proposed methods (theories) provides the most logical description of observed behavior and best predictions, because they all contain the consequence of this dilemma. Can we focus the discussion on this dilemma?

Philosophical and Social Aspects of the Cold Fusion Controversy

Presented at the

IVe Congrès de la Société de Philosophie des Sciences

June 1, 2012, Montreal, Canada

Ludwik Kowalski (see Wikipedia)
Professor Emeritus
Montclair State University, NJ, USA

Abstract

The area of research known as Cold Fusion (CF) is the arena of a science-and-society feud. The conflict is unprecedented in terms of duration, intensity, the caliber of combatants, and the deviation from basic principles of scientific methodology. It is also unprecedented in terms of two formal governmental investigations of the field. The US Department of Energy (DOE) has evaluated the CF claim--a chemical process triggering a nuclear process. The claim was rejected on "theoretical grounds," not by performing better experiments. The self-correcting nature of scientific progress, in both social and natural sciences, depends heavily on peer review. Depriving PhD-level scientists of that process, as practiced by editors of some scientific journals, violates the "New American Physical Society's Ethics Guidelines," described in the January 2003 issue of Physics Today. Such distortions of scientific methodology are worth studying.

1. Introduction

Scientific methodology (1,2) refers to the set of norms developed to deal with mistakes and controversies in scientific research. Most mistakes are recognized when new results are discussed with colleagues, or via the peer review process. Occasional errors in published papers are subsequently discovered during replications conducted by other researchers. Scientific results, if valid, wrote Huizenga, must be reproducible on demand. “When errors are discovered, acknowledged and corrected, the scientific process moves quickly back on track, usually without either notice or comment in the public press (3).” The process, in other words, is expected to be self-corrective.

The so-called "scientific method" is not a list of divine commandments. It is a set of norms described by scientists, and by those who observe their ways of working. The author of this article is a retired nuclear physicist who has observed cold fusion researchers over the last ten years, and participated in several CF conferences and three cooperative replication projects (in which the claimed results were not confirmed). The CF episode is an unusual controversy resulting from a sensational 1989 announcement made by Fleischmann and Pons (F&P). The event (4,5,6,7,8) divided physical scientists into two feuding camps (9,10,11,12,13,14). This is a rare example of a situation in which the expected self-correction of the scientific process was essentially stopped by two formal governmental interventions.

2. Role of Accepted Scientific Theories.

Why is the CF controversy unresolved? Because CF experimental claims are not reproducible on demand, and because they conflict with the generally accepted theory of nuclear reactions. A theory, in this context, is a logical/mathematical structure that agrees with a wide range of already verified experimental data. Scientists know the rule--theories guide but experiments decide. But they are very reluctant to abandon accepted theories. To be reluctant means to insist on additional verification of new experimental results.

Referring to such situations, Huizenga wrote (3): “There are occasionally surprises in science and one must be

prepared for them." Theories are not carved in stone; scientists do not hesitate to modify or reject them when necessary. Rejecting a claim because it conflicts with a theory is not as convincing as rejecting it on the basis of reliable empirical data. In that sense methods of validation of claims in physical and social sciences are similar. Scientific theories are models of objective reality; they are often changed, or modified, when new facts are discovered.

3. Levels of Confidence in Scientific Claims: Data and Explanations.

A discovered experimental fact is usually presented to the scientific community, to be independently confirmed or refuted. Experimental results are accepted--at a high level of confidence--when they become reproducible on demand. Absence of such reproducibility justifies suspicion of possible errors or fraud. Methods of validation of theories (explanations of facts) are slightly different. A new scientific theory is also presented to a community of experts, to be independently evaluated. Their level of confidence in a theory depends on the validity of underlying assumptions and on the rigor of quantitative analysis. But even a most reliable scientific theory, called a law, is said to be falsifiable, in principle, when conflict with reproducible-on-demand data becomes undeniable (15). Such unusual conflict could trigger a scientific revolution (16).

To explain something usually means to identify causes and to construct a logically satisfying model of reality. An attempt to explain a fact, or to resolve an apparent logical conflict, usually leads to discoveries of other facts. A classical example was the discovery of planet Neptune, in 1846. A more recent and less widely known example was the discovery of a subatomic particle named neutrino. Experimental data collected in the 1920's showed that beta rays (electrons emitted in radioactive decay) had lower mean energies than expected on the basis of the theoretical $E=mc^2$ formula. Austrian theoretical physicist W. Pauli solved this "logical inconsistency" by suggesting that tiny neutral particles, later named neutrinos, were responsible for the missing energy. His hypothesis was formulated in 1933. Experiments confirming the reality of neutrinos were performed, 23 years later.

4. Unfortunate Terminology

The essence of the discovery announced by F&P was "excess heat." Their small electrolytic cell generated more thermal energy than the electric energy supplied to it. Trying to establish priority, under pressure from University of Utah administration, the scientists announced their results at a sensational press conference (March 23, 1989). They wanted to study the CF phenomenon for another year or so but were forced to prematurely announce the discovery.

The unfortunate term "cold fusion" was imposed on them (17). Why unfortunate? Because it created the unjustified impression that cold fusion is similar to the well known hot fusion, except that it takes place at much lower temperatures. This conflicted with what had already been known--the probability of nuclear fusion of two heavy hydrogen ions is negligible, except at stellar temperatures. It was a mistake to interpret experimental data before the results were recognized as independently reproducible. In fact, F&P had no evidence for the emission of energetic ^{1}H, ^{3}H and ^{3}He products, listed in their first published paper (4). The only thing they knew was that the measured excess heat could not be attributed to a known chemical reaction. Claiming that the measured excess heat was due to a nuclear process was premature. The adjective "non-chemical" does not automatically translate into "nuclear."

Suppose the discovery had not been named cold fusion; suppose it had been named "anomalous electrolysis." Such a report would not have led to a sensational press conference; it would have been made in the form of an ordinary peer review publication. Only electrochemists would have been aware of the claim; they would have tried to either confirm or refute it. The issue of "how to explain the heat" would have been addressed later, if the reported phenomenon were recognized as reproducible-on-demand. But that is not what happened. Instead of focusing on experimental data (in the area in which F&P were recognized authorities) most critics focused on the disagreements with the suggested theory. Interpretational mistakes were quickly recognized and this contributed to the skepticism toward the experimental data. Using unconfirmed data to justify the nuclear origin of excess heat, by F&P, was inconsistent with the prevailing norms of scientific methodology. A more recent case of violation of scientific norms, by a CF researcher, Andrea Rossi, is described in (14).

5. Two US Government Investigations of CF.

The significance of CF, if real, was immediately recognized. Some believed that ongoing research on high-temperature fusion, costing billions of dollars, should be stopped to promote research on CF. Others concluded, also prematurely, that such a move would be opposed by “vested interests” of mainstream scientists. Responding to such considerations, the US government quickly ordered a formal investigation.

A panel of scientists, named ERAB (Energy Research Advisory Board), and headed by John Huizenga, was formed to investigate CF in 1989. The final report (18), submitted to the DOE several months later, negatively interfered with the normal development of the field. Modest financial support for additional CF research, by the DOE, NSF, and other agencies, was practically stopped after the report was published.

It is interesting that only one of the ERAB's six conclusions referred to CF experiments; the remaining five conclusions were about anticipated practical uses of CF, and about various aspects of the suggested interpretation of results. Instead of focusing on reality of excess heat, critics focused on the fact that the hypothesis was not consistent with what was known about hot nuclear fusion. The same observation can be made about the six ERAB recommendations. Only one of them referred to possible experimental mistakes. It is clear that the ERAB observations were based mostly on ”theoretical grounds,” not on independently performed experiments. The unfortunate governmental intervention had one serious and unprecedented consequence--editors of some scientific journals started rejecting manuscripts written by CF scientists, bypassing peer review (19).

The second DOE investigation (20) of CF was announced in March 2004, nearly 15 years after the first. A group of 18 experts was selected to review new CF claims, such as linear correlation between excess heat and generation of helium. Helium was reported to be produced at the rate of one atom for approximately 24 MeV of released thermal energy. This was consistent with the theoretical $E=mc^2$ formula for the suggested radiation-free D+D->He fusion. But the DOE experts were not asked to perform correlation experiments; they were asked to read the report submitted by five CF scientists (21), and to vote on whether or not the evidence for the claim was conclusive. Such a way of dealing with a controversy was not consistent with the scientific method.

Ideologically and politically motivated rejections of scientific claims are not new. Giordano Bruno and Galileo Galilei are well known examples. Lysenkovism--Stalin's discrimination of geneticists--is a more recent illustration. And cybernetics, in the Soviet book entitled “Short Philosophical Dictionary,” was defined as “bourgeois pseudo-science serving American imperialism.” Ludwik Kowalski accepted this kind of "truth" as a communist student in Poland (22). What can be done to make sure that similar discrimination will not be used in the US, to impose "the truth" about evolution, stem cell research, etc.?

6) Conclusion: More Questions Than Answers

Long-lasting controversies about scientific discoveries are not new. Alfred Wegener's theory of continental drift is a good illustration. Mainstream geologists rejected experimental data supporting his now-accepted theory for half a century. The CF controversy, however, seems to be different both in terms of governmental involvement and in the caliber of adversaries on both sides of the divide. Huizenga and Fleischmann were indisputable leaders in nuclear science and electrochemistry. Most leading CF researchers are PhD-level scientists. The same is true for many scientists who reject CF claims.

The long-lasting CF episode is a social situation in which the self-correcting process of scientific development was not allowed to evolve. To what extent was this due to extreme difficulties in making progress in the new area, rather than to negative effects of competition, greed, jealousy, and other "human nature" factors? Such unanswered questions (23) are worth addressing in the context of debates about science and society.

One thing is undeniable; the world is still waiting for the first reproducible-on-demand demonstration of a nuclear effect correlated with a chemical process. No progress is possible when reported experimental data cannot be reliably replicated in other laboratories. Considering potential CF benefits, and relatively low costs of research in this area, the DOE should have helped to resolve the controversy, one way or another, in a well-equipped national laboratory, during the second investigation. But it failed to do so. How can such a policy be explained? Why is CF research

allowed to stagnate without financial support? These questions also belong to debates about science and society. Will the past 23 years be recognized as the painful beginning of a new paradigm, similar to those described in (16), or will this period be known as a pseudoscientific episode, similar to those described in (24)? How can the persistence of the CF controversy be explained? Were the US government interventions necessary or not?

414) Another Sample of Messages

March 21, 2013

Ludwik Kowalski
, Professor Emeritus
Department of Mathematical Sciences
Montclair State University Montclair, NJ 07043

==========

An interesting sequence of posts appeared on the CMNS list during the last three days. On March 18, 2013, I wrote: "I suggest that X1 et al. send [to the journal Naturwissenschaften] an article describing a reliable protocol for a demonstration of biological transmutation. Confirmation of their results, in another biological laboratory, would be a highly desirable step toward recognition of the main CMNS claim--a nuclear effect due to a chemical effect."

1) Responding to this X1 informed us that his article has been "accepted for publication in the very famous physical (nuclear) Elsiver journal and will be published this summer."

2) Quoting my suggestion Abd ul-Rahman Lomax (ARL) wrote: " Yes. It's an obvious possibility, an article on biological transmutation. The problem is that there has been no replication or confirmation. However, if someone does replicate, that might make for a fantastic joint paper for Naturwissenschaften. I'm not ruling out X1's submission, and, of course, it would be up to the editors of NW whather or not to accept it. But I do have concerns."

3) Then ARL added: "Dr. X1 gave me permission to share this email with the list; he wrote: "This process is possible in:

(a) any rapidly growing microbiological system (pure culture or microbiological association)

(b) at absence in a nutrient medium of required synthesized chemical element (e.g. iron) and its biochemical analogues (atoms with similar valency and
close ionic radius) and at presence of

(c) others micro- and macro-elements (that are necessary for growth) and

(d) chemical elements that are necessary for required synthesis (e.g. Mn55
and D)..... "

4) This was followed by my post. Addressing X1, I wrote:

*) First congratulations for publishing an important article in Elsiver. I hope it contains the description of a detailed reproduction protocol. If not then such a protocol is worth publishing, either by you or by a senior microbiologist working with you, in a journal read mostly by biologists. This would increase the probability that someone will actually try to replicate your results.

*) Responding to ARL you wrote: "I have one remark to the term 'biological transmutation. It is not a correct term! In our opinion, there are no reasons to consider the process of transformation of isotopes and elements during grows of biological system to be separate and different from the general physical forms of nuclear transmutation that can occur from comparable forms of transformation of isotopes through transmutation that can occur through alternatived processes, controlled by the laws of physics."

I also used the term "biological transmutation," first because other people used it, and second, because it is correct, in my opinion. It does not imply that physics is different. As we all know, physics is at the base of chemistry and chemistry is at

the base of biology. The "induced by neutrons," or "induced by alpha particle," does not mean it is not physics. The same is true for the term "induced by bacteria." or "biologically induced." Good luck,

5) Responding to another ARL's post, X1 wrote: "You wrote that 'For 'rapidly growing biological system' substitute 'any palladium metal.' For 'at absence' substitute 'loaded with deuterium.' Perhaps my concept is clear. Let's not make that mistake again.

This is incorrect and does not lead to positive results. One of the key words in the condition of biological transmutation is 'GROWING microbiological system'. Such transmutation process is possible only in 'GROWING' (dynamical, nonstationary) systems. In such systems the process of coherent suppression of Coulomb barrier action is possible (e.g. by formation of coherent correlated state). At use of dead microbiological cultures (stationary system from the physics point of view) our experiments always were unsuccessful! This is the general rule (for both biological and pure physical systems) - in stationary system LENR experiments always are unsuccessful."

==========

Then a different thread of messages appeared. It was triggered by an article posted by Peter Gluck, at his own website:

http://egooutpeters.blogspot.ro/2013/03/early-history-of-cold-fusion-three.html

1) Responding to this Ed Storms, the author of a well known book on Cold Fusion, wrote: " Peter has raised an important subject, ... I see no solution to the general rejection until a device having a demonstrated level of commercial power has been achieved. Only then will the claim be accepted even by people who insist the phenomenon violates accepted theory. ..."

2) Responding to this I wrote: "Yes, durable commercial success would convince skeptics that something new has been discovered and became useful. But I would not use the word "only." A reproducible-on-demand device, demonstrating transmutation (of any kind), would also convince honest skeptics."

3) Responding to this Storms wrote: "The problem with reproduction on demand is that the person doing the reproduction has to invest in a special calorimeter, learn how to use it, and spend time and money while not believing the effect is real. In addition, the level of power must exceed any imagined error. This is a lot to ask of a skeptic.

If transmutation is sought, investment must be made in the equipment required to make such studies. This cost is not trivial. People have already shown demonstrations without much effect. I believe that the ONLY proof would be a device that could be bought ready made and would be easily to setup anywhere. This device would have to make energy without stopping. Of course we can dream that science is fair and objective, but I think we have evidence that this is not true."

4) Referring to my suggestion to X1, not to mix theoretical considerations with experimental results, ARL wrote: " It's possible to present theoretical speculation in an original research report, but it must be done in such a way as to not overshadow the experimental results. For example, made up for an original paper from Pons and Fleischmann:

--- Conclusions ---

We have found anomalous energy in palladium deuteride at a density of X joules per cm^3, far in excess of what is known to be possible for chemistry, and we have exercised great care to rule out artifact. Given that heavy water results are far stronger than otherwise identifical experiments with light water, this leads to an obvious speculation of a nuclear source, but no nuclear products have been found that are commensurate with the anomalous energy, and a nuclear reaction under these conditions radically defies expectations. More research is needed to understand the source of this mysterious energy, and to confirm that there is no unidentified artifact.

5) Yes indeed, CMNR history would be different if the original CF paper ended with a similar conclusion. Thinking about this I wrote: "I would email this to Martin Fleischmann, if he were still alive, and ask him what prevented them from ending the 1989 publication in this way. Perhaps someone in contact with Stanley Pons will ask address this question to him. The reply would be an important contribution to history of science. And, if I recall correctly, Abd has nothing against being quoted outside of this list, provided it is attributed ho him."

6) ARL responded: " Sure. No problem. Perhaps I could answer. It just did not occur to them that they would be so viciously attacked. They made some mistakes, that's all.

The biggest mistake was probably a failure to fully disclose their experimental situation. The initial presentation of their results led to an assumption that one could just pour some heavy water in a jar, stick a palladium cathode in it, and load the cathode with deuterium, a well-known process, and, presto! a nuclear reacion, with neutrons, no less.

That led to a frenzy of attempted replications, it's said that something on the order of a million dollars a month was being spent -- or equivalent resources diverted from other pursuits -- in almost entirely failed replication attempts. And, then, finding no confirmation, physicists, especially, were *angry*.

I don't know that it could have been anticipated. Maybe. But maybe not. I bring this up now, not to criticize Pons and Fleischmann, whose major discovery far outshines whatever errors they may have made, but so that we can avoid repeating the errors."

7) To which X2 responded: "The original F,P & H paper was thoroughly bad all round, from a man (MF) who never wrote bad papers. This I attribute to haste, an excess of lawyers and administrators, and severe distraction on the part of Martin and Stan. The conclusions could have been better, errors could have been eliminated and more technical details could (should) clearly have been provided. This last might have bounded some of the more inept attempts at "replication".

But I submit that no amount of semantic or sociological tweaking would have changed the basic outcome. If F&P were correct in their basic claim of nuclear level heat in the electrochemical D/Pd system (as now seems clear), then a large number of the sultans of science (the high energy and particle physicists) would be seen to be wrong in their basic thinking and approach to energy. Their access to a steady stream of unquestioned funding would be threatened. This could not be allowed. A nasty, threatening, passive aggressive over-response was the natural way for this group to respond (in much the same way some individuals do)."

8) Then Storms added: " I agree with Mike. In fact, the experience at LANL was typical. Initial interest was high and money was devoted to replication. We even talked with Martin and Stan directly. Nevertheless, even though the claims were demonstrated at LANL, the right people did not have success. The claims could not be replicated to the satisfaction of the physics community. Based on many discussions with physicists, such people simply cannot understand the need for a special chemical environment to initiate the process. They, like many people, reject the idea that chemistry has any effect on a nuclear reaction. Consequently, if the nuclear effect cannot occur only by applying energy, it is impossible. When this attitude is added to the need to protect self-interest, the future rejection of CF was inevitable regardless of what F-P said.

9) There might be other messages; but I will stop reporting by showing what was just posted by Paul Biberian, who has been in contact with Stanley Pons. Paul wrote: " Dear all, I believe the answer to the lack of acceptance of CF is in the first paragraph that Stan Pons wrote for my book:

'**My name is Stanley Pons.** In March of 1989, I was one of the co-authors of a public announcement made on behalf of the University of Utah (USA) of the results of a set of scientific experiments conducted there regarding a phenomenon that was soon to be labeled “Cold Fusion”. I will not dwell here on the overwhelming maelstrom of life-changing, personally catastrophic events immediately following that announcement, other than to say that within a short period of time I found the subject had already been declared American dead, American embalmed, and American buried, and myself unofficially exiled forever by the then “president’s men”.

The last two words indicate the source of the problem. Regards."

==========

415) Another CF Conference is Approaching

July 1, 2013

Ludwik Kowalski

http://csam.montclair.edu/~kowalski/life/intro.html

* * *

1) The next International Cold Fusion conference, ICCF18 will begin in four weeks.

http://iccf18.research.missouri.edu/program.php

This probably explains why so many messages, both theoretical and experimental, have been posted on our private list for CMNS researchers. Responding to a post from X1, I wrote:

2) I am sorry to repeat trivia--not every heat-generating process, especially when thermal energy is generated at the rate of 1 W or less, is nuclear.

The NS part, in the name of our field, refers to unexplained nuclear processes, such as transmutation (for example, generation of helium or copper), emission of nucleons (such as energetic neutrons, protons and alpha particles), emission of gamma rays, changes in isotopic compositions, etc.

Demonstrations of nuclear signatures are extremely valuable, even when there is no evidence of excess heat. The same is true for demonstrations of unexplained excess heat, not correlated with a nuclear process. Such demonstrations are also important, both scientifically and technologically. But they do not belong to our CMNS field. Do you agree?

3) Responding to this, X2 asked: "Would you consider Deep Dirac Levels to be atomic or nuclear?" My reply was also short: "Deep Dirac Levels cannot be characterized as either only atomic or only nuclear. I was thinking about experimental signatures of CMNS."

4) Responding to X2, X3 wrote: "I get very confused by such discussions. First of all, a clear separation exists between chemical and nuclear behavior based on the huge difference in energy and the centuries of experience that show a clear difference between chemical and nuclear behavior. Outside of CF, these conflicts in understanding do not exist. In fact, the clear understand in conventional science is that CF simply cannot occur in a chemical environment, hence is a false claim.

The Deep Dirac Level is pure imagination that X2 is trying to relate to a behavior. Only the behavior of CF allows this DDL structure to be suggested because X2 can claim the normal rules of chemistry and/or nuclear physics do not apply to CF. Once the accepted rules are applied, the DDL must be rejected.

I suggest the Deep Dirac Level is neither only chemical nor only nuclear. It falls in the twilight zone occupied by the hydrino. It might apply to CF but if it does, it would also apply to many

chemical processes where its action would be easy to detect. Unfortunately, X2 [in earlier messages] has not shown this connection so the relationship to chemistry is unknown and apparently unknowable.

The experimental signatures of CMNS are clearly nuclear, as Ludwik says. Therefore, we must find a way to explain how this happens in a chemical structure without violating the basic rules accepted by conventional science. Any other approach will fail, as has been the case so far.

5) Responding to my message, X4 wrote: "Ludwik, what an odd and unexpected statement.

If one-watt heat signals without a corresponding nuclear signal are outside the scope of CMNS, then so is the seminal work of Fleischmann and Pons. Their nuclear
claim rested on the observation that the energy produced in their cells exceeded known chemistry, so the "hitherto unknown process" must be nuclear. So, I strongly disagree with your statement.

6) Instead of asking about "odd an unexpected," I wrote: Let me say the same thing in a slightly different way. Presence of unexplained excess heat may or may not be due to a nuclear process; it can be due, for example, to a totally unknown process, as just stated by X4, or to a combination of two or three known processes (perhaps optical and magnetic). What is wrong with such observations?

7) Quoting my first post, X5 wrote: "I strongly disagree with Ludwik's statement. He has missed the point entirely. The energy output is undefined. To attribute it to cold fusion is self-limiting. Limiting LENR to fusion is the basic error of the field.....[The last sentence, about being "trapped in a metaphor," is omitted; I do not understand it.]

8) Quoting X5, X3 wrote: "I think you have missed the point instead of Ludwik. We have proof that a nuclear process occurs in what appears to be ordinary material that produces energy and detected nuclear products. When this happens, it is called CMNS. Of course, other sources of novel energy might exist in Nature without a nuclear reaction being produced. However, these processes are not called cold fusion. We need to be clear about this. The energy source is defined. We only are uncertain about the process.

If you want to discuss a different source, you are free to do this, but do not confuse it with LENR."

9) Responding to X3, X2 wrote (in part): "It is legitimate for you to say you disagree with my view [an explanation based on Dirak levels] and then decline to say why or to decline to defend your position. But, your repeated statements and innuendos are simply an indication of your frustration at your models not being listened to in the way you insist....."

10) X6 wrote: Pons and Fleischmann turned out to be correct, the process was indeed nuclear. However, the energy density was circumstantial evidence of "nuclear," not direct evidence, and some other unknown but non-nuclear reaction could have been causing the apparent high-energy-density anomaly.

A fundamental error was made in asserting a paradigm shift without direct evidence.

I do understand why it happened, but we must understand this point, because we keep focusing on weak evidence, circumstantial evidence, before we have clearly conveyed the *direct evidence. *

Weak evidence of "nuclear":

1. Excess Heat. Suppose the source of the heat is hydrinos, or some other unknown non-nuclear

phenomenon. If the reaction is "unknown," what is the basis for asserting that it is *nuclear.* It is a *reasonable surmise,* but against this reasonable surmise would be a huge weight of assumption about what is possible.

2. Transmutations other than to helium, including tritium, radiation, etc. These are all at levels *far* below those needed for association with the observed excess heat. These *are* nuclear evidence, but could indicate some reaction other than what is producing the XP. Perhaps nobody ever looked so carefully before. This evidence was plagued by irreproducibility and vulnerability to various artifacts, and this is exactly what was the case with the original PF claim of neutrons. Some experiments rise to the level of strong evidence that "something nuclear is taking place,* but *what*? *It may have nothing to do with the heat-producing effect.*

Direct evidence became available with heat/helium, and that remains practically the *only* direct nuclear evidence as to the main show in the FPHE.

11) Commenting on the last sentence above I wrote: " Instruments needed to replicate the heat/helium experiments certainly exist in several US national laboratories, and elsewhere. They are probably used, by highly qualified scientists, to conduct different kinds of investigations. The DOE knows this. The cost of organizing several independent heat/helium experiments, similar to those already performed, would be a small fraction (probably much less than one percent) of the approved DOE or NSF budgets. What can be done to force the DOE or NSF to organize several independent replications?

12) X6 responded, in part:

... While I do have personal ideas about what should be done, my real proposal is to develop community process, so that what we do is a community effort, with broad consensus behind it. .....If the DoE or other interested agency is *not* convinced of the reality of cold fusion, and regarding helium as the major ash of the FP Heat Effect, after a full review of the literature on heat/helium, then it would be urgent to confirm or falsify the claim of a heat/helium correlation. That is a *central issue,* for anyone not convinced. I advise rigorous refusal to speculate on the specific mechanism, I would use the word "mystery," over and over. "Mystery" does not attack existing physics, but, of course, it allows room for something new to be found. ...

13) Two other researchers also commented. I hope the topic will be discussed at the upcoming ICCF18 conference, and that either DOE or NSF will subsequently organize attempts to replicate helium/heat experiments.

14) On Jul 2, 2013, X3, replying to another post, wrote:

Past experience shows that most of the He is NOT trapped in the cathode. The He is produced so near the surface that at least 1/2 leaves the material. The remaining He can be released by melting the metal, as you say. In the case of the sample covered with gold, even less helium might remain in the metal. However, in this case, only the gold would have to be melted if the NAE is in the gold.

Replying to this, I wrote:

If this is true then the following method can be used to determine the number of He-4 atoms per square centimeters accurately.

Suppose a Pd foil (with a layer of He-4 atoms below its surface) is exposed to a beam of alpha particles, or protons, of known energy, for example, 10 MeV, from an accelerator. Differential cross sections of Rutherford scattering, at various angles (for example 150 degrees), are easy to calculate from the well known (and experimentally confirmed) textbook formula.

Knowing the cross section one can easily calculate the "target" mean thickness (the number of He-4 atoms/cm^2) from the measured beam intensity (counts per second per steroradian), at a known angle. The method is very reliable; I have used it many times in working with various thin targets. But this was about 30-50 years ago. Our thin solid targets were always in the center of a vacuum chamber. The accuracies, typically 1 to 3 percents, were usually sufficient for our purposes.

A gas target below a metallic surface is likely to present some specific technical problems. But distinguishing ions scattered on He from ions scattered on Pd or Au (at a given angle) would not be difficult (on the basis of their kinetic energies). The kind of scattered ions, their energy, and scattering angles (better several than one), should be chosen carefully. Instruments (and experts) to perform such measurements are likely to be available in many nuclear labs, for example, in Berkeley, Brookhaven, Los Alamos, etc.

P.S. I forgot to emphasize the obvious--what is measured is the amount of He remaining, not the amont of helium created during electrolysis. Some He-4 atoms might escape from the cathode during electrolysis, others might escape during subsequent manipulations, for example, into air or into the vacuum of a scattering chamber.

Suppose that 90% of He-4 escapes. Suppose that this fact is not known, when the amount of thermal energy per atom (created during electrolysis) is calculated. In that case the calculated MeV/atom would be ten times higher than in reality.

ADDED ON AUGUST 5, 2013 (AFTER THE ICCF18 CONFERENCE)

14) X7 wrote:

Having read all the proposed theories in an attempt to find one that can guide useful research, I'm at a loss to answer a basic question. The current belief is that no theory successfully explains cold fusion. While I agree, I ask how can this situation be changed?

For a theory to be accepted, it must pass agreed upon tests. To do this, the tests must be clearly identified and given enough importance to encourage their undertaking. No time and money will be used to test a theory that contains obvious flaws, is ignored by scientific peers, or does not identify the required unambiguous tests. Reading the various papers describing theory and listening to the discussion on CMNS and Vortex, I see no effort to satisfy these requirements. I see no effort being made to actually find and test an explanation for cold fusion. Instead, everyone has a theory based on his own limited knowledge of the phenomenon using his own limited understanding of Nature. None of these proposed explanations contain testable behavior or even plausible insight. A few explanations have been given wide circulation in the literature, but no general acknowledgement of their being correct is given by other theoreticians. I see no results from successful tests being published, even by the originator of the theory. In other words, I see no serious effort being made to actually agree on an explanation - the myth of no explanation being sufficient.

The idea behind a predictive test is also not clear because this requirement is generally applied to mathematical theories. Such theories spring from the imagination, after which a prediction needs to be compared to how Nature behaves. But, theories can also be based on how Nature actually behaves using a large collection of behavior that is combined in the theory, such as the Laws of thermodynamics. Such laws can be said to be tested even before they are fully formulated. They are accepted because they are consistent with a wide range of behavior, most of which was obtained before the theory was even created.

I suggest the latter kind of theory must be created to explain cold fusion. Thousands of behaviors have been observed related to the phenomenon. We are no longer ignorant about how cold fusion behaves. In addition, modern science understands what behavior is possible and what is not within a chemical structure. Only lacking is knowledge of these facts by people attempting to provide an explanation. Is it asking too much for this knowledge to be focused on trying to determine which explanation to test and apply? Is it asking too much to stop playing mental games and get down to work trying to actually find a useful explanation? Can we agree on the reality of basic behavior when CF occurs and

on basic conflict with known laws and expected behavior when a theory is examined?

15) Responding to the above, I wrote:

The following three steps toward the first accepted CMNS theory are widely known:

a) Someone describes a protocol for a reproducible-on-demand demonstration of a nuclear effect (such as transmutation, emission of gamma rays, etc) due to a chemical process (such as electrolysis).

b) The demonstration is independently confirmed by others.

c) The reliable protocol and experimental results are then formally published in a refereed journal, for example, in our own JCMNS.

Many theoretical physicists are probably waiting for such publications. The first tentative theory will start guiding experimental research. It will become less tentative when theoretical predictions of unknown facts are confirmed.

This website contains other cold fusion items.

416) Reproducibility

Ludwik Kowalski; 9/19/2013
Department of Mathematical Sciences
Montclair State University, Montclair, NJ, 07043

CMNR researchers are well aware of the frustrating problem of irreproducibility of experimental results. This has been recognized in many posts at the CMNS forum to which I belong. Let me share the most recent posts on this subject; the authors are veteran CMNR researchers.

X1 wrote:

The problem has a temporal component, there are setups that were reproducible in the past, but we need systems that are reproducible NOW. Patterson is a very tragic example.

X2 responded:

I keep hearing about reproducibility, but the concept seems ill defined. Do you mean reproducible with the same material in the same device by the same experimenter, materials from different sources, attempts by different experimenters with different systems and different materials??? How long does the experimenter try till they give up?

Do you mean just blindly going through similar motions without regards to such things as (I have seen all these problems-) disregard as to handling cathode surfaces, leaving D2O open in humid environments, connecting to constant voltage instead of constant current, loading at high currents to "speed things up", disregard as to the temperatures when loading, not anodize cleaning, having electrical joints inside of cells, venting to the humid atmosphere directly instead of through bubblers.

It is nearly impossible to tell people everything they shouldn't do. It is like going into McDonald's and saying I don't want a pizza, I don't want spaghetti, I don't. .... How many things would you have to say not to do? You tell them what you do want and hope that they are "skilled in the art" and have done 20 years of their homework.

I will admit that I cannot just take a random raw piece of Pd or Ni and get identical results. But if you let me screen them, I can get better success ratios. Such selection criteria has been around since '94 - ICCF-4, and at least one protocol on cold working and cathode prep. since '04 - ASTI-5.

Perhaps the most forgiving approach seems to be co-deposition onto Au or Au plating. But I know I was saddled with trying to do a project where they wanted me to follow a specific co-dep protocol that called for co-dep on Cu. Disaster. I think they wanted failure for political purposes. But if you want a high level of success I would say start with co-dep of Pd (or even better Pd with additives) onto Au in D2O and with a Pd anode.

The next point is that some comments above seem to tout "significant levels of power". I don't really know what that means to others. I guess people have been looking at the claims of kW and MW by some. To me significant levels is just 5 or more sigma above your error bars.

So to me the arguments concerning "reproducibility" are just red herrings. Even if I get 1 out of 5 systems to give heat after carefully screening and handling materials and get 4 or 5 sigma signals, I think that is very significant. Many great technologies started with much less. (say early rockets, early transistors- I remember going to the old TI quonset

huts, where DFW airport is now, and going through barrels of out of spec transistors to make my shortwave radio).

The problem is not reproducibility; it is that people choose to not believe. There is enough data out there for those who look.

X3 responded:

Nice post X1. The apparent irreproducibility simply means we do not recognize, acknowledge, understand or control all important input parameters to the effect (or effects) we are studying. There is no magic here, our systems are causal, what comes out is conditioned and determined exactly and completely by what goes in. This speaks to the need for more science, more research, to specify completely all relevant input variables. In some ways the apparent irreproducibility is comforting since systematic errors tend to exactly reproduce. But as Peter (G) suggests, it is tiresome and an impediment to the engineering scale up desired both for practical reasons and to persuade those who choose not to look at data already generated.

If we cannot control everything that is needed (in part because we do not know what they all are), one thing is to ensure that a multiplicity of desired input configurations are present, while ensuring that none of the known undesirable conditions occur, and that a multiplicity of potentially relevant stimuli are provided. Such an experiment is your " co-dep of Pd (or even better Pd with additives) onto Au in D2O and with a Pd anode" to which I would add "stimulated by as wide a range of frequencies and modes as you can launch and accurately measure". Co-dep is guaranteed to be irreproducible - what you are relying on is that the necessary input configuration is present in sufficient quantity (somehow and somewhere) to observe an effect. I "know" (i.e. strongly suspect) that the effect we are seeking is multi-resonant so i want to provide a trigger with as many frequencies and amplitudes present as possible.

X1 might say that this is cheating. The proposed experiment is intended to achieve an artificial statistical reproducibility by acknowledging a basic lack of knowledge of what we need to construct and how we need to stimulate it. But given such statistical reproducibility we could begin to refine the deposition process to see how particular morphologies perform, and hone our inputs to see which are effective, preferably by interrogating the system and using feedback. It is not so hard. What you acutely state is correct: knowing what not to do (and then not doing it) is the key.

X4 responded:

Reproducibility means that a new sample can be made the same way and produce the same behavior. It means that this can be done at will. The electrolytic method has become increasingly reproducible, as you describe, but only in the hands of an expert. However, even using these methods, success is not assured. As you say, many ways to screw-up are available. Nevertheless, a reproducible method is one that can be described easily and works in the hands of an idiot while producing a result at a magnitude that cannot be ignored by an idiot.

The gas loading method is not reproducible except perhaps in Rossi's hands. Z1, Z2, Z3 and Z4 have provided public demonstrations, but at such low power levels that the result can be easily rejected as error or chemical effect. On the other hand, you have seen the difficulty Rossi has had in demonstrating even a kW of power. Yes, people do not want to believe the effect is real. Even certain people in the field do not want to believe basic science is involved. If we want conventional scientists to believe, we need to act like conventional scientists and use the knowledge conventional science accepts as being true and correct, or give a very good reason why expectations are violated. This is not being done.

Significant level of power means a level that can be easily measured, perhaps in excess of 1 watt. It also means a level that does not require an excessive amount of time to collect detectable He or tritium. The exact numbers are unimportant since the levels generally are not close to what is required for effective study anyway.

Let's assume you are an industrialist who whats to fund a study. He comes to your laboratory and sees one or two people working in what can be called a hobby level. You show him a device you say is hotter than it should be. So he

asks questions:

1. How do you know it is hot? How do I know you have measured correctly?
2. How hot should it be? How do you know that?
3. What is making it hot? How do you know this?
4. Can it be scaled to useful levels? Have you tried?
5. Can you provide 50 pounds of the active material for my people to study at my company?

Can you answer all of these question in a way that can be understood by a person who only has a degree in business administration?

X1 added (responding to X2)

m
I have has some success using white noise stimulation.

I do have a problem with the term reproducible. I think that people tend to use it as having heat a large ratio of times for attempts and not reaching a point where you have reproducible results= same ratio of heat vs. attempts. That is to say: is it reproducible if you do 10 sets of 10 runs each and you get 3 out of 10 excess heat events on all 10 sets of 10? That is reproducible results- always getting 33% of them giving you heat. OH well. Again, no one seems to ever define what the mean by reproducible and I have asked.

m- I often "cheat" these days with multiple frequencies (white noise or shot noise) and having samples with thousands of different sites. (I am still using the Pd or Ni in powdered C with mesopores- I still think you need a lattice). I figure that having an array of sizes and sites and using a range of frequencies mean I will have better odds of getting something each attempt. The levels may change but there is something each time. - also I tried sparking through a fluidized powder system. It increases my success/trial but not the average excess level/event. (which is reproducible??) That seems to work "most" of the times but my control and input measurements are the pits.

Right now I am using solid state (packed loaded C and gas) with fast rise time current. (fast rise time short duty cycles seem to help) - I will just say : interesting. Right now I am playing with Ni and it is looking like that adding a little D to the H is useful. Like what we found with CETI- some D2O in there with the H2O helps.

Step 1 - load cold and slow.
Step 2 - treat your chemistry with respect
Step 3 - add heat and some B field
Step 4 - establish some non-equilibrium conditions for the D or H.

Or as I said in Boston - fill and slosh.

I have basically given up on the "prove it to me" route. I have also given up on the make electricity to charge something (car, light,. ..) I am now in make a heater and heat the lab mode. It may just be COP 1:1.25, but I will try. My wife says: you are having to heat the lab with electrical power already, just go ahead and heat it with CF- have fun.

D2
Ah, but a man's reach should exceed his grasp... Or what's a heaven for? - Browning

X5 responded:

X1 wrote: "Perhaps the most forgiving approach seems to be co-deposition onto Au or Au plating. But I know I was saddled with trying to do a project where they wanted me to follow a specific co-dep protocol that called for co-dep on Cu. Disaster. I think they wanted failure for political purposes. ... " **I worked on the same co-dep project as X1 describes above. The directive I received from one of the project managers was to "test the known protocol but produce XP if you can by any reasonable means". This is a paraphrase.**

Like X1, I didn't see excess power from bare copper cathodes but found when I plated gold over the copper cathode and then plated palladium over the gold I observed excess power on every test.

I also had to modify the original Szpak-Boss protocol slightly to use a lower concentration of PdCl2 at a higher initial current.

X1 added:

I so wish they had told me "any reasonable means" instead of stating a specific protocol in my "contract".

I never could get the original recipe on Cu to work. I could see some chemical loading events but never any sustained activity.

I would recommend that any one trying to do the co-dep to try to plate onto Au or Au plated surfaces. I also could get co-dep to work on Ag plates.

I also had higher excess in co-dep devices when I used additives with the Pd and when I used Pd anodes.
For me, I got the most "reliable" excess (for co-dep systems) when I used DC pulses at around 400 Hz and 10% duty cycles(but keeping about a 1V bias to prevent de-loading, higher temp runs (but loading at 10-15C).

X6 responded:

From this POV, X2 is so correct.

What X1 sees as a 'problem', is not. It reflects that presumptuous demands might be part of the problem.

Those of us who are actually working in the field of CF/LANR, and who have given, or are giving, open demonstrations cannot just drop what we're doing (probably working on improvements) and answer the same kinds of questions and demands, repeatedly.

The fact is that an open demonstration takes more than cahones, requiring also money, time, energy, persistence, and in a larger amounts (and requiring longer times) than "Monday morning quarterbacks" may realize.

Also, if X2 had not moved on from his earlier demo, he would be stalled and not doing further R&D, and he may not have developed his system(s) and learned and discovered, even more, which he did.

So, to summarize, it is not really a 'problem', but a probably the result of the experimentalist considering the risk/benefit ratio of continuing the 'same old thing' vs. trying something(s) excitingly, and interestingly, new with 'shift' and 'drift' of engineering and design and diagnostics, etc. etc. .

DEVICE, IN PARTICULAR A NEUTRON GENERATOR, HAVING A DETACHABLE HIGH-VOLTAGE CONNECTION

The invention relates to a device having a high voltage connection comprising a first insulator for supporting parts at high voltage of the device and a second insulator which comprises a second high voltage supply line, a gap between the said insulators being filled with an insulating liquid.

From the German Auslegeschrift I, I 65,706 a high voltage connection is known in whic insulating liquid is pressurized pneumatically in a gap between two insulators. In this high voltage connection the insulating liquid, for example oil, does not flow.

It is an object of the invention to the invention to improve the dielectric strength of such a high voltage connection. A further object of the invention is to provide a device having such a high voltage connection in which the insulating liquid is also used as a coolant.

According to the invention a device of the type mentioned in the first paragraph is characterized in that the device comprises an inlet and a.n outlet for the said insulating liquid and that the insulating liquid flows through the said gap. The insulating liquid preferably also flows through a cooling circuit in the said parts at high voltage.

By causing the insulating liquid to flow it is achieved that no so-called bridges are formed from contaminations in the insulating liquid. The flowing liquid may then alsa be. used for dissipating thermal energy to, for example, a heat exchanger. The dielectric strength of the connection is considerably improved by the invention. In devices of the type mentioned in the first paragraph producing ionizing radiation, for example neutron generators and X-ray tubes, the insulating properties of said oil under the influence of the ionizing radiation would moreover reduce rapidly when the oil is stationary in. the said gap. Since a large quantity of oil is used in a device according to the. invention of which a small part is present in the device for a short time only and is then subjected to the ionizing radiation, the insulating properties of the oil are maintained for a long . eriod of time so that the oil need be refreshed less p ft o en.

In a device according to the invention the said second insulator preferably hasa conical part which comprises an axial duct for supplying or draining the insulating liquid.

A device according to the invention may be in particular a neutron generator having an ion source at high. voltage with respect to metal parts of an envelope comprising a low pressure gas atmosphere, in which the said ion source is supported in the said envelope by a first fixed insulator which forms part ofthe said envelope and of a detachable high voltage connection, said high voltage connection furthermore. comprising a second detachable insulator which has a high voltage supply line and comprises a conical part and an axial duct and in which an insulating cooling liquid flows in a circuit which is formed by the said axial duct, a cooling circuit in the said ion source and a gap between the said fixed and detachable insulators.

The drawing shows a cross-section of the preferred .neutron generator.

The. invention will be described in greater detail.with reference to the accompanying drawing of a neutron generator according to the iμvention.

The 11eutron generator shown in the drawing comprises an envelope **1** which has a low pressure gas atmosphere and is provided with a metal part **2** and a fixed insulator 3. The fixed insulator **3** forms part of a detachable high-voltage connection **4** which furthermore comprises a detachable insulator **5** which comprises a high-voltage supply line **6.** The insulator **3** is conical and the detachable insulator **5** also has a conical part **7.** A narrow gap **8** is present between the insulator **3** and the conical part7 of the insulator **5.** An ion source**9** is supported in the envelope **1** by the fixed insulator **3.** Viathe high voltage supplyline**6** a positive voltage of approximately 250 kV with respect to the grounded metal parts **2** of the envelope **1** is supplied to the ion source 9. The ion source 9 comprises an anode **10** which cor1veys a positive anode voltage of approximately 5 kV w.ith respect to the cathodes *29a* and *29b* and the remaining metal. parts. of the ion source. Said anode voltage is supplied via a conductor I I whi.ch is present coaxially in the high voltage supply line 6,and the conductors **16** and **17.** In order to preverit breakdown, the gap **8** is filled with oil. The oil flows through the gap and is supplied via aninlet **12** and drained via an .outlet **13.** Via the space betwen the coaxial conductors **6** and **11** the oil reaches the ion source 9. In the ion source **9** the oil flows through a member of oil ducts of which one is denoted by **14** and which are provided in the metal part **22** of the ion source, and then reaches the space **15.** From the space **15** the oil flows via the conical gap **8** to the outlet **13.** The'average 'tlbw rate of the oil in the gap **8** is approximately IO m/mih. With the described construction a large dielectric strength of the detachable high voltage connection **4** is achieved and also a good cooling of the ion source **9.** A further advantage is that he qu lity f the.oil used, for which any of the known msulatmg 01ls may be chosen, reduces only slowly as a result of the neutr?n.radiation generated by the. neutron g nerato!. _This 1s ca se b the fact that a lar e quantity of 01I 1s used which 1s circu- l ted by pumpm so that onlya small part ?f !he quant1ty of 01I u edm ex o e_d to neutron, radiat!on. Asresul_t of this the rehab1hty of t_he total cqmpmen 1s considerably pr moted. Upon d1sassem_bly of the high voltage connection **4** the detachable _msulator **5** together with the conductors **6** and·**11** and with the metal parts **18**_ of the envelope. are removed. The separation between the· parts **18** and the part **2** of the envelope takes place at' 19. The separation between the high voltage supply line **6** and the ion source **9** takes place at **20.** The separation between the conductor **11** and the conductor16 takes place at 21. lt is to be noted that the tube **23** is manufactured from insulation material. The anode voltage of 5 kV is set up across the tube **23.** The space inside the tube **23** communicates with the evacuated space inside the ion source 9. From this it appears that upon disassembly of the high voltage connection **4,** the vacuum, or rather the low pressure gas atmosphere, is maintained.

Although not strictly necessary for a good understanding of the above-described invention, the operation of the neutron generator will hereinafter be roughly described.

The neutron generator shown is of the sealed off type, that to say that during use it is not connected to a vacuum pump and is evacuated only once during the

manufacture. The envelope **1** comprises a gas mixture consisting of *501:k* deuterium and 50% tritium **with** a pressure of approximately I o :[1]mm Hg. The gas mixture is supplied and the pressure thereof is maintained at the correct value by a pressure control 24. The pressure control comprises a large quantity of the gas mixture absorbed in a finely" divided titanium powder, and can supply this by heating.

The mixture of deuterium and tritium is ionized in the ion source **9** by means of electrons which move in the electric field between the ariode **10** and the cathodes ***29a*** and ***29b*** and in the axial magnetic field of the permanent magnets **31** and **32.** So the ion source is of the known "Penning'" type. A beam **25** consisting" of positive deuterium ions and tritium ions having a current intensity of approximately 15mA is extracted from the ion source by the acceleration electrode **26.** The ion source is at a positive voltage of 250 kVoit_relative to the acceleration elecfrode **26** which forms part of the grounded part **2** of the envelope. The ion beam formed passes the screen electrode **30** and impinges upon the target **27.** The target27 consists of a base plate of a material having a small coefficient of absorption and diffusion for deuterium and tritium (for example copper) and a reaction layer.of a material having a large coefficient of absorption for deuterium and tritium.The reaction layer consists of a 5 *μ.m* thick layer of titanium. The target **27** is provicied in the neutron generator without being saturated with deuterium and tritium and in the first hours of life of the generator absorbs deuterium and tritium from the ion beam impingi,ng upon. the targeL **27.** Th'e absorbed deuterium . and. triti m cannot diffuse away to any considerable extent to places in the target which are situated deeper than the t_hickness of the reacti.on layer because. the bas_e plate ha_s a small coefficient of absorption and diffusion for deuterium and tritium. The result is that the reaction layer is satu ated with deuterium and tritium to an ever increasing extent so that the .neutron yeild begins. The neutron generation results in particular from the reaction between deuterium and.tritium. The collision with an energy of 250keV betwe n a deuterium nucleus and .a tritium nucleus provides a neutron having an energy of 14 MeV and an a-particle having an energy of 3.6 MeV. It is to be noted that neutrons are also formed to a small extent from the reaction between two deuterium nuclei. Said neutrons have a much smaller energy. The. neutrons having an energy of 14. MeV form the effective yield of approximately I 0^{12} neutrons per second of the generator. Said neutron yield is achieved after the generator has been in operation for approximately **1** hour when the saturation of the reactio.n layer with deuterium ,and tritium has reached its equilibrium. condition.

The screening electrode **30** has a, negative potential of a few·kV relative to the target **727** so as to prevent secondary electrons which are formed on the target **27** from being accelerated towards the ion source 9. The neutron generator furthermore comprises an ionisation manometer for checking the gas pressure.

The neutron generator may be used inter alia for scientific purposes as activation analysis and due to its large neutron yield and compact construction it is also particularly suitable for medical applications such as cancer therapy, "total body" activation analysis and measurements of. the blood .circulation.

I claim:

1. Apparatus for making high voltage connection to and cooling an ion source, .comprising an ion source having a cooling duct, a first insulator for supporting said ion source, and a detachable high voltage connection.comprising a second insulator adapted to fit in spaced relation to said first insulator with a gap therebetween in communication with one end of said cooling duct of said ion source,said second i_nsulator having a duct connecting with the other end of said cooling duct to form a conduit for continuously carrying cooling and insulatiµg fluid through said duct of said second insulator, said cooling duct of said ion source and said gap between said first and second insulators, and a high voltage supply conductor carried by said second insulator for connection across said conduit to said ion source.

2. Apparatus as defined in claim **1** wherein said high voltage supply conductor is coaxial with said duct of said seqmd insulator at least in the vicirii_ty of connection thereof with said ion source.

3. Apparatus as defined in claim **2** wherein said second insulator is conical in the vicinity of said ion source arid said duct of said second insulator is coaxial therewith at least in the vicinity of said ion source,

4. Apparatus as defined in claim 3 w_herein said apparatus forms part of a neutron generator.

5. Apparatus comprising an ion source at high voltage· with respect to metal parts ofan envelope, characterized in tnat said ion source is supported in said envelope by a first fixed insulawr which forms part of said envelope and of a·detachable high voltage connection, said high voltage connection furthermore comprising a second detachable insulator which has a high voltage supply line and comprises a conical part and an axial duct;'and in which an insulating cooling liquid flows in a circuit which is formed by the said axial duct, a cooling circuit in said ion source and a gap hetween said fixed and detachable insulators.
